

The SAGE Handbook of  
Research Methods in  
Political Science and  
International Relations

2 Volume set

Edited by  
Luigi Curini and  
Robert Franzese

The SAGE Handbook of  
**Research Methods in  
Political Science and  
International Relations**

**SAGE** was founded in 1965 by Sara Miller McCune to support the dissemination of usable knowledge by publishing innovative and high-quality research and teaching content. Today, we publish over 900 journals, including those of more than 400 learned societies, more than 800 new books per year, and a growing range of library products including archives, data, case studies, reports, and video. SAGE remains majority-owned by our founder, and after Sara's lifetime will become owned by a charitable trust that secures our continued independence.

## VOLUME 1

Preface: So You're A Grad Student Now? Maybe You Should Do This <i>Gary King</i>	1
<b>PART I FORMULATING GOOD RESEARCH QUESTIONS AND DESIGNING GOOD RESEARCH PROJECTS</b>	<b>5</b>
1. Asking Interesting Questions <i>William Roberts Clark</i>	7
2. From Questions and Puzzles to Research Project <i>Adam McCauley and Andrea Ruggeri</i>	26
3. The Simple, the Trivial and the Insightful: Field Dispatches from a Formal Theorist <i>Branislav L. Slantchev</i>	44
4. Evidence-Driven Computational Modeling <i>Ravi Bhavnani, Karsten Donnay and Mirko Reul</i>	60
5. Taking Data Seriously in the Design of Data Science Projects <i>Mitchell Goist and Burt L. Monroe</i>	79
6. Designing Qualitative Research Projects: Notes on Theory Building, Case Selection and Field Research <i>Ezequiel González-Ocantos</i>	104
7. Theory Building for Causal Inference: EITM Research Projects <i>Thomas Bräuninger and Tilko Swalve</i>	121
8. EITM: Applications in Political Science and International Relations <i>John Aldrich and Jim Granato</i>	142

<b>PART II</b>	<b>METHODS OF THEORETICAL ARGUMENTATION</b>	<b>159</b>
9.	Political Psychology, Social Psychology and Behavioral Economics <i>Rose McDermott</i>	161
10.	Institutional Theory and Method <i>Maxfield J. Peterson and B. Guy Peters</i>	173
11.	Applied Game Theory: An Overview and First Thoughts on the Use of Game Theoretic Tools <i>Adam Meirowitz and Kristopher W. Ramsay</i>	192
12.	The Spatial Voting Model <i>James Adams, Samuel Merrill III and Roi Zur</i>	205
13.	New Directions in Veto Bargaining: Message Legislation, Virtue Signaling, and Electoral Accountability <i>Charles Cameron and Nathan Gibson</i>	224
14.	Models of Coalition Politics: Recent Developments and New Directions <i>Lanny W. Martin and Georg Vanberg</i>	244
15.	Models of Interstate Conflict <i>James D. Morrow and Jessica S. Sun</i>	261
16.	Models of the Judiciary <i>Deborah Beim</i>	277
17.	Wrestling with Complexity in Computational Social Science: Theory, Estimation and Representation <i>Scott de Marchi and Brandon M. Stewart</i>	289
18.	Learning and Diffusion Models <i>Scott J. LaCombe and Frederick J. Boehmke</i>	311
<b>PART III</b>	<b>CONCEPTUALIZATION AND MEASUREMENT</b>	<b>329</b>
19.	Conceptualization and Measurement: Basic Distinctions and Guidelines <i>Gerardo L. Munck, Jørgen Møller and Svend-Erik Skaaning</i>	331
20.	Measurement Models <i>Christopher J. Fariss, Michael R. Kenwick and Kevin Reuning</i>	353
21.	Measuring Attitudes – Multilevel Modeling with Post-Stratification (MrP) <i>Lucas Leemann and Fabio Wasserfallen</i>	371

<b>PART IV</b>	<b>LARGE-SCALE DATA COLLECTION AND REPRESENTATION METHODS</b>	<b>385</b>
22.	Web Data Collection: Potentials and Challenges <i>Dominic Nyhuis</i>	387
23.	How to Use Social Media Data for Political Science Research <i>Pablo Barberá and Zachary C. Steinert-Threlkeld</i>	404
24.	Spatial Data <i>David Darmofal and Christopher Eddy</i>	424
25.	Visualizing Data in Political Science <i>Richard Traummüller</i>	436
26.	Text as Data: An Overview <i>Ken Benoit</i>	461
27.	Scaling Political Positions from Text: Assumptions, Methods and Pitfalls <i>Benjamin C.K. Egerod and Robert Klemmensen</i>	498
28.	Classification and Clustering <i>Sarah B. Bouchat</i>	522
29.	Sentiment Analysis and Social Media <i>Luigi Curini and Robert A. Fahey</i>	534
30.	Big Relational Data: Network-Analytic Measurement <i>Ernesto Calvo, Joan C. Timoneda and Tiago Ventura</i>	552

## VOLUME 2

<b>PART V</b>	<b>QUANTITATIVE-EMPIRICAL METHODS</b>	<b>575</b>
31.	Econometric Modeling: From Measurement, Prediction, and Causal Inference to Causal-Response Estimation <i>Robert Franzese</i>	577
32.	A Principled Approach to Time Series Analysis <i>Suzanna Linn and Clayton Webb</i>	599
33.	Time-Series-Cross-Section Analysis <i>Vera Troeger</i>	616
34.	Dynamic Systems of Equations <i>Mark Pickup</i>	632

35.	Duration Analysis <i>Kentaro Fukumoto</i>	659
36.	Multilevel Analysis <i>Marco Steenbergen</i>	679
37.	Selection Bias in Political Science and International Relations Applications <i>Tobias Böhmelt and Gabriele Spilker</i>	701
38.	Dyadic Data Analysis <i>Eric Neumayer and Thomas Plümper</i>	717
39.	Model Specification and Spatial Interdependence <i>Scott J. Cook, Jude C. Hays, and Robert Franzese</i>	730
40.	Instrumental Variables: From Structural Equation Models to Design-Based Causal Inference <i>Christopher L. Carter and Thad Dunning</i>	748
41.	Causality and Design-Based Inference <i>Jake Bowers and Thomas Leavitt</i>	769
42.	Statistical Matching with Time-Series Cross-Sectional Data: Magic, Malfeasance, or Something in between? <i>Richard A. Nielsen</i>	805
43.	Differences-in-Differences: Neither Natural nor an Experiment <i>Luke Keele</i>	822
44.	The Regression Discontinuity Design <i>Matias D. Cattaneo, Rocío Titiunik, and Gonzalo Vazquez-Bare</i>	835
45.	Network Analysis: Theory and Testing <i>Jennifer N. Victor and Elsa T. Khwaja</i>	858
46.	Network Modeling: Estimation, Inference, Comparison, and Selection <i>John P. Schoeneman and Bruce A. Desmarais</i>	876
47.	Bayesian Methods in Political Science <i>Jong Hee Park and Sooahn Shin</i>	895
48.	Bayesian Ideal Point Estimation <i>Shawn Treier</i>	910
49.	Bayesian Model Selection, Model Comparison, and Model Averaging <i>Florian M. Hollenbach and Jacob M. Montgomery</i>	937
50.	Bayesian Modeling and Inference: A Postmodern Perspective <i>Jeff Gill and Simon Heuberger</i>	961

51.	Laboratory Experimental Methods <i>Rebecca Morton and Mateo Vásquez-Cortés</i>	985
52.	Field Experiments on the Frontier: Designing Better <i>Betsy Sinclair</i>	999
53.	Field Experiments, Theory, and External Validity <i>Anna M. Wilke and Macartan Humphreys</i>	1007
54.	Survey Experiments and the Quest for Valid Interpretation <i>Gustavo Diaz, Christopher Grady, and James H. Kuklinski</i>	1036
55.	Deep Learning for Political Science <i>Kakia Chatsiou and Slava Jankin Mikhaylov</i>	1053
56.	Machine Learning in Political Science: Supervised Learning Models <i>Santiago Olivella and Kelsey Shoub</i>	1079
<b>PART VI QUALITATIVE AND ‘MIXED’ METHODS</b>		1095
57.	Set Theoretic Methods <i>Adrian Duşa</i>	1097
58.	Mixed-Methods Designs <i>Imke Harbers and Matthew C. Ingram</i>	1117
59.	Case Study Methods: Case Selection and Case Analysis <i>Chiara Ruffa</i>	1133
60.	Comparative Analyses of Foreign Policy <i>Klaus Brummer</i>	1148
61.	When Talk Isn’t Cheap: Opportunities and Challenges in Interview Research <i>Claire Greenstein and Layna Mosley</i>	1167
62.	Focus Groups: From Qualitative Data Generation to Analysis <i>Virginie Van Ingelgom</i>	1190
63.	Interpretive Approaches in Political Science and International Relations <i>Xymena Kurowska and Berit Bliesemann de Guevara</i>	1211
	Editors’ Afterword <i>Luigi Curini and Robert Franzese</i>	1231
	<i>Index</i>	1232

*This page intentionally left blank*

# List of Figures

1.1	Relationship between the height of fathers and sons	12
1.2	Partisanship and beliefs about ‘room to maneuver’: the conditional effects of knowledge and age	19
2.1	From specific to abstract (and vice versa)	29
2.2	Where good research questions come from	32
2.3	On research question types	34
2.4	Stylized democratic peace research agenda	36
2.5	Stylized civil war research agenda	36
4.1	Model development process	65
4.2	Flow diagram for MERIAM EDM	66
4.3	Data construction overview	68
4.4	EDM modeling cycle	70
4.5	Mock-up of SAMT (main window)	73
4.6	Mock-up of SAMT (intervention configuration)	74
5.1	Searches for ‘basketball’ have the expected seasonality and a plausible pattern of growth	88
5.2	The prominent dynamic in searches for ‘islam’ is the same as that in searches for ‘essays’	89
5.3	Comparing to a reference term captures more relevant shifts in attention	90
5.4	Profiling of open-ended responses in the Mood of the Nation Poll (Wave 4), run by Penn State’s McCourtney Institute for Democracy	92
5.5	Downsampling aggregates pixels (observations) into new pixels, reducing the resolution of the image	94
5.6	Effect of dimension reduction through singular value decomposition (SVD)	96
5.7	A kernel density estimation of the Lincoln images pixel intensities convolves a Gaussian curve (normal distribution) over the observed distribution of values	97
5.8	Effect of convolutional image kernels	97
7.1	Models, theoretical implications, and features of the real world	125
7.2	Entry game	129
8.1	Simulated and actual volatility	150
8.2	Deregulation effects	150
11.1	The bargaining problem with unilateral outside options	195
12.1	Illustrative placements of a voter $v$ and parties $A, B$ , on left–right ideology	206
12.2	Illustrative placement of a voter $v$ and parties $L$ and $R$ in a two-dimensional space	207
12.3	How two-party, positional competition motivates party convergence	209
12.4	The dynamics of three-party positional competition	210
12.5	Centripetal incentives in a four-party election: the peripheral parties converge toward their ideological ‘neighbors’	211
12.6	Example of four-party Nash equilibrium configuration in competition over a bimodal voter distribution	211

12.7	Distribution of American survey respondents' Left–Right self-placements and their mean party placements, 2016 National Election Study	212
12.8	Distributions of citizens' Left–Right self-placements and their mean party placements in the UK, Germany, Canada and Finland	213
12.9	How valence affects voter choice in a model with one positional dimension	214
12.10	Party strategies in elections with one positional and one valence dimension	215
12.11	Examples of probability distributions over the median voter's position	217
12.12	How party positioning affects parties' election prospects when there is uncertainty over the median voter position	218
13.1	Passage margin of cloture votes, 2009–2018	234
13.2	Futile cloture votes, 1975–2018	234
14.1	Laver–Shepsle ministerial autonomy model	251
19.1	The parts of a concept: term, sense and reference	333
19.2	The structure of a concept: levels and relationships	334
19.3	Conceptual systems I: typologies	335
19.4	Conceptual systems II: two hierarchical structures	335
19.5	The concept–fact interface	337
19.6	The production of data on indices: two basic situations	345
19.7	Combining data on properties: reflective and formative measurement models	346
20.1	Latent variables and item parameters	357
20.2	Example of additive scale function	358
20.3	Identification issues in latent variables	360
21.1	Cantonal estimates and true approval rate	375
21.2	Cantonal estimates and uncertainty	376
22.1	Response from the Wikipedia API (Mannheim page views between November 3 and November 9, 2018)	390
22.2	Response from the Wikipedia API (Mannheim coordinates)	391
22.3	Interpreted version of the Mannheim Wikipedia page (excerpt), November 13, 2018	394
22.4	Source code of the Mannheim Wikipedia page (excerpt), November 13, 2018	395
22.5	Response from the <i>Google Translate</i> server to the query	400
25.1	Four scatter plots of four data sets that show wildly different patterns – although summary statistics are identical	437
25.2	Left panel: average number of figures in all articles published in the <i>AJPS</i> , 2003–18. Right panel: relative frequency of graphical formats	439
25.3	The relationship between graph use and citation counts of <i>AJPS</i> articles, 2003–17. Left panel: simple scatter plot with jitter along the x-axis. Right panel: adjusted variable plot relating residuals of figure count to residuals of citations eliminating the effect of publication date	441
25.4	Table lens plots of Swiss census data 2010	443
25.5	Parallel coordinate plot of the policy preferences of over a thousand political candidates	447
25.6	Parallel coordinate plot of the policy preferences of over a thousand political candidates. Axes have been re-sorted	447
25.7	Parallel coordinate plot of the policy preferences of over a thousand political candidates. Lines are colored according to party affiliation	447
25.8	Parallel coordinate plot of the policy preferences of political candidates of the FDP and the Left	448

25.9	Parallel coordinate plot of the policy preferences of political candidates of the CDU/CSU and SPD	448
25.10	Parallel coordinate plot of the policy preferences of political candidates of the AfD and the Greens	448
25.11	Small multiples of support for school vouchers by geography and income (Gelman, 2009)	449
25.12	Small multiples of support for school vouchers by geography, income and ethno-religious group (Gelman, 2009)	450
25.13	Small multiples of support for school vouchers by geography, income and ethno-religious group. Rows have been re-sorted by support	451
25.14	Plot ensemble for exploratory model analysis of the determinants of civil war onset	452
25.15	Line-up visual inference with 20 histograms	455
25.16	Line-up for the relation between the individual education effect on political participation (y-axis) and state-level education (x-axis)	456
25.17	Line-up for the relation between survival vs. self-expression values (x-axis) and traditional vs. secular-rational values (x-axis) clustered by cultural zone	457
26.1	From text to data to data analysis	464
26.2	From text to tokens to matrix	482
26.3	Word cloud of influential hashtags from a sample of Tweets about Brexit	491
27.1	On a scale from Medvedev to Putin	506
27.2	Perception and governor speeches	507
27.3	Validating Wordfish estimates against a human benchmark	510
27.4	Which words define the policy space?	511
27.5	How the performance of scaling algorithms vary with the comparability of texts	514
27.6	Document length and performance of scaling models	515
27.7	Error in scales and bias in econometric models	519
30.1	API interface and pre-processing of large Twitter network	555
30.2	Sample code to create a dataframe with selected variables	558
30.3	Twitter ‘Trump’ network (1)	559
30.4	Twitter ‘Trump’ network (2)	564
30.5	A complex network with three local topologies: (a) a ring subnetwork, (b) a fully connect subnetwork and (c) a follow the leader subnetwork	565
30.6	Activation of eight different hashtags during the Kavanaugh Confirmation Hearings, September 19, 2018	569
30.7	Primary connected network of #Kavanaugh	570
30.8	Sampling distribution of the bandwidth selection procedure (250 samples with 100 observations each)	571
30.9	PWR results in the network format	572
31.1	The logically necessarily sigmoidal relation $p(y) = f(x)$	585
31.2	‘Multiple Hands on the Wheel’ model of complex context-conditionality in monetary policymaking	587
31.3	Substantive dynamic-effect estimates of real interest-rate net of growth impacts on public debt	588
31.4	Maps depicting the initial (left panel) and LRSS (right panel) spatial ALM-spending responses to +1 shock in Germany	590

31.5	BSVAR Estimated responses from a system of Israel↔Palestinian, US→Israel, US→Palestinian actions	592
32.1	IRF and CIRF for the effect of consumer sentiment on presidential approval	608
32.2	IRFs for three variable VAR model of economic performance consumer sentiment and presidential approval	610
34.1	Impulse response and dynamic multiplier functions	639
34.2	Structural impulse response function	640
34.3	Two-dimensional space	648
34.4	Smooth states for vote intention	656
36.1	Three canonical multilevel-data structures	680
36.2	Three types of random-coefficient models	684
36.3	Conceptualizing ordinal outcomes	695
39.1	Manifestations of spatial association	733
41.1	Distribution of Difference-in-Means estimator as $h \rightarrow \infty$	777
41.2	Distribution of Difference-in-Means estimates under (a) unblocked and (b) blocked assignment	779
41.3	Distribution of Difference-in-Means test statistic under test of strong null of no effect when $\mathbf{z}_g$ is the realized assignment	784
41.4	Distribution of observed test statistic	785
41.5	Distribution of Fisherian $p$ -values for test of strong null of no effect under all realizations of data as the size of the experimental pool grows from one copy of the study, $h = 1$ ( $n = 6$ ); to two copies of the study, $h = 2$ ( $n = 12$ ); to three copies of the study, $h = 3$ ( $n = 18$ )	788
41.6	Distribution of Neymanian $p$ -values under all realizations of data	790
41.7	Distribution of type I error probabilities for different $\alpha$ levels	791
41.8	Distributions of Difference-in-Means test statistic under strong null of no effect when $\mathbf{z}_g$ is the realized assignment under (a) a model where an unobserved covariate has no effect on odds of treatment, $\Gamma = 1$ , and (b) a model where an observed covariate doubles the odds of treatment, $\Gamma = 2$	797
42.1	The number of articles per year using statistical matching in the 12 leading IR journals	806
43.1	Schematic representation of response in treated and control groups, before and after treatment, with and without transformation to log scale	825
44.1	Estimated density of running variable	850
44.2	RD effects on predetermined covariates	851
44.3	RD effects on predetermined covariates	852
44.4	Effect of victory at $t$ on vote margin at $t + 1$ . Incumbent party, Brazilian mayoral elections, 1996–2012	853
44.5	Window selector based on covariates. Incumbent party, Brazilian mayoral elections, 1996–2012	853
46.1	Density plots for degree distribution and betweenness centrality for all three networks	884
47.1	The number of journal articles containing Bayesian as a keyword excluding game theory papers	900
50.1	How Markov Chain Monte Carlo works	968
50.2	Categories illustration	971
50.3	Posterior predictive probabilities by ordered outcomes	971
50.4	Posterior predictive probabilities by outcome categories	972

50.5	Log-likelihood functions for configurations of component likelihoods	978
53.1	A directed acyclic graph (DAG) for a non-parametric bargaining model	1009
53.2	The hazards of trying to stitch experimental results together to form a theory	1015
53.3	Three selection graphs	1021
55.1	Machine learning and related tasks	1055
55.2	Building a hierarchy of complex concepts out of simpler concepts	1058
55.3	Visualization of features	1059
55.4	Examples of Digital Globe (left) and Planet (right, Michoacán) imagery	1059
55.5	Convolution of a black and white image of a heart – the essential elements	1060
55.6	Convolution of a black and white image of a heart – step one	1060
55.7	Convolution of a black and white image of a heart – step two	1061
55.8	Convolution of a black and white image of a heart – step three	1061
55.9	Max pooling operation – using a 2×2 input window and stride 2	1062
55.10	The task in image classification is to predict a single label (or a distribution over labels as shown here – percentages indicating level of confidence) for a given input image	1062
55.11	Illustration of a single-layer convolutional neural network architecture for sentence classification	1064
55.12	Illustration of a convolutional neural network for sentence classification	1065
55.13	A simple RNN network with a feedback loop. A simple RNN, $A$ , looks at some input, $x_t$ , and outputs a value, $y_t$	1066
55.14	A sequence of simple RNNs	1067
55.15	The repeating module in a standard RNN with a single layer (A1) and an LSTM with four interacting layers (A2)	1067
55.16	The BreakingNews dataset	1069
56.1	Left panel: feature space comprised of ages and education levels, partitioned into regions that are relatively homogeneous with respect to probability of turnout (indicated with lighter shades of gray for every combination of feature values). Right panel: binary-tree representation of feature-space partition depicted on the left panel	1082
56.2	Left panel: post-stratified predictions of turnout during the 2008 presidential election in the United States at low levels of demographic aggregation. Predictions produced by a multilevel model along the y-axis, and predictions along the x-axis produced by a Bayesian additive regression tree model. Right panel: post-stratified predictions of vote intention for McCain during the 2008 presidential election in the United States at low levels of demographic aggregation	1086
56.3	Left panel: classifying by a Maximum-Margin Hyperplane: a linearly separable problem, with the corresponding separating line (solid line) and classification margins (dashed lines). Right panel: non-linearly separable classification problem of Class A (outer light gray triangles) and Class B (inner dark gray circles) instances	1087
56.4	Illustration of kernel trick: tilted projection of instances depicted in right panel of Figure 56.3 onto space with an additional dimension $z = -(X_1^2 + X_2^2)$ (original two-dimensional representation can be seen at the bottom)	1089
57.1	Calibration in the set of developed countries	1104
57.2	Other possible calibration functions	1104
57.3	Correlation (left) and subset sufficiency (right)	1108

57.4	Fuzzy correlation (left) and fuzzy subset sufficiency (right)	1109
57.5	Incomplete inclusion/large coverage (left) and complete inclusion/ low coverage (right)	1109
57.6	Unique coverage of A (hashed area)	1110
57.7	X as a trivial necessary condition for Y	1111
57.8	Bidimensional vector space (left) and the corresponding truth table (right)	1113

46.4	Plots of latent space positions for the LSMs along two dimensions	888

46.5	SBM block assignment plots	889
47.1	Summary by journals: the number of journal articles containing ‘Bayesian’ in the abstract excluding game theory-related articles	900
47.2	Summary by topics: top 15 words sorted by the topic-word probability using text2vec package (Selivanov and Wang, 2018)	901
47.3	Bayesian R Packages: Bayesian packages hosted in CRAN	901
49.1	Evaluating theories of Congress: median estimates and 95% credible intervals for Table 3 in Richman (2011) (Models 1–4) and two garbage-can models	940
49.2	BIC and approximation to Bayes factor	945
49.3	Log marginal likelihood and Bayes factor using bridge sampling	946
49.4	Information criteria for evaluating theories of Congress	951
49.5	Loo information criteria for evaluating theories of Congress with standard errors	952
49.6	Model weights based on stacking	955
50.1	Posterior quantiles, ordered model for survey of political executives	969
50.2	Posterior quantiles, GLMDM for survey of political executives	980
53.1	Equilibrium prices for first ( $\pi_n^1$ ) and second ( $\pi_n^2$ ) moving customers and average treatment effect ( $\tau_n$ ) of the customer moving first for games with $n$ possible rounds	1023
53.2	Estimation of model parameters using the correct model	1026
53.3	Estimation of average treatment effects using difference-in-means (DIM) and parameter estimation (MLE)	1026
53.4	Extrapolation	1027
53.5	Diagnosis of design without randomization	1029
53.6	Diagnosis of design with incorrect model (assume $q = 0$ )	1030
53.7	Diagnosis of design with incorrect yet observationally equivalent model	1030
55.1	Overview of machine learning methods and examples from political science	1056
56.1	Popular SVM kernels	1089
57.1	Set intersection for crisp sets	1099
57.2	Set union for crisp sets	1099
57.3	Set negation for crisp sets	1100
57.4	Per capita income (INC), calibrated to fuzzy sets membership scores (fsMS)	1103
57.5	Boolean minimization example	1113
60.1	Leadership trait analysis	1156
60.2	The ‘norming group’ of leadership trait analysis	1158

# Notes on the Editors and Contributors

## THE EDITORS

**Luigi Curini** is Professor of Political Science at the University of Milan, Visiting Professor at Waseda University of Tokyo, and chair of MetRisp (the Standing Group on Political Methods and Research of the Italian Political Science Association). His research focuses on comparative politics, valence politics and text analytics. He is the (co-)author of seven books, including *Corruption, Ideology, and Populism* (2018) and *Politics and Big Data* (2017), and more than 50 articles and chapters.

**Robert Franzese** is Professor and Associate Chair of Political Science, Director of the Program in International and Comparative Studies, Research Professor in the Center for Political Studies of the Institute for Social Research at the University of Michigan and a past President of the Society for Political Methodology. He is the (co-)author or (co-)editor of seven books or collections, including the forthcoming *Empirical Analysis of Spatial Interdependence*, and more than 50 articles, chapters and papers, including most germane to this *Handbook*, ‘Spatial-Econometric Models of Cross-Sectional Interdependence in Political-Science Panel and Time-Series-Cross-Section Data’, ‘A Spatial Model Incorporating Dynamic, Endogenous Network Interdependence: A Political Science Application’ and ‘Interdependence in Comparative Politics: Substance, Theory, Empirics, Substance’.

## THE CONTRIBUTORS

**James Adams** is Professor of Political Science at UC Davis. He received a PhD in Political Science from The University of Michigan, and a BA in economics from Princeton University. His research analyzes voting behavior, parties’ vote-seeking strategies and election outcomes. He has authored two books: *Party Competition and Responsible Party Government* and *A Unified Theory of Party Competition* (with Bernard Grofman and Samuel Merrill III). He has published over 50 papers in peer-reviewed journals including the *American Political Science Review*, the *American Journal of Political Science* and the *Journal of Politics*.

**John Aldrich** is the Pfizer-Pratt University Professor of Political Science at Duke University. His research focuses on American politics, political parties, Congress and elections, and on EITM-based research using both formal theory and quantitative empirical research.

**Pablo Barberá** is an Assistant Professor in the School of International Relations at the University of Southern California. His research agenda examines how the adoption of social media platforms is transforming different aspects of democratic politics: ideological polarisation, incivility in political discussions, politicians’ responsiveness to their constituents, the emergence of social protests, public diplomacy, etc. To answer these questions, he develops

new network science and text analysis methods that can provide researchers with the necessary tools to collect and analyse digital trace data.

**Deborah Beim** is an Assistant Professor in the Department of Political Science at the University of Michigan. She studies American politics in general and judicial politics in particular, with a focus on interactions between the US Supreme Court and the Courts of Appeals. She is also interested in applied game theory. Her work has been published in the *American Journal of Political Science*, *Journal of Politics* and other outlets.

**Ken Benoit** is a Professor, Part-Time, at the Australian National University, and he has previously held positions in the Department of Political Science at Trinity College Dublin. He received his PhD (1998) from Harvard University, Department of Government. His current research focuses on computational, quantitative methods for processing large amounts of textual data, mainly political texts and social media. His current research includes software development for text analysis (the R package *quanteda*) and the analysis of big data, including social media, and methods for text mining using combinations of crowd-sourced annotations, statistical methods and machine learning.

**Ravi Bhavnani** is a Professor in the International Relations and Political Science Department at the Graduate Institute. He received his PhD in Political Science (Comparative Politics and Methodology) and a Degree Certificate in Complex Systems from CSCS from the University of Michigan, Ann Arbor. His research explores the micro-foundations of violent conflict by means of agent-based computational modelling and disaggregated empirical analysis. More specifically, his work examines the endogenous relationships among: 1) the characteristics, beliefs and interests of relevant actors; 2) social mechanisms and emergent social structures that shape attitudes, decision-making and behaviour; and 3) patterns of conflict and violence.

**Berit Bliesemann de Guevara** is a Reader in International Politics and the Director of the Centre for the International Politics of Knowledge at Aberystwyth University's Department of International Politics. Her current research explores ways and problems of knowing in international politics, specifically in conflict and intervention contexts, as well as the use of arts-based methods in social-scientific research. She has used interpretive approaches in studies of the role of politicians' field visits in foreign and defence policymaking, myths in international politics and international peacebuilding in the Balkans. Her current hermeneutical research includes an Arts and Humanities Research Council (AHRC) project on local conflict knowledge among conflict-affected communities in Myanmar, and a Newton Fund-Colciencias project on demobilised guerrilla fighters' subjectivities in their reincorporation process into Colombian society.

**Frederick J. Boehmke** is Professor of Political Science at the University of Iowa and Director of the Iowa Social Science Research Center in the Public Policy Center. His research focuses on American state politics and quantitative research methods. Lately, this has included a particular focus on state policy adoption and diffusion, including developing the SPID database, featuring over 700 policy diffusion episodes and a series of articles evaluating methods to leverage multiple policies to better understand policy diffusion.

**Tobias Böhmelt** is a Professor of Government at the University of Essex and Associate Editor of the *British Journal of Political Science*. His current research interests are based in the areas of transnational diffusion processes, party politics, migration and population movements, environmental politics, international mediation and civil-military relations. His recent work has been published in the *American Political Science Review*, *American Journal of Political*

*Science, Journal of Politics, International Organization, International Studies Quarterly, European Journal of Political Research* and others.

**Sarah B. Bouchat** is an Assistant Professor at Northwestern University, affiliated with the Department of Political Science and Northwestern Institute for Complex Systems. They completed a PhD in the Department of Political Science at the University of Wisconsin–Madison in 2017. With research interests in political methodology, comparative political economy and authoritarian politics, Sarah's current work focuses on text-as-data, Bayesian modelling and machine learning, with applications to the study of low-information, authoritarian regimes like Myanmar.

**Jake Bowers** (<http://jakebowers.org>) is an Associate Professor of Political Science and Statistics University of Illinois at Urbana-Champaign. He was a Fellow on the White House Social and Behavioral Sciences Team (<http://sbst.gov>) and Office of Evaluation Sciences in the General Services Administration of the US Government (<http://oes.gsa.gov>) from 2015–19. He is Methods Director and a board member for the Evidence in Government and Politics network (<http://egap.org>), co-founder of Research4Impact (<http://r4impact.org>) and a research affiliate with the Center for Advanced Studies in the Behavioral Sciences (<http://casbs.stanford.edu>). His research in applied statistics and political methodology focuses on questions of statistical inference for causal effects in randomised experiments and observational studies.

**Thomas Bräuninger** is a Professor of Political Economy at the University of Mannheim and Associate Editor of the *American Political Science Review*. His area of research is comparative politics and formal theory with a focus on the effect of political institutions on policy outcomes. His current research focusses on voting behaviour, party competition, electoral systems, legislative politics and propaganda. His work has been published in, among other journals, the *British Journal of Political Science, Journal of Politics, Journal of Conflict Resolution, Legislative Studies Quarterly, Political Analysis* and *Political Science Research and Methods*.

**Klaus Brummer** holds the chair of International Relations at the Catholic University of Eichstätt-Ingolstadt. He is co-editor-in-chief of the journal *Foreign Policy Analysis* and served as president of the Foreign Policy Analysis section of the International Studies Association (ISA) in 2015–16. He has published in peer-reviewed journals such as the *British Journal of Politics and International Relations, Foreign Policy Analysis, Government and Opposition, International Politics* and the *Journal of European Public Policy*, and he is the co-editor of *Foreign Policy Analysis beyond North America* (2015) and *Foreign Policy as Public Policy?* (2019).

**Ernesto Calvo** (PhD, Northwestern University 2001), Professor of Government and Politics at the University of Maryland, Director of the Interdisciplinary Lab for Computational Social Science (iLCSS) and Field Editor of the *Journal of Politics* (JOP-Comparative). His work uses big data to study comparative political institutions, political representation and social networks. He is the author of *Non-Policy Politics* (2019), *Legislator Success in Fragmented Congresses in Argentina* (2014) and over 50 publications in Latin America, Europe and the United States. The American Political Science Association has recognized his research with the *Lawrence Longley Award*, the *Leubbert Best Article Award* and the *Michael Wallerstein Awards*.

**Charles Cameron** is Professor of Politics and Public Affairs at Princeton University. He is the author of many articles in leading journals of political science as well as *Veto Bargaining:*

*Presidents and the Politics of Negative Power* (2000), which won the American Political Science Association's Fenno Prize and William Riker Award. He has been a Research Fellow at the Brookings Institution, a National Fellow at the Hoover Institution, a Visiting Scholar at Princeton's Center for the Study of Democratic Politics and he has a recurrent visiting affiliation as Professor at New York University School of Law.

**Christopher L. Carter** is a PhD candidate in political science at the University of California, Berkeley and research associate at Berkeley's Center on the Politics of Development. His current work adopts a multi-method approach, combining natural experiments, surveys, lab-in-the-field experiments, archival data and extensive interviewing to examine indigenous-state relations in the Americas. He has also published on party systems in Latin America, decentralization in the developing world and regulation of the gig economy in the United States. He received a Master's in Latin American Studies at the University of Cambridge as a Gates-Cambridge scholar. He also holds a B.A. in Political Science and History from the University of North Carolina at Chapel Hill, where he studied as a Morehead-Cain scholar.

**Matias D. Cattaneo** is Professor of Operations Research and Financial Engineering at Princeton University. His research spans mathematical statistics, econometrics, data science and quantitative methods in the social, behavioural and biomedical sciences. Matias earned a PhD in economics in 2008 and an MA in statistics in 2005 from the University of California at Berkeley. He also completed an MA in economics at Universidad Torcuato Di Tella in 2003 and a BA in economics at Universidad de Buenos Aires in 2000. Prior to joining Princeton in 2019, he was a faculty member in the departments of economics and statistics at the University of Michigan for 11 years.

**Scott de Marchi** is Professor of Political Science and Director of the Decision Science program at Duke University. His work is currently funded by the Department of Defense, the National Science Foundation, and USAID. His research focuses on mathematical methods, especially bargaining theory, computational social science, machine learning, and mixed methods. Substantively, he examines decision-making in contexts that include the American Congress, coalition and crisis bargaining, interstate conflict, and voting behaviour. He is also collaborating with the DevLab@Duke to use machine learning models to forecast regime backsliding and civic space closures.

**Kakia Chatsiou** is a Senior Research Officer at the Institute for Social and Economic Research, University of Essex. Her research focuses on public administration, data science and natural-language processing. In her research, she studies how data can fuel positive changes to society and individuals and how the challenges of artificial intelligence, ethics, privacy and safeguarding can be overcome through compliance and transparency. Previously, she was a researcher at the Department of Government, where she worked with local authorities and voluntary-sector organisations in the UK building capacity in text analytics and data sharing as part of the Catalyst Project. She is a member of the Berkeley Initiative for Transparency in the Social Sciences and a member of the Wider Eastern Information Stakeholder Forum, UK. She holds a PhD in computational linguistics from the University of Essex.

**William Roberts Clark** is Charles Puryear Professor in Liberal Arts at Texas A&M University. He is currently a Weatherhead Scholar at the Weatherhead Center of International Affairs and Visiting Professor in the Department of Government at Harvard University. He previously taught at the University of Michigan, New York University and Georgia Institute of Technology.

He is the author, with Matt and Sona Golder, of *Principles of Comparative Politics* and the author of *Capitalism, Not Globalism: Capital Mobility, Central Bank Independence, and the Political Control of the Economy*. He has published papers in prominent journals on subjects such as the politics of monetary policy, electoral laws and party systems, the resource curse and the testing of context-dependent hypotheses.

**Scott J. Cook** is an Assistant Professor and Co-Director of the Research Methods Program in the Department of Political Science at Texas A&M University. He earned his PhD at the University of Pittsburgh (2014), where his doctoral work received the John T. Williams Dissertation Prize from the Society for Political Methodology. His research has appeared in the *American Journal of Political Science*, *Political Analysis* and *Political Science Research and Methods*, among other journals. His current work includes the forthcoming *Empirical Analysis of Spatial Interdependence* and *National Science Foundation-supported research on spatiotemporal patterns of terrorism*.

**David Darmofal** is an Associate Professor of Political Science at the University of South Carolina. His research interests focus on American politics and political methodology. He has substantive interests in voting behaviour, public opinion and political geography, and methods interests in spatial analysis, survival analysis and time series analysis. He is the author of *Spatial Analysis for the Social Sciences* and *Demography, Politics, and Partisan Polarization in the United States, 1828–2016*, the latter co-authored with Ryan Strickler. His research has also appeared in a variety of journals, including the *American Journal of Political Science*, *Journal of Politics*, *Political Geography*, *Political Behavior*, *Political Psychology*, *Political Research Quarterly* and *State Politics and Policy Quarterly*.

**Bruce A. Desmarais** is the DeGrandis-McCourtney Early Career Professor in Political Science, Associate Director of the Center for Social Data Analytics, and an Affiliate of the Institute for Cyber Science at Penn State University. His research is focused on methodological development and applications that further our understanding of the complex interdependence that underlies politics, policymaking, and public administration. Methodologically, Bruce focuses on methods for modeling networks, analyzing dynamics on networks, and experiments on networks. Primary application areas of interest to Bruce include public policy diffusion, campaign finance, legislative networks, and internal government communication networks.

**Gustavo Diaz** is a PhD candidate in the Department of Political Science at the University of Illinois at Urbana-Champaign. He studies Comparative Politics and Political Methodology, with focus on the political economy of developing countries and improving causal inference in experimental and observational studies. His research has been funded by the Lemann Institute for Brazilian Studies.

**Karsten Donnay** is an Assistant Professor in the Department of Political Science at the University of Zurich. In his research, he combines an interest in data science, (big) data analytics, statistical and computational modeling with applied interdisciplinary research across different disciplines in the social and behavioral sciences. Karsten holds a PhD from ETH Zurich and was a postdoctoral researcher at the Graduate Institute Geneva and the University of Maryland. Prior to joining the University of Zurich in 2020, he was an Assistant Professor in the Department of Politics and Public Administration at the University of Konstanz.

**Thad Dunning** is Robson Professor of Political Science at the University of California, Berkeley. He studies comparative politics, political economy and research methodology.

Dunning has written on methodological topics including causal inference, statistical analysis and multi-method research. He chaired the inaugural project of the Evidence in Governance and Politics (EGAP) group's Metaketa Initiative, which aims to achieve greater cumulation of findings from experimental research on international development and political accountability; the project resulted in an article in *Science Advances* and a book at Cambridge University Press. His methods work also includes *Natural Experiments in the Social Sciences: A Design-Based Approach* (2012, Cambridge University Press), which won the Best Book Award from the American Political Science Association's Experiments Section. He received a PhD in political science and an MA in economics from the University of California, Berkeley (2006) and was formerly Professor of Political Science at Yale University.

**Adrian Duşa** works at the Department of Sociology at the University of Bucharest, teaching social statistics, research methodology and measurement in the social sciences. He is also the President of Romanian Social Data Archive (RODA) – having been involved in data archiving for almost 20 years, in partnership with the Council of European Social Science Data Archives (CASSDA). His primary research interest is qualitative comparative analysis (QCA) – a novel methodology for social research that inspires a growing community, which he serves as a member of the Advisory Board and Steering Committee at COMPASSS, and he publishes extensively on methodological aspects, with a key interest in the programming of the minimisation algorithms. His main programming environment is R, to which he contributed a number of packages, including a highly advanced and sophisticated QCA software.

**Christopher Eddy** is a PhD student in the Department of Political Science at the University of South Carolina. His research and teaching interests are in American politics and public administration/public policy.

**Benjamin C.K. Egerod** an assistant professor at the Department of International Economics, Government and Business, Copenhagen Business School and a Bradley Fellow at the Stigler Center, Booth School of Business, University of Chicago. In his research, he focuses on business–government interactions. Because these typically are very difficult to observe, much of his research concerns the development of new tools for measuring them on a large scale – for example, through the use of political text.

**Robert A. Fahey** is a Research Associate at the Waseda Institute of Political Economy (WINPEC) at Waseda University in Tokyo. His research focuses on the use of text mining and network analysis methods to analyse behaviour and opinion-forming on social media, and the use of social media data to supplement and improve public-opinion research. His English-language work on these topics has been published in journals including *Social Science and Medicine* and the *International Journal of Information Management*, and he has presented research into the spread of populist ideas on social media in Japan at major conferences, including the *APSA Annual Meeting* and *ECPR General Conference*.

**Christopher J. Fariss** is an Assistant Professor in the Department of Political Science and Faculty Associate in the Center for Political Studies at the University of Michigan. Prior to these appointments, he was the Jeffrey L. Hyde and Sharon D. Hyde and Political Science Board of Visitors Early Career Professor in Political Science in the Department of Political Science at Penn State University. He is also an Affiliated Scholar at the Security and Political Economy (SPEC) Lab at the University of Southern California. In June 2013, he graduated with a PhD in political science from the University of California, San Diego. He also studied

at the University of North Texas, where he graduated with an MS in political science (2007), a BFA in drawing and painting (2005) and a BA in political science (2005).

**Kentaro Fukumoto** is Professor of Political Science at Gakushuin University and was a Visiting Scholar at Harvard University and at Washington University in St. Louis. He received his PhD from the University of Tokyo in 2007. His research interests include political methodology, electoral studies, legislative studies and Japanese politics. He is the author of *Nihon no Kokkai Seiji: Zen Seifu Rippo no Bunseki* [Politics in the Japanese Diet: A Statistical Analysis of Postwar Government Legislation] (2000) and *Rippo no Seido to Katei* [Legislative Institutions and Process] (2007). His articles have appeared in the *American Political Science Review*, *American Journal of Political Science*, *Behaviormetrika*, *Electoral Studies*, *Japanese Journal of Political Science*, *Journal of American Statistical Association*, *Journal of Politics* and *Legislative Studies Quarterly*. He is an editor of the *Japanese Journal of Political Science* and is on the editorial boards of *Political Analysis* and the *Asian Journal of Comparative Politics*.

**Nathan Gibson** is a PhD candidate in the Politics Department at Princeton University and is affiliated with the Center for the Study of Democratic Politics in the Woodrow Wilson School of Public and International Affairs. His research focuses on the American presidency, bureaucracy and Congress and has been published in *Congress and The Presidency* as well as the SSRC Anxieties of Democracy volume *Can America Govern Itself?* His web page and other research can be found at <https://www.ndgibson.com>.

**Jeff Gill** is a Distinguished Professor of Government, a Professor of Statistics and a Member of the Center for Behavioral Neuroscience at American University. His research applies Bayesian modelling and data analysis (decision theory, testing, model selection, elicited priors) to questions in general social science quantitative methodology, political behaviour and institutions, medical/health data analysis (especially physiology, circulation/blood and pediatric traumatic brain injury) and epidemiological measurement/data issues using computationally intensive tools (Monte Carlo methods, MCMC, stochastic optimisation and non-parametrics).

**Mitchell Goist** is a PhD candidate in political science, with a minor in social data analytics, at Pennsylvania State University. His political science research is in comparative politics, with a particular interest in extremist politics. His methodological research is in machine learning, deep learning, text-as-data and political networks. His dissertation develops a transfer learning approach to multilingual text analysis and applies the technique to the cross-national study of populist and extremist political parties. He successfully defended his PhD in 2019.

**Ezequiel González-Ocantos** (PhD, Notre Dame, 2012) is Associate Professor in the Department of Politics and International Relations at the University of Oxford, and Professorial Fellow of Nuffield College. He is the author of *Shifting Legal Visions: Judicial Change and Human Rights Trials in Latin America* (2016), which won best book awards from the American Political Science Association, the International Studies Association and the Latin American Studies Association. His research has also appeared in the *American Journal of Political Science*, *Comparative Politics*, *Comparative Political Studies*, *International Studies Quarterly*, *Law and Society Review* and *Sociological Methods and Research*, among others. In 2018, Ezequiel received the Philip Leverhulme Prize in Politics and International Relations.

**Christopher Grady** is a PhD candidate in the Department of Political Science at the University of Illinois at Urbana-Champaign. His primary interests are political psychology, intergroup

conflict, media and observational learning, and international development. His research has been funded by the National Science Foundation, International Foundation for Electoral Systems, and Evidence in Governance and Politics.

**Jim Granato** is Executive Director and Professor at the University of Houston's Hobby School of Public Affairs. His research focuses on EITM, Political Economy, and Time Series Analysis.

**Claire Greenstein** is an Assistant Professor of Political Science at the University of Alabama at Birmingham. Her research is mainly on transitional justice, primarily reparations, with a regional focus on Europe and Latin America.

**Imke Harbers** is Associate Professor of Political Science at the University of Amsterdam. Her research focuses on subnational politics, state capacity and state–society interactions, with a specific emphasis on the territorial reach of the state. Her work has appeared, or is forthcoming in, *Political Science Research and Methods*, *Political Analysis* and *Comparative Political Studies*, among others. She has held visiting positions at the University of California, San Diego, and her current research is funded by a Marie Curie Fellowship from the European Commission.

**Jude C. Hays** is an Associate Professor of Political Science at the University of Pittsburgh. His research has been published in journals such as the *American Journal of Political Science*, *Political Analysis* and *Political Science Research and Methods*, among others. He is the author of *Globalization and the New Politics of Embedded Liberalism* and co-author of the forthcoming *Empirical Analysis of Spatial Interdependence*.

**Simon Heuberger** is a PhD candidate in political science at American University in Washington, DC, concentrating on American government and quantitative methods. His research focuses on the statistical advancement of survey measurement tools, causal inference and the psychological underpinnings of public opinion. He also works as the official replicator for *Political Analysis*.

**Florian M. Hollenbach** is an Assistant Professor in the Department of Political Science at Texas A&M University. Hollenbach's research focus is political methodology and comparative politics. In his work in political methodology, he primarily studies the consequences of spatial dependence and Bayesian statistical methods. In his substantive research, he is specifically interested the development of state/fiscal capacity and fiscal policy. Dr. Hollenbach's work has appeared or is forthcoming in the *American Political Science Review*, *the Journal of Politics*, *Political Analysis*, *Sociological Methods & Research*, *the British Journal of Political Science* and *Political Science Research & Methods*.

**Macartan Humphreys** is Professor of Political Science at Columbia University and Director of the Institutions and Political Inequality group at the WZB Berlin. He works on the political economy of development, with ongoing research focusing on post-conflict development, ethnic politics, political authority and democratic development. His recent work has appeared in the *American Political Science Review*, *Journal of Development Economics*, *Science Advances* and elsewhere. Macartan has written or co-authored books on ethnic politics, natural resource management and game theory and politics.

**Matthew C. Ingram** is Associate Professor of Political Science at the University at Albany, State University of New York. His research focuses on justice reform, violence and methods. He is the author of *Crafting Courts in New Democracies: The Politics of Subnational Judicial*

*Reform in Brazil and Mexico* (2016) and co-editor of *Beyond High Courts: The Justice Complex in Latin America* (2019). His publications have also appeared in peer-reviewed journals, including *World Development*, *Comparative Politics*, *Political Analysis* and *Political Science Research and Methods* and in several edited volumes. He has held visiting positions at the University of California, San Diego, and the University of Notre Dame, and in 2019 he won a Fulbright US Scholar award for research in Mexico. He holds a BA from Pomona College and an MA, JD and PhD from the University of New Mexico.

**Slava Jankin Mikhaylov** is Professor of Data Science and Public Policy at the Hertie School of Governance. He is the Director of the Hertie School Data Science Lab. His research and teaching is primarily in the field of natural-language processing and machine learning. Before joining the Hertie School faculty, he was a Professor of Public Policy and Data Science at University of Essex, holding a joint appointment in the Institute for Analytics and Data Science and Department of Government. At Essex, Slava served as a Chief Scientific Adviser to Essex County Council, focusing on artificial intelligence and data science in public services. He previously worked at University College London and London School of Economics. Slava holds a PhD in Political Science from Trinity College Dublin.

**Luke Keele** (PhD, University of North Carolina, Chapel Hill, 2003) is an Associate Professor at the University of Pennsylvania with joint appointments in Surgery and Biostatistics. Professor Keele specialises in research on applied statistics with a focus on causal inference, design-based methods, matching, natural experiments and instrumental variables. He also conducts research on topics in educational-programme evaluation, election administration and health-services research. He has published articles in the *Journal of the American Statistical Association*, *Annals of Applied Statistics*, *Journal of the Royal Statistical Society, Series A*, *The American Statistician*, *American Political Science Review*, *Political Analysis* and *Psychological Methods*.

**Michael R. Kenwick** is an Assistant Professor in the Department of Political Science at Rutgers University, New Brunswick. He graduated with a PhD in political science from the Pennsylvania State University in the summer of 2017. He was also a Post-doctoral Research Fellow at the University of Pennsylvania's Perry World House. His research is in the area of international relations, with emphases on conflict processes, civil–military relations and border politics. Broadly, his work develops novel measurement and research-design strategies to better understand whether and how states respond to domestic and international security threats.

**Gary King** is the Albert J. Weatherhead III University Professor at Harvard University – one of 25 with Harvard's most distinguished faculty title – and Director of the Institute for Quantitative Social Science. King develops and applies empirical methods in many areas of social science, focusing on innovations that span the range from statistical theory to practical application. He is an elected Fellow in 8 honorary societies and has won more than 55 prizes and awards; he has written 175 journal articles, 20 open-source-software packages 8 books, and 14 patents. He helped reinvigorate the modern quantitative and qualitative methods subfields in political science; created the standards and methods widely used to evaluate partisan and racial redistricting; implemented 'politically robust' designs that make possible research in difficult circumstances, including the largest-ever experiments in media studies and in health policy; reverse-engineering Chinese censorship, industry–academia relationships, and methods for interpersonal incomparability in surveys. These and his many other projects are among the most widely cited in political science and across fields.

**Robert Klemmensen** is a Professor of Political Science at the University of Southern Denmark. He has published broadly on topics related to political psychology and political responsiveness. Klemmensen's work draws heavily on text-as-data methods for estimating elite policy positions and relating them to mass preferences.

**Elsa T. Khwaja** is a Doctoral Candidate in public policy at the Schar School of Policy and Government at George Mason University. Her research involves international development policy and aid effectiveness in fragile and conflict-affected zones. She holds a Master's Degree in Public and International Affairs from the University of Pittsburgh Graduate School of Public and International Affairs and a Bachelor's Degree in Global Affairs and Political Science from the University of Minnesota, Twin Cities.

**James H. Kuklinski** is Professor Emeritus in the Department of Political Science at the University of Illinois at Urbana-Champaign. He is a recipient of the Hazel Gaudet Erskine Career Achievement Award by the Political Psychology Section of the American Political Science Association. His primary interests include the nature and quality of citizen decision-making, the relationship between public opinion and legislative policymaking, and the use of experiments in social scientific research.

**Xymena Kurowska** is Associate Professor of International Relations at Central European University in Budapest and Vienna. She works within international political sociology and at the intersection of psychoanalysis and politics, with particular focus on security theory and practice, subjectivity, ideological formations and interpretive methodologies. She has applied interpretive methods in her fieldwork for a variety of projects in European security and border security policy, as well as for exploring the role of researchers' reflexivity in relational knowledge production. Her current interpretive research includes the study of norms in cyber diplomacy for the European Commission-funded project EU Cyber Direct and refining instruction in interpretive methods in International Relations at Central European University.

**Scott J. LaCombe** is a PhD candidate in political science at the University of Iowa. Scott focuses on American politics and political methodology, with an emphasis on the role of institutions in state politics, and he has published papers on policy diffusion as well as the role of direct democracy in state politics. In his dissertation, he studies the role of state institutions, measuring how states design their institutional configuration, how institutional design mediates the relationship between public opinion and policy and how institutional design affects how citizens perceive state governments. Within the diffusion literature, he researches new ways to understand state policy diffusion, including the role of state similarity, how broadband internet has changed diffusion networks and how a policy's ideological appeal alters diffusion pathways.

**Thomas Leavitt** is a PhD candidate in political science at Columbia University, where he specialises in methodology and comparative politics. His current research develops methods in design-based causal inference and Bayesian statistics. He applies these methods to substantive questions on historical political economy, racial and ethnic politics and political transitions, with a regional focus on South Africa and sub-Saharan Africa more broadly. His field experiments and qualitative research in Africa have been funded by the Center for the Study of Development Strategies (CSDS), the Center for Development Economics and Policy (CDEP) and the Abdul Latif Jameel Poverty Action Lab (J-PAL).

**Lucas Leemann** is an Assistant Professor for Comparative Politics at the University of Zurich. He obtained his PhD at Columbia University in 2014 and started as a lecturer at University College London. In 2016, he joined Essex University as a Reader. His research centres on democratic institutions, representation and data science. In comparative politics, he focuses on representation and political institutions that enable representation. Within data science, he has worked extensively on measuring attitudes. His past research has been published in the *American Political Science Review*, *American Journal of Political Science*, *Journal of Politics* and *Political Analysis*.

**Suzanna Linn** is a Liberal Arts Professor of Political Science at Penn State University. Her research focuses on time series methodology and the dynamics of American public opinion and election outcomes, with a current focus on developing tests for long-run equilibria in time series analysis and expanding theories of retrospective voting to include the effects of health and well-being outcomes. She is a Fellow of the Society for Political Methodology and president of the Society for Political Methodology (2019–21). Her work has appeared in the *American Political Science Review*, *American Journal of Political Science*, *Political Analysis*, *Statistics in Medicine* and other journals. Her book *The Decline of the Death Penalty and the Discovery of Innocence*, with Frank Baumgartner and Amber E. Boydston, received the Gladys M. Kammerer Award for the best book on US national policy.

**Lanny W. Martin** is a Professor of Political Science in the Department of Social and Political Sciences at Bocconi University, in Milan, Italy. He is also a Resident Research Fellow in the Politics and Institutions unit of the Dondena Centre for Research on Social Dynamics and Public Policy.

**Adam McCauley** is a Doctoral Candidate in the Department of Politics and International Relations at the University of Oxford. He is currently a Stipendiary Lecturer in Politics at Brasenose College (Oxford) and a Senior Lecturer at the Royal Military Academy at Sandhurst. His research focuses on insurgencies and political violence, with a particular emphasis on how violent non-state groups adapt and survive. Prior to Oxford, Adam worked as a journalist reporting on conflict and international security. His journalistic work has been nominated for numerous industry awards and has appeared in *The New York Times*, *The Atlantic*, *The New Yorker*, *TIME Magazine* and *Al Jazeera*.

**Rose McDermott** is the David and Mariana Fisher University Professor of International Relations at Brown University and a Fellow in the American Academy of Arts and Sciences. She works in the area of political psychology. She received her PhD (political science) and MA (experimental social Psychology) from Stanford University and has taught at Cornell and UCSB. She has held fellowships at the Radcliffe Institute for Advanced Study, the Olin Institute for Strategic Studies and the Women and Public Policy Program, all at Harvard University. She has been a Fellow at the Stanford Center for Advanced Studies in the Behavioral Sciences twice. She is the author of five books, a co-editor of two additional volumes and the author of over 200 academic articles across a wide variety of disciplines encompassing topics such as gender, experimentation, intelligence, identity, emotion and decision-making, cyber security and the biological and genetic bases of political behaviour.

**Adam Meirowitz** is the Kem C. Gardner Professor of Business at the David Eccles School of Business, University of Utah. He is Director of the Marriner S. Eccles Institute for Economics and Quantitative Analysis. His research focuses on applied game theory and political economy

**Samuel Merrill III** is Professor Emeritus of Mathematics and Computer Science at Wilkes University. He received a PhD in Mathematics from Yale University and an MS in Statistics from Penn State University. His current research involves mathematical and statistical modeling in political science, particularly spatial models, party competition, political cycles and polarization. He is the author of three books, including *A Unified Theory of Party Competition* (with James Adams and Bernard Grofman). He has published over 60 research papers in a number of journals, including the *American Political Science Review*, the *American Journal of Political Science* and the *British Journal of Political Science*.

**Jørgen Møller** is Professor in the Department of Political Science, Aarhus University. His research interests include the conceptualisation of democracy and the rule of law, dynamics of democratisation, conflict and democratic stability, regime change and international order, state formation and comparative methodology. His work has been published in journals such as *International Studies Quarterly*, the *Journal of Democracy* and *Sociological Methods and Research*, and in books with Routledge, Palgrave Macmillan and Oxford University Press. He is currently completing a book (with Agnes Cornell and Svend-Erik Skaaning) on *Democratic Stability in an Age of Crisis*.

**Burt L. Monroe** is Liberal Arts Professor of Political Science, Social Data Analytics and Informatics at Pennsylvania State University. He is Director of the Center for Social Data Analytics, Head of the Program in Social Data Analytics and Chief Scientist for the McCourtney Institute of Democracy's Mood of the Nation Poll. His research is in comparative politics, examining political communication and the impact of electoral and legislative institutions on political behaviour and outcomes, and methodology, especially text-as-data and other data-intensive and computationally intensive settings at the intersection of data science and social science. He is particularly interested in the development of multilingual text-as-data techniques to study democratic representation, party competition and political opposition through parliamentary speech.

**Jacob M. Montgomery** is an Associate Professor at Washington University in St. Louis in the Department of Political Science. Montgomery's research focuses on incorporating advanced computational methods into core social science tasks including measurement, causal inference and prediction. His work especially focuses on Bayesian methods including publications on Bayesian model averaging, ensemble Bayesian model averaging and Bayesian causal inference. He also researches American politics with a specific focus on American parties. He has published articles in the *American Political Science Review*, the *American Journal of Political Science*, *Political Analysis* and the *Journal of Politics*.

**James D. Morrow** is AFK Organski Collegiate Professor of World Politics and Research Professor at the Center for Political Studies, both at the University of Michigan, having also taught at the Graduate Institute of International Studies in Geneva, Stanford University, the University of Rochester and Michigan State University, and visited at Nuffield College, University of Oxford. His research addresses crisis bargaining, the causes of war, military alliances, arms races, power-transition theory, links between international trade and conflict, the role of international institutions, international law and domestic politics and foreign policy. He is the author of *Order within Anarchy*, *Game Theory for Political Scientists*, co-author of *The Logic of Political Survival* and he has contributed over 30 articles in refereed journals and 30 other publications. Professor Morrow is a member of the American Academy of Arts and Sciences. He received the Karl Deutsch Award from the International Studies Association in

1994. He was President of the Peace Science Society in 2008–9 and has held fellowships from the Social Science Research Council and the Hoover Institution.

**Rebecca Morton** is a Professor of Politics with a joint appointment between NYUNYC and NYU Abu Dhabi. She is also Associate Dean of Social Science and the Director of the Social Science Experimental Laboratory at NYUAD. She is the author or co-author of four books and numerous journal articles on experimental methods, which have appeared in outlets such as the *American Economic Review*, *American Journal of Political Science*, *American Political Science Review*, *Journal of Law and Economics*, *Journal of Politics* and the *Review of Economic Studies*. She was a co-founding editor of the *Journal of Experimental Political Science*, a co-founder of the NYU-CESS Experimental Political Science Annual Conference, held annually at NYUNYC, and the founder of the Winter Experimental Social Science Institute, held annually at NYUAD. She is currently an Advisory Editor at Games and Economic Behavior and the Chair of the Experimental Research Section of the American Political Science Association.

**Layna Mosley** is Professor in the Department of Political Science at the University of North Carolina at Chapel Hill. Her research focuses on the politics of the global economy, including multinational production and global supply chains, labour rights and sovereign borrowing. She is the editor of *Interview Research in Political Science* (2013).

**Gerardo L. Munck** is Professor of Political Science and International Relations at the University of Southern California (USC). His research focuses on democracy and democratisation, Latin America, methodology and the science of social science. His books include *Measuring Democracy: A Bridge Between Scholarship and Politics* (2009), *Regimes and Democracy in Latin America* (2007), *Passion, Craft, and Method in Comparative Politics* (with Richard Snyder, 2007) and *Authoritarianism and Democratization. Soldiers and Workers in Argentina, 1976–83* (1998). He is currently completing two books: *How Advances in the Social Sciences Have Been Made: The Study of Democracy and Democratization Since 1789* and (with Sebastián Mazzuca) *A Middle-quality Institutional Trap: Democracy and State Capacity in Latin America*.

**Eric Neumayer** is Professor of Environment and Development at the London School of Economics and Political Science (LSE). He is currently the School's Pro-Director (P-VC) Faculty Development, overseeing the School's recruitment, review, promotion, retention and pay policies, but will move to the Pro-Director Planning and Resources role in September 2019. He studied economics, political science and development studies in Germany and at the LSE. His main research interests lie in environmental economics, international political economy and research methods. He has published widely in a range of journals across different social science disciplines and he is the author of four books, most recently *Robustness Tests for Quantitative Research* (with Thomas Plümper), Cambridge University Press, 2017.

**Richard A. Nielsen** is an Associate Professor in the Department of Political Science at the Massachusetts Institute of Technology. He studies and teaches on Islam, political violence, human rights, economic development and research methods. Richard's first book, *Deadly Clerics*, offers a new explanation for why some Muslim clerics adopt the ideology of militant Jihad while most do not. His current book project explores how the internet is changing the nature of Islamic authority. Richard's other research has been published or is forthcoming in the *American Journal of Political Science*, *International Studies Quarterly*, *Political Analysis* and *Sociological Methods and Research*. He holds a PhD in government (2013) and an AM in

statistics (2010) from Harvard University, and a BA in political science (2007) from Brigham Young University.

**Dominic Nyhuis** is a Post-Doctoral Researcher at the Institute of Political Science, Leibniz University Hannover. He conducts research on parties, parliaments and subnational politics. Methodologically, he focuses on automated web data collection, quantitative methods for the social sciences and quantitative text and video analysis.

**Santiago Olivella** received his PhD in Political Science from Washington University in St Louis. He specialises in defining and implementing Bayesian latent-variable models, with a wide range of applications in electoral and legislative politics. His work has appeared in the *American Journal of Political Science*, *Journal of Politics* and the *British Journal of Political Science*, among others. He is Assistant Professor of Political Science at the University of North Carolina, Chapel Hill.

**Jong Hee Park** is a Professor in the Department of Political Science and International Relations, Seoul National University. He is the director of International Relations Data Center, Seoul National University. His research covers Bayesian statistics, time series analysis, network analysis, panel data analysis and international political economy. His work appears in many journals including *American Journal of Political Science*, *Bayesian Analysis*, *Network Science* and *Social Science History*.

**B. Guy Peters** is Maurice Falk Professor of Government at the University of Pittsburgh and founding President of the International Public Policy Association. He is also editor of the *International Review of Public Policy* and associate editor of the *Journal of Comparative Policy Analysis*. His most recent books are *Policy Problems and Policy Design* (2018), *The Politics of Bureaucracy* (7th edition, 2017), *Governance and Comparative Politics* (with Jon Pierre, 2016), and *Institutional Theory in Political Science* (4th edition, 2019).

**Maxfield J. Peterson** is a PhD candidate in Political Science at the University of Pittsburgh. His work focuses on the intersection of political economy and institutional design, with a topical emphasis on energy and environment. His dissertation explores how political incentives and patronage impact energy policy in sub-Saharan Africa through a mixed-methods approach that includes interviews, qualitative case comparisons, archival research and quantitative analysis. Max's research has appeared in *Political Studies Review* (forthcoming). Prior to graduate study, Max worked in the financial industry, and received his Bachelor of Arts in Politics with distinction from Willamette University in Salem, Oregon.

**Mark Pickup** is an Associate Professor in the Department of Political Science at Simon Fraser University. Mark is a specialist in political behaviour, political psychology and political methodology. Substantively, his research primarily falls into three areas: political identities and political decision-making; conditions of democratic responsiveness and accountability; and polls and electoral outcomes. His research focuses on political information, public opinion, political identities, norms and election campaigns within North American and European countries. His methodological interests concern the analysis of longitudinal data (time series, panel, network, etc.), with secondary interests in Bayesian analysis and survey/lab experiment design.

**Thomas Plümper** is Professor of Quantitative Social Research at the Vienna University of Economics. He studied political science and economics at the Free University of Berlin. His main research interests lie in social science methodology and in comparative and international

political economy. He has widely published in a diverse set of journals across a range of social science disciplines on research methodology and research designs, natural disasters, the political economy of international economic relations and international conflict. He has authored three books including *Robustness Tests for Quantitative Research* (with Eric Neumayer), Cambridge University Press, 2017. He also co-founded the European Political Science Association and currently serves as the association's vice-president.

**Kris Ramsay** is Professor of Politics at Princeton University. He is Co-director of the Program in Quantitative and Analytical Political Science at Princeton, Director of the PhD Program in Political Economy and the Director of the Emerging Scholars in Political Science Program. He specialises in strategic analysis and its applications to violent conflict, war and political economy.

**Mirko Reul** is a PhD Candidate at the Graduate Institute for International and Development Studies Geneva. He holds a Master's degree from the Graduate Institute and was a Fulbright Scholar at American University, Washington, DC. His dissertation project on popular allegiance in social conflicts is funded by the Swiss National Science Foundation and draws on a broad range of methods, including evidence-driven computational modelling, archival research and a lab experiment.

**Kevin Reuning** is an Assistant Professor of Political Science at Miami University in Oxford, Ohio. He graduated with a PhD in political science from the Pennsylvania State University in the summer of 2018. His research and teaching focus on political parties and social movements in the United States as well as latent-variable modelling and social network analysis.

**Chiara Ruffa** is Academy Fellow at the Department of Peace and Conflict Research at Uppsala University and Associate Professor in War Studies at the Swedish Defense University. Chiara's research interests lie at the crossroads between political science, sociology and peace and conflict research, with a specific focus on ideational variables, such as cultures, norms and frames, civil-military relations and soldiers on peacekeeping missions. Her work has been published or is forthcoming in the *European Journal of International Relations*, *Security Studies*, *Acta Sociologica*, *International Peacekeeping*, *Armed Forces and Society*, *Security and Defence Analysis*, *Small Wars and Insurgencies*, *Comparative European Politics* and several edited volumes. She is the author of *Military Cultures in Peace and Stability Operations* (University of Pennsylvania Press, 2018) and *Composing Peace* (with Vincenzo Bove and Andrea Ruggeri, Oxford University Press, 2020). She is an editorial board member of *Armed Forces and Society*.

**Andrea Ruggeri** is Professor in Political Science and International Relations and Director of the Centre for International Studies at the University of Oxford. He joined Brasenose College and the Department of Politics and International Relations in 2014. Previously, from 2010, he was Assistant Professor of International Relations at the University of Amsterdam. He holds a PhD in government (Essex, 2011), an MA in international relations (Essex, 2006) and a BA in diplomatic and international sciences (Genova, 2005).

**John P. Schoeneman** is a PhD Candidate in political science and social data analytics at Pennsylvania State University. His substantive research interest is international political economy, with a particular interest in trade and foreign direct investment networks. His methodological research is in social network analysis, machine learning, and deep learning. His dissertation applies social network analysis to better understand structural dependence in international corporate networks. He expects to complete his PhD in December 2019.

**Sooahn Shin** is a PhD student in the Department of Government, Harvard University, studying political methodology and political economy.

**Kelsey Shoub** is an Assistant Professor of Political Science at the University of South Carolina, Columbia. Her work focuses on the study of the public-policy process in the United States using big data and text analysis methods. She is a co-author of *Suspect Citizens: What 20 Million Traffic Stops Can Tell Us about Policing and Race* (2018) and has been published in *Politics, Groups, and Identity* as well as other outlets.

**Betsy Sinclair** is Professor of Political Science at WUSTL, where she specialises in the study of American political behaviour. She is the author of two books, *The Social Citizen* and *A Connected America*.

**Svend-Erik Skaaning** is Professor of Political Science at Aarhus University. His research interests include comparative methodology and the conceptualisation, measurement and explanation of democracy and human rights. His books include *Democracy and Democratization in Comparative Perspective* (with Jørgen Møller, 2013) and *The Rule of Law* (with Jørgen Møller, 2014). Among other things, he is currently completing a co-authored book, *Varieties of Democracy: Measuring Two Centuries of Political Change* and working on another book project on *The Rise of Modern Democracy*.

**Branislav Slantchev** is Professor of Political Science at the University of California, San Diego. He uses formal modeling, statistical analysis, and historical cases to study crisis escalation and coercion, war fighting and termination, stability of authoritarian regimes, and choices in international organizations. His work has been funded by the National Science Foundation, among others. He is currently working on the emergence of the fiscal state, and the domestic politics of threat perception.

**Gabriele Spilker** is Associate Professor of International Politics in the Department of Political Science and Sociology of the University of Salzburg. She holds a PhD from ETH Zurich. Before joining the University of Salzburg, she was a Postdoctoral Researcher at ETH Zurich and a Fritz Thyssen Fellow at the Weatherhead Center of International Affairs at Harvard University. Her main research interests are in the areas of international political economy, international cooperation, globalization and environmental politics. Her work has been published in major peer-reviewed journals, such as *International Organization*, *International Studies Quarterly* and the *Journal of Politics*. She is the author of *Globalization, Political Institutions and the Environment in Developing Countries* (2013).

**Marco Steenbergen** is professor of political methodology at the University of Zurich. His research interests include multilevel analysis, measurement, electoral behavior, political parties, and political psychology. His publications have appeared in the major political science journals and with the major academic presses.

**Zachary C. Steinert-Threlkeld** is an Assistant Professor of Public Policy at the University of California, Los Angeles' Luskin School of Public Affairs. He uses computational methods to study protest dynamics, with a particular interest in how social networks affect individuals' decision to protest. He has used text analysis to study mobilisation during the Arab Spring, information warfare in Ukraine and activists' online strategies, and his work with images measures how violence, social cleavages and free riding affect protest dynamics. His other work includes simulations of protest diffusion and studying how governments attempt to influence

individuals' online behaviour. USAID's Understanding Social Movements programme supported some portions of this research.

**Brandon M. Stewart** is an Assistant Professor of Sociology and Arthur H. Scribner Bicentennial Preceptor at Princeton University, where he is also affiliated with the Politics Department, the Office of Population Research, the Princeton Institute for Computational Science and Engineering and the Center for the Digital Humanities. He develops new quantitative statistical methods for applications across computational social science. He completed his PhD in government at Harvard in 2015, where he had the good fortune of working with the interdisciplinary group at IQSS. He also earned a Master's degree in statistics from Harvard in 2014.

**Jessica S. Sun** is a PhD Candidate in political science at the University of Michigan, a visitor in the Political Science department at the University of Rochester and an incoming Assistant Professor in Political Science at Emory University. Her research focuses on formal theory, civil conflict and autocratic regimes.

**Tilko Swalve** is a Post-Doctoral researcher at the University of Hamburg. He received his PhD from the Graduate School of Economic and Social Sciences at the University of Mannheim in 2019. His research areas are comparative political economy, judicial behaviour and empirical legal studies. He teaches courses on game theory, quantitative methods, the political economy of institutions and comparative judicial politics.

**Joan C. Timoneda** is a Postdoctoral Research Associate at the DevLab@Duke and the Department of Political Science at Duke University. His work focuses on the comparative political economy of regime change, with particular interest in transitions within authoritarianism and democratic backsliding. His methods research interests include text analysis, network analysis using big relational data and statistical models for panel/TSCS data.

**Rocío Titiunik** is Professor of Politics at Princeton University. She specialises in quantitative methodology for the social sciences, with emphasis on quasi-experimental methods for causal inference and political methodology. Her research interests lie at the intersection of political science, political economy and applied statistics, particularly on the development and application of quantitative methods to the study of political institutions. Rocío received her PhD in agricultural and resource economics from UC-Berkeley in 2009. Between 2010 and 2019, she was a faculty member in the Department of Political Science at the University of Michigan.

**Richard Traummüller** Professor of Empirical Democracy at the University of Mannheim. Previously, he has held positions at the Universities of Konstanz, Berne, Mannheim, Essex and Frankfurt. Previously, he held positions at the Universities of Konstanz, Berne, Mannheim and Essex. He has taught courses on data visualisation at these universities and as an instructor for the Essex Summer School in Social Science Data Analysis and the International Program in Survey and Data Science. His work has appeared in journals such as the *British Journal of Political Science*, *Comparative Political Studies* and *Political Analysis*, among others. His book project on data visualisation for the social sciences is under contract with Cambridge University Press.

**Shawn Treier** is a Senior Lecturer at the School of Politics and International Relations at The Australian National University and a visiting scholar at the United States Studies Centre at the University of Sydney. His work has been published in *American Journal of Political Science*, *Journal of Politics*, *Political Analysis*, *Public Opinion Quarterly* and elsewhere. He is also the

co-author, with Jeremy C. Pope, of the forthcoming book *Founding Factions: How Majorities Shifted and Aligned to Shape the U.S. Constitution*. His research concerns the development of Bayesian models of measurement and application to American political institutions, behavior and development, and the measurement of democracy.

**Virginie Van Ingelgom** is a Research Associate Professor F.R.S – FNRS at the Institut de Sciences Politiques Louvain-Europe, University of Louvain and an Associate Researcher at the Centre for European Studies and Comparative Politics, Sciences Po Paris. She is the author of more than 30 articles and chapters, on the issue of legitimacy, both at the national and European levels, on policy feedbacks and on the methodological issues of using qualitative comparative analysis. She is the author of *Integrating Indifference* (2014) and co-author of *Citizens' Reactions to European Integration Compared. Overlooking Europe* (2013). Her current teaching commitments include courses at the UCLouvain Master in Political Sciences (political sociology) and at the ECPR Summer and Winter School in Methods and Technics (focus groups). In 2017, she was awarded with an ERC Starting Grant for her project Qualidem – Eroding Democracies.

**Georg Vanberg** (PhD, University of Rochester, 1999) is Professor of Political Science and Law at Duke University. His research focuses on political institutions, including courts, legislatures and coalition governance.

**Gonzalo Vazquez-Bare** is Assistant Professor of Economics at the University of California, Santa Barbara. His research focuses on designing econometric methods for causal inference and policy evaluation. Gonzalo earned a PhD in economics and an MA in statistics from the University of Michigan. Prior to his PhD, he worked as a consultant for the Inter-American Development Bank and the World Bank in Washington, DC.

**Mateo Vásquez-Cortés** is an Assistant Professor of Political Science at Instituto Tecnológico Autónomo de México (ITAM). His research focuses on the political economy of conflict and development, with an emphasis on topics related to violence and crime. In particular, his work analyses the causes and consequences of violence, the determinants of the successful reintegration of ex-combatants after conflict and how emotions can affect violent and non-violent political participation. In his work, he uses both formal theory and empirics, including both experimental and quasi-experimental designs. He holds a PhD in politics from New York University.

**Tiago Ventura** is a Ph.D. Candidate in Government and Politics at the University of Maryland, College Park, and a researcher at the Interdisciplinary Lab for Computational Social Science (iLCSS). His research centers on comparative politics and computational social science, with particular attention to political economy and crime in Latin America, and political communication. His methodological interests center on the use of computational techniques for text-analysis and natural language processing, network analysis, and big data, with an emphasis on causal inference estimation in observational data. He also holds a Master's and a Ph.D. degree in Political Science from the State University of Rio de Janeiro, Brazil.

**Jennifer N. Victor** is Associate Professor of Political Science at the Schar School of Policy and Government at George Mason University. Her work has been published in the *British Journal of Political Science*, *American Politics Research*, *Interest Groups and Advocacy* and elsewhere. She is co-editor of the *Oxford Handbook of Political Networks* (2017) and co-author of *Bridging the Information Gap: Legislative Member Organizations in the United States and the European Union* (2013). She holds a PhD (2003) and an MA (1999) in political science from

Washington University in St. Louis. She is a past President of the National Capital Area Political Science Association and a past chair of the APSA organised section on Political Networks. She is a co-founding contributor to the political science blog *Mischiefs of Faction* on Vox.com, and she has blogged for *The Conversation*, *Medium*, *OUP Blog* and the *LSE US Politics* blog.

**Fabio Wasserfallen** is Professor of Comparative and European Politics at Zeppelin University in Friedrichshafen. Previously, he was Associate Professor of Political Economy at the University of Salzburg, Fung Global Fellow at Princeton University, Research Fellow at Harvard University and Guest Professor at the University of Zurich, where he also earned his PhD. His research interests include European integration, public opinion, policy diffusion, federalism and direct democracy. The findings of his research have been published, among other journals, in the *American Political Science Review*, *American Journal of Political Science*, *British Journal of Political Science* and the *European Journal of Political Research*.

**Clayton Webb** is an Assistant Professor of Political Science at the University of Kansas. His research focuses on time series methodology and the domestic political dynamics of foreign policy. His work has appeared in the *American Journal of Political Science*, *Political Analysis*, *Political Research Quarterly* and other journals.

**Anna M. Wilke** is a PhD candidate in Columbia University's Department of Political Science. Her research interests concern the political economy of development, with a focus on crime and violence in sub-Saharan Africa. Recently, she has worked on violence against women, community policing and mob justice in Uganda and South Africa. Her work draws on quasi- and field experimental methods as well as game theory. Prior to her doctoral studies at Columbia, she graduated with a Master's degree (MRes) in political economy from the University of Essex.

**Roi Zur** is a Lecturer (Assistant Professor) of Comparative Politics at the Department of Government at the University of Essex. He studies voting behavior, electoral strategies of political parties and political institutions in Western democracies. His work has been published in the *British Journal of Political Science*, *European Journal of Political Research* and *German Politics*.

# An Introduction

Luigi Curini and Robert J. Franzese

Fifty years ago, Paul Lazarsfeld and Morris Rosenberg advanced a definition of ‘methodology’ in their edited volume *The Language of Social Research*, which remains as enlightening and necessary today as then: ‘methodology consists of a reflection on empirical research, on the appropriateness of the procedures and the assumptions used in relation to the intellectual intent of the researcher’ (Lazarsfeld and Rosenberg, 1955: 4). Even as discussions of methodology elucidate the criteria for assessing the quality of research and enumerate the standards that any ‘good scientific’ study must meet, yet still these criteria and standards cannot be reduced to some list of ‘instructions’ to follow or coded into some sophisticated script to run. Notice in this regard that this definition of methods emphasizes the appropriateness of the techniques *to the intellectual intent of the researcher*. That is, the optimality of methodologies chosen is specific to the research questions and aims to which they are applied. And in a broader perspective, critical

reflection on research design and methods is crucial to the balanced and conscious development of any discipline, including political science and international relations.

In the postwar period, the study of political science and international relations began to turn from configurative description and normative evaluation toward a positive social science, a scientific discipline particularly interested in questions surrounding the establishment, maintenance, and security of democracy and peace, for the obvious historical reasons. Over the course of the ‘behavioral revolution’ of the next decade or two, this new scientific discipline’s interest in methods and methodology emerged and grew, with increasing momentum through to today. According to a *Jstor* search query, for instance, the number of articles published in the political science journals mentioning ‘method\*’ explicitly in their abstracts grew from a yearly average of 41 between 1960 and 1990 to 133 in the following decade, and to 241 from 2001 through 2017 (*Jstor* search

date: 22 November 2017)). A very similar trend, albeit of lesser magnitude, is found in the international relations journals: from an average of four abstracts per year explicitly mentioning ‘method\*’ between 1960 and 1990 to nine a decade later and an average of 15 per year since 2001.

These strongly upward trends are hardly surprising given the extraordinary vivacity of methodological development and debate in recent decades, in both the quantitative and qualitative empirical-research traditions and methodologies: from the development of parametric and non-parametric techniques for more accurate and effective causal estimation and more robust and credible causal inference, the growing interest in the Bayesian approach in both quantitative and qualitative research, the developments in experimental and quasi-experimental design, and the opportunities and challenges posed by big data to the development of ‘mixed’ designs and configurational analysis – to name just a few. These trends seem surely destined only to strengthen further in the future. The present *Handbook* aims to encompass this wealth of developments, offering brief introductions to and expositions of theoretical and empirical research methods from across political science and international relations through a series of chapters authored by leading scholars of these methods. The *Handbook* sections are organized sequentially along the lines of applied research in the discipline: from formulating good research questions and designing a good research project, various modes of theoretical argumentation, conceptualization and measurement of the variables, the moving parts, of the research contribution, and collection, representation, and preliminary exploration of these empirical data to empirical methods of quantitative and qualitative analysis, including the concluding movements: the drawing of theoretical inferences and the interpretation of substantive estimates.

The chapters are each designed to reflect the current state of thinking on their topic, but

equally to provide an accessible contribution that informs a diverse audience – graduate (and ambitious undergraduate!) students, young and established professors and academics, researchers in the private, non-profit, and public sectors, and PhDs working in other modes of teaching, research, or applied work – searching for an informed take on a topic and to understand how a method works and/or is best applied. The aim is to provide a comprehensive resource by which this diverse audience of scholars and applied researchers in political science and international relations can learn about empirical methods and how to use them most effectively.

Given its targeting of a broad audience and its structuring through the steps of a research project, agenda, and career, the *Handbook* begins, in the Preface, with a welcome address given at the common starting point that connects us all: graduate training in political science and international relations. The chapters that follow are organized along the arc of a research project, from formulating questions, to theory building, operationalization and measurement, through to quantitative and qualitative research design and empirical analysis and the drawing of conclusions. Notwithstanding its considered, sequential organization, however, this *Handbook* is not intended be read linearly, chapter-by-chapter (although one is certainly more than welcome to try that if so inclined!). Rather, we suggest the reader follow some different ‘intentional routes’ through select chapters according to her needs. For example, a reader interested in network analysis or developing a network-analytic research project could start from Chapter 45, which introduces network analysis in a relatively non-technical way, then move to Chapter 46, a more technical offering that moves the reader to advanced issues, and then to Chapter 30, which applies network analysis to social media data, with several operative examples. Similarly, a reader interested in machine-learning techniques applied to text analysis could begin with Chapters 55

and 56, two chapters that introduce a variety of machine-learning algorithms, then move to Chapter 26 for an introduction to text analytics, and then to Chapters 27, 28 and 29 for their applications to texts from a variety of sources (including social media data). Finally, a reader keen to improve her knowledge about qualitative methodologies could begin with Chapter 6, which presents a discussion on how to apply qualitative methods to theory building, before moving to the last section, several chapters devoted to presenting different approaches to qualitative methods and studies.

We will conclude this short introduction with some comments perhaps especially important for a *Handbook* of research methodology. First: research scientists do not generally deploy a methodology, however sound and sophisticated, for its own sake. Rather, the ambition is that one's scientific work will be creditable because of the soundness of its conceptualization and design and the sincerity, care, and appropriateness of its conduct and methods, and that it will be *important*, meaning that it will be 'worth to be known' (*wissenswert*: Weber, 1994). Second: also meriting heavy emphasis at the beginning of a research-methodology *Handbook* is the Weberian advice that, even though perfection in this regard is impossible to obtain, scientists must be as *objective* as possible and try to acknowledge explicitly any unavoidable limitations therein as much as possible. Third: we would notice and stress also that these aims, these prescripts, and these advanced methods of scientific work have nothing to do with the work's 'practical or policy relevance and importance', as supposedly somehow opposed to its 'academic or intellectual weight', as is sometimes alleged. If we study something important (asking and offering answers to *important* questions, meaning something people care about – 'worth their knowing', as Weber puts it) and have something positive (not normative), scientific and rigorous to say about it – which means theory developed and propounded as

tightly as possible, and empirical analysis conducted as soundly, openly, and honestly as possible – then the work will be relevant inside and also, *perforce*, outside academia (Collingridge and Reeve, 1986). And it will in this way be policy-relevant and practically important *without (necessarily)* bearing normative prescriptions.

This is because positive (not normative) political science and international relations are about how the socio-politico-economic world works – the physics and mechanics of it – not how we want (or should want) it to work (the metaphysics). It is for politicians and 'the people' to decide those desires. What we can do as (political science and international relations) researchers is work to describe the machine that produces this socio-politico-economic functioning. As scientists, we do this by posing interesting, previously unanswered questions about some aspects of this world, constructing theoretical arguments and models that offer useful understandings of how those aspects may work, and conducting careful empirical analyses to test whether and to estimate how these mechanisms actually operate empirically; that is, we provide useful theoretical and empirical simplifications. Research methodology, from this perspective, is the approaches and techniques that make political science and international relations research capable of producing these theoretically, empirically, and therefore practically, useful generalizations.

## SECTIONS AND SECTION EDITORS

We extend, in closing, our enormous gratitude and appreciation to the section editors, without whose close and wonderfully constructive readings of their section's contributions this tremendous collection of masterworks would not have been possible. In particular, we want to thank Branislav Slantchev for the section 'Formulating Good

Research Questions and Designing Good Research Projects', Kris Ramsay and Adam Meirowitz for the section 'Methods of Theoretical Argumentation', Lucas Leeman and Robert Klemmensen for the sections 'Conceptualization and Measurement' and 'Large-Scale Data Collection and Representation Methods', Vera Troeger and Richard Nielsen for the section 'Quantitative-Empirical Methods', and, finally, Chiara Ruffa for the section 'Qualitative and "Mixed" Methods'.

# Foreword

We begin our *Handbook's* tour of the scientific research project/agenda with the starting point that connects us all, which is graduate training in political science and international relations. Whether we are entering graduate school, working through it, just starting on our career in political science or international relations research and teaching, or continuing to advance it after many years, Gary King's encouraging welcome address to entering graduate students about how to succeed in graduate school on the road to becoming a research scientist in political science and international relations provides excellent advice about preparing for and doing research (and is a very pleasant read as well).

*This page intentionally left blank*

# So You're A Grad Student Now? Maybe You Should Do This

Gary King<sup>1</sup>

Congratulations! You've made it to graduate school. This means you're in a select group, about to embark on a great adventure to learn about the world and teach us all some new things. This also means you obviously know how to follow rules. So I have five for you – not counting the obvious one that to learn new things you'll need to break some rules. After all, to be a successful academic, you'll need to cut a new path – and so if you do exactly what your advisors and I did, you won't get anywhere near as far, since we already did it. So here are some rules, but break some of them, perhaps including this one.

First, you're probably wondering how in the world you can write a dissertation – something like 250 pages – from scratch. Well, remember this: a dissertation is both *easy* and *irrelevant*. It's *easy* because a dissertation is the equivalent of maybe three to five papers, and you must have written that number every year for at least the last ten. So write a paper, then another, and then another; at worst,

you'll wind up with a series of articles as a dissertation, which often works out great; at best, you'll initiate a whole research program with a sequence of papers that sums up to more than the parts, or possibly a great book (which is something like four articles' worth of effort and maybe six in terms of credit). After all, you probably haven't the slightest idea how to write a book; so start writing articles and see where you wind up. Maybe a book will pop out naturally, but there's no reason to force it. (The same applies after grad school: all eight of the books I've written started out as articles that I couldn't figure out how to fit into 40 or so pages.)

A dissertation is also *irrelevant*, because this assignment is not about writing 250 pages; it's about reorienting your life, making the transition from a student taking classes – and doing what you're told – to being an independent, active professional, making regular contributions to the collective enterprise, competing and cooperating with your colleagues in pursuit of common

goals. To do all this, you need to arrange your whole life, or at least the professional portion of it, around this goal. You should not try to change into a dissertation writer (or a dissertator!) but into a professional academic, looking for opportunities to make contributions to the scholarly community that make a difference in the world. If you do that successfully, you'll get a dissertation for free along the way.

Second, in graduate school, *never shoot for the immediate goal; aim for the one after that*. Let's start with the dissertation prospectus, the text of which will not matter five minutes after it's approved. No one will ever ask you whether you did what you promised in your prospectus, and even you are unlikely to read it again. One reason for this is that writing a prospectus is itself almost logically impossible: you are supposed to convince three experienced faculty that you will discover something that will surprise them and they do not now believe to be true. And you're supposed to do that how? By speculating about what you will find, and how important it will be, if you ran some hypothetical analysis on an imaginary dataset you do not even have access to yet and may not even exist.

So don't write a traditional prospectus; instead, write an article or chapter and bring it to your prospectus committee (stapled to a one-page outline of your imagined dissertation to meet the formal goal). Then you will have made some progress on the goal after the next one and, at a minimum, will switch the conversation from armchair speculation to a productive discussion and useful advice about your work.

The same idea applies to dissertations, which are also useless five minutes after approval. Instead, try to write papers that will work as publishable articles or a manuscript that will make a book publisher happy. Just skip the step of writing a dissertation (and certainly do not use the word 'dissertation' in your dissertation; just refer to your 'work' or 'manuscript'). Similarly, don't waste your time attending dissertation defenses (except

for your friends' – and especially your own!), but go to all the job talks you can and imagine yourself standing at the front of the room, thinking of how you might respond to each question.

Third, everything you write from now on must answer this one question: *whose mind will you change about what?* This means you are not choosing a 'dissertation topic'. You've already done that by your choice of subfield and maybe even your graduate program. You should instead lead with a finding, discovery, result, or argument (and should at least be able to begin with 'In this work, I demonstrate that...'). Then rigorously organize your work to answer this key question. Remove *every* point, section, sentence, or paragraph that does not directly answer this question or address your argument. (Keep deleted portions in a folder for other projects to avoid separation anxiety, but get them out of this work.) The point of your dissertation is not (or not only!) to show how smart you are; it's to prove your point, make your argument, or solve a problem. Everything else that gets in the way of your contribution goes.

Here's a measure of whether you've succeeded: your argument (and its structure) should be crystal clear from your table of contents, without reading the text. Keep the table of contents as a separate file and keep editing it as you write. The advice you got in eighth grade about writing the outline before the text is a nice theory but doesn't work because you learn about your argument by writing it out. (You know how authors of fiction explain that they wanted to end the story in one way but the characters caused them to end it in a different way? Pretty much the same thing applies to nonfiction. The story takes on a life of its own. It is one reason we write down ideas.) Although you probably can't satisfy your eighth-grade teacher now, keep iterating between the text and table of contents. When you're done, the table of contents should be so clear it can tell the story on its own, and the text will then be unencumbered by

scaffolding or the vestige of old monsters trying to distract readers from your argument.

That monumental throat-clearing exercise called a 'literature-review section' is a great example. Fuhgeddaboutit. Those people have their own books and articles, where they make their own points; they don't get to be in your dissertation unless they help you make your point. I know you're accustomed to writing literature reviews, but that's for your teacher, testing your knowledge for class. You've now passed that test and don't need to keep taking it: do not include a literature-review section. At the same time, be professional: leave out gratuitous or fawning citations to your professors or anyone else; tell them how great they are in person if you like, but don't let them get in the way of making your contribution clear.

A final way to focus on your point is to not insist that your dissertation have 'symmetric' evidence: present all available observable implications of your theory, even if one is an ethnography of a restaurant and another is a cross-national quantitative study. Any good evidence or argument can help you evaluate your claim and demonstrate whose mind you're going to change about what. Avoid selection bias, but do not distract your audience with forced symmetry that sends you off collecting the same data from every state merely for aesthetic reasons that do not help support the evidence.

Fourth, you obviously need to get the social science right, but present your results so others not only understand what you are saying but have *no choice* but to read your work. Until graduate school, at least one person was always paid to read what you wrote. After graduate school, if you don't write so that others find they must read your work, it could be the case that no one ever reads it. You could even write a great paper, get it published in a top journal, and the only person who ever reads it is you.

The job of an academic, and the mission of the university, is the creation, preservation, and dissemination of knowledge. If no one

reads your work, you will change no one's mind, make no difference, and get no credit. Modern political reinterpretations notwithstanding, Christopher Columbus would have gotten tenure, but Lief Erikson would have had to go back on the market. Thus, your title needs to grab readers by the lapels and yank them into the page so they feel they must read your abstract; your abstract needs to interest readers enough so that they feel their own work is at risk, or they are so interested that they immediately read your introduction; and so on. Doing 'good work' is no longer good enough.

Imagine two dissertations, identical in all respects except that the title, abstract, and introduction in one is rewritten so that it resonates with your audience. The author of that one will get a great job and have a great future. The other not so much. You might as well be the one to learn this. Try out your idea on your grad-school colleagues, your friends, your parents, and non-academics. If they don't get it, it isn't because they weren't trained. Figure out how to convey what you're doing so anyone can understand it.

Graduate school is a transition from being a private citizen taking classes to a public figure writing for a big amorphous, ill defined audience that it is your responsibility to define, find, and engage. This is not easy, and it accounts for most of the frustration scholars have with the peer-review process. It will take more time than you think (even after adjusting for this sentence). It will require rewriting, recasting your argument, reconceptualizing your theory, recollecting your evidence, remeasuring your variables, or reanalyzing your data. You'll have to revise more than you want and you thought possible. But try not to get discouraged; they call it *research*, not *search*, for a reason! Be your usual relentless self and get it done.

In my experience, almost all dissertations are written in about four months, even though it takes many people years and a spark of motivation like a job offer or graduation deadline to get started. In the end, it

is simple: educate your advisor that you're ready to graduate (yes, that's your responsibility!) and then she who shows up with the pile of paper gets the degree.

Finally, the process may sometimes seem like drudgery, but remember one last rule: you're allowed to have a life. Go have some fun. And also do not forget that you are tremendously privileged to participate in science and academia and discovery and learning – by far the most exciting thing to 99 percent of the faculty at your university. The thrill of discovery, knowing you're part of something bigger, the adrenalin-producing ah-ha moments, the feeling of learning something that no one in the history of the world

has ever known before but, because of you, many will now know are more exciting than all the skiing and mountain biking you could pack into a lifetime. Don't miss how intoxicating and thrilling it all really is.

### **Note**

- 1 This preface comes from a talk at the Graduate School of Arts and Sciences at Harvard University on a panel called 'The Dissertation: Strategies for Getting from the Beginning to the End of the Process'. My thanks to Cynthia Verba for the inspiration and for arranging this panel, and to my own dissertation committee for help getting me started – Leon Epstein, Art Goldberger, Barbara Hinckley, and Bert Kritzer.

PART I

# Formulating Good Research Questions and Designing Good Research Projects

*This page intentionally left blank*

# Asking Interesting Questions

William Roberts Clark<sup>1</sup>

Good research is driven by impatience with bad answers to interesting questions. But where do interesting questions come from? Since this is the opening chapter of a handbook on research methods, it is imperative to point out at the start that there is no ‘method’ to asking research questions, in the sense of a cookbook you can follow that will lead, inexorably, to scientific ‘discovery’. There *may* be a scientific method for evaluating answers, but there is certainly no scientific method for asking questions or generating answers. And there is certainly room for a lot of creativity in developing interesting and enlightening research designs, and serious shortcomings to ‘cookbook’ approaches.<sup>2</sup> Karl Popper (1962, 2003), for example, argued that science begins after a scientist has conjectured an answer to a question. The scientific method, therefore, is more (perhaps only) useful in evaluating answers to questions. Generating questions and answers, in contrast, is as much an art as it is a science.

But that is not to say that the process is random or lacks structure. Thomas Kuhn

(1962: 763) says that episodes of scientific discovery begin with an individual with the ‘skill, wit, or genius to recognize that something has gone wrong in ways that may prove consequential’. But, he hastens to add, ‘anomalies do not emerge from the normal course of scientific research until both instruments and concepts have developed sufficiently to make their emergence likely and to make the anomaly which results recognizable as a violation of expectation’.

In the parlance of social media, scientific discovery begins with a ‘WTF’ moment. Scientific discovery begins when a scholar observes something contrary to expectations and recognizes that this anomalous observation ‘may prove consequential’. Note that the motivating fact may be an observation about the world, but it may also be about what others have said about the world.<sup>3</sup>

But not just any surprise will do. Anyone who has ever parented a young child is familiar with the questions, born out of wonder, such as those that our children asked my partner and me: ‘Why is the sky blue?’ ‘Where does

the sun go (at the end of the day)?’ ‘If my brain controls my body, why do I have to go to the doctor to find out what’s wrong with me when I am sick?’ Answers to all of these questions (assuming they are consistent with what scientists currently believe) are discoveries for the inquirer because they change what *they* know, but they do not lead to *scientific* discoveries unless they change what *we* know. The fields of optics, astronomy and neuroscience have their respective answers to the questions above (although the last question is probably less settled than the other two).

So, questions often begin with surprise, but good research questions begin with well-informed surprise. If you alone are surprised by an observation, the answer to your ‘WTF moment’ is likely to be personally rewarding. If most well-informed observers are surprised by an observation, then an answer is likely to be socially and, therefore, *scientifically* valuable.<sup>4</sup>

But sometimes science proceeds when an individual recognizes that the answers embodied in what ‘we know’ about a subject are not very good. For example, for millennia ‘we’ knew that the answer to the question ‘where does the sun go’ was something like ‘the sun circles a stationary earth, so at a certain point each day it leaves our sight while shining on the other half of the planet only to return the next morning’. Eventually, however, scientists with ‘the skill, wit, or genius’ to recognize the mounting anomalies created by models based on a geocentric view of the universe came to the conclusion that a better answer was needed. At first these better answers came in attempts to modify the heliocentric view with elaborate patches meant to explain away anomalous observations. In addition to skill, wit, and genius, it required a great deal of courage to challenge the existing view in a more fundamental fashion.

So, good questions come from knowing what ‘we’ know. But they also come from thinking deeply about what we know

and being sufficiently unsatisfied with bad answers to take the risk of thinking differently about a problem. As with all the arts, good science seems to come from individuals and groups that engage in a certain kind of practice. I would like to begin this chapter by commenting on what I see as a common structure of many great contributions to political science and international relations. Specifically, I will put forward a list of five questions that, when answered well, are likely to produce work that asks and answers interesting and important questions and gives us a reason to be confident in those answers. In the second half of the chapter I will ruminate on the kind of practice that I expect to lead to good question asking and good answer giving.

## FIVE QUESTIONS

When I was in graduate school, one of my professors, D. Michael Shafer, taught me how to read. He did so by encouraging me to employ a template he created so students could record the key parts of what they read: ‘What is the dependent variable?’ ‘What are the independent variables?’ ‘What is the logic that ties them together?’ etc. I found this enormously helpful in getting through the ridiculous amount of reading required in my graduate classes. When I began teaching I shared this list with my students and over the years I have refined it for various reasons. I have come to believe that this list of questions is useful not just in focusing our reading efforts, but also in our research efforts. If you ask what the author’s answer to each of the following questions is, you will have a good summary of most articles or books in our discipline.<sup>5</sup> If you ask whether the author has a good answer to each of the questions, you will have a good critique of the paper in question. And if you are impatient with any bad answers provided by the author, and develop better ones, you will be on your way

to making your own contribution to the literature. Consequently, I have come to believe that these questions can also serve as an excellent guide when designing a research project. If you have good answers to these five questions (and at least one of these answers is an improvement over existing work), you will have a good paper, dissertation or book. These questions also correspond to the organization of the modal paper in our discipline: 'Introduction', 'Literature Review', 'Theory', 'Research Design' and 'Findings'.

It is important to add that research questions need not be generated by reading. They can just as easily, and perhaps more profoundly, be provoked by our interaction with and observation of the social world. We might observe behavior and ask: 'Why does that happen?' It is good practice to offer one's tentative answer to such a question unencumbered by 'the literature'. But it is imprudent to spend very much time on such activity before evaluating existing answers to your question.

### **Question 1: What Do I Wish To Explain? (The Introduction)**

Following Kuhn's description of scientific revolutions, most good work begins with a puzzling observation. Beginning with observation is important because good readers would like to be convinced that the phenomenon you are explaining actually occurs (though it is frequently fruitful to engage in thought experiments about things that have

not occurred). This step is by no means trivial and considerable methodological sophistication may be necessary to accurately describe the real world events or, better still, patterns of events which you wish to explain.

Samuel Huntington's classic *Political Order in Changing Societies* (1968) seeks to explain the rising political instability he observed around the world. As evidence of this rising instability, on page 4 of this 462-page book, the author presents US Department of Defense data showing that the number of nations around the world experiencing military conflicts of various types rose almost monotonically from 34 in 1958 to 57 in 1965 (Table 1.1). This is a dramatic increase: in less than a decade the number of conflicts nearly doubled! The problem, however, is that, as a result of decolonization, the number of independent countries in the world also grew rapidly during this period. If one takes Huntington's numbers and divides them by the number of independent countries in each year (as a measure of the opportunity for military conflict), the *relative frequency* of military conflict actually declined over this period. Since military conflict was just one proxy for political instability, it is entirely possible that political instability actually increased during the observed period. But if you believe that the relative frequency of conflict is a better indicator of political instability than the raw frequency, you would be justified in wondering if the phenomenon explained in the subsequent 400 or so pages actually occurred.

The first order of business, therefore, in demonstrating that something that may

**Table 1.1 Military conflicts, 1958–65**

	1958	1959	1960	1961	1962	1963	1964	1965
Prolonged, irregular or guerrilla insurgency	28	31	30	31	34	41	43	42
Brief revolts, coups, uprisings	4	4	11	6	9	15	9	10
Overt, militarily conventional wars	2	1	1	6	4	3	4	5
Total	34	36	42	43	47	59	56	57

prove consequential has happened is to demonstrate that *that* thing has happened. This crucial task is often best accomplished with clearly presented, well thought out, descriptive evidence. While this often requires a fair amount of methodological skill, sometimes it simply requires numeracy – which, unfortunately, is often in short supply. Effectively presenting evidence for one's explanandum is perhaps best described in the breach. For example, you can read newspaper headlines on almost a daily basis that purport to capture some important change in the world that is, in fact, not supported by the text of the accompanying article. Would that it were the case that these mistakes were rare in academic work.

One common mistake is to make a claim about inter-temporal change in a variable by citing only current values of that variable. 'Tenure-track jobs are disappearing', reads the title of an article, but the article makes no reference to the number of such jobs that were available in the past. How do we know that change has occurred? A related issue that requires a bit more methodological skill to avoid is to point out a difference between the values of a few recent values of a variable and preceding values and claim that they are evidence of a new trend, without comparing the new observations with a long enough trend of data to determine whether they represent a meaningful deviation from the trend or, as is often the case, just typical variation within the trend.

Another common error is what might be called 'the denominator problem' – the failure to choose a denominator that would transform the data into a variable appropriate for the conceptual comparison relevant to the discussion at hand. We already saw an example of this when Huntington confused a trend in the raw frequency of a variable for a trend in the relative frequency of the data, which I argued would have been more appropriate. But it is also possible that the raw number is what most interests us – in which case we should not be distracted by

an apparently related ratio. To return to the 'disappearing tenure-track jobs' problem we often hear about in the popular press. In the rare instances where inter-temporal data is presented in an attempt to establish this trend, the quantity presented is typically the ratio of tenure-track jobs to the total number of college teaching jobs. This is problematic because it is entirely possible for the *share* of tenure-track jobs to be declining when the *number* of tenure-track jobs is increasing (as has been the case in the United States for decades). And it is probably the latter number that is of interest to most readers (for example, current doctoral students hoping to forecast future demand for people with the credentials they are working hard to obtain).

### **Question 2: Why Does It Need To Be Explained? (The Literature Review)**

Having explained that *this* thing has occurred, it is important for authors to demonstrate that (a) this thing violates expectations in some way (i.e., 'something has gone wrong') and (b) this violation may 'prove consequential'. In other words, in the words of Miles Davis, 'so what?'

Once again, it might be easier to say what one should not do. I once attended a practice job talk where a smart, hard-working and, subsequently, very successful scholar, when pressed to say what he was trying to explain, said that he was trying to explain why a particular variable varies. Being less supportive than I should have been, I asked, 'do you have a theory that leads us to expect this variable to be a constant?' Variables vary. It is even in their name. Observing that variation, therefore, hardly constitutes a surprise. So if variation in a variable does not constitute a violation of expectations, what does?

As a comparative politics scholar, it pains me to say that I have attended many seminar talks over the past few decades, most given

by successful and influential senior scholars, where the work in progress is motivated by an assertion that is some variant of the following ‘puzzle’:

Theory  $Q$  claims that high levels of variable  $X$  should cause  $Y$  to happen, but in country  $i$  at time  $t$ ,  $X$  was very high, and  $Y$  did not occur.

The problem with this ‘puzzle’ is that once the misunderstanding on which it is based is cleared up, it is no longer a puzzle. The misunderstanding is this: with very few exceptions (I cannot think of one), the empirical implications of social scientific theories are best treated as probabilistic (Lieberson, 1991). Whether one traces the reasons to the intrinsically probabilistic nature of all human behavior deriving from human agency, the limitations of our understanding, the fact that most (all?) social phenomena have multiple, context-dependent causes or the possibility of classification error (did  $Y$  occur or did it not? was  $X$  really high or low? and compared to what?), it is best to think of our hypotheses as probabilistic. This means the most that theory  $Q$  can claim is that ‘high levels of variable  $X$  should make  $Y$  more likely to happen’. Consequently, the fact that  $Y$  did not occur in country  $i$  at time  $t$ , despite the fact that  $X$  was very high, is not, at least to my ear, particularly puzzling. Unlikely events are expected to happen occasionally. Consequently, one cannot reasonably call a probabilistic conjecture into question with a single null case. Doing so is like being puzzled about one’s uncle who lived to a ripe old age despite being a heavy smoker. This is not puzzling, because the best scientific evidence is that smoking increases the *likelihood* of cancer, not that it *always* leads to cancer. In contrast, it would be surprising to find an entire sub-sample of the population that appears to be immune to the deleterious effects of smoking, or that, after controlling for income or education (or any other potential confound), smokers are not more prone to cancer than non-smokers. In sum, since our theories typically justify expectations about patterns of

data, it takes observations about patterns of data, not discrete data points, to violate those expectations.

While recognizing a pattern in the data is often necessary for generating surprise, it is by no means sufficient. Going back to the many comparative politics seminars I have attended: be wary of the scholar who selects a small sample of observations and demonstrates that a widely corroborated empirical regularity, such as the incumbency advantage, the democratic peace, Gamson’s Law, Duverger’s Law or the resource curse, ‘doesn’t hold’ in that subsample. Why? Because social behavior is probabilistic, so even highly predictive empirical models yield predictions with non-zero errors. As a result, one can always find a sub-sample of data where the broader pattern does not hold. Take any ‘football shaped’ scatter plot, such as the famous (Freedman, Pesani, and Purves, 2007) scatter plot shown in Figure 1.1.<sup>6</sup> One can select out a sub-sample of cases, such as those in the ellipse, to suggest that the regression line is flat or even negative even though there is clearly a positive relationship in the sample on the whole.

Recall that I said to ‘be wary’ of a scholar who motivates their study with a sub-sample of cases that appear to run contrary to a well-corroborated set of expectations. But I would not encourage you to dismiss such a scholar. It is, for example, entirely appropriate to show that there are boundary conditions on even the most well-corroborated empirical regularities. But the mere existence of such a sub-sample does not constitute a puzzle until one can convince the reader that the sub-sample constitutes a comprehensible category and is not just the result of felicitous (from the standpoint of the author seeking something to write about) case selection. Further, if one does take as their project the task of explaining why a well-corroborated regularity does not apply to a particular sub-sample, it is incumbent upon them to develop an explanation for why the sub-sample is different that yields new predictions other

**Figure 1.1 Relationship between the height of fathers and sons**

Source: Freedman, Pisani and Purves (2007) added random noise to data from Pearson and Lee (1903) who only had data to nearest inch: <http://myweb.uiowa.edu/pbreheny/data/pearson.html>

than the fact that the sub-sample is different. Otherwise, they are engaged in both post-hoc and ad-hoc reasoning.

Yet another problem can arise when one generates their research project by gazing at a scatter plot. Many will look at a figure such as Figure 1.1 after estimating a regression line and be disturbed that so many observations fall far from the regression line. It is okay to want the model to fit the data well, but given the probabilistic, multi-causal nature of our hypotheses, it is not puzzling that some observations fall far from the regression line. My father was six feet tall, while I, ahem, am not. That is not surprising because other factors enter into height at adulthood other than my genetic inheritance from my father – diet and contributions from my mother’s genetic make-up come to mind. Being puzzled in this way is a slightly more sophisticated version of the ‘if  $X$  is high in country  $i$  at time  $t$ , why do we not observe  $Y$ ’ problem. Both methods are frequently used to

justify the claim that ‘existing explanations are incomplete’. The problem is that any explanation the author comes up with is likely to be susceptible to the same criticism.

I want to be clear: there is nothing wrong with being unsatisfied with explanations that do not fit the data well. However, if the only result of pointing out observations that fall off the regression line is a new model that marginally increases measures of goodness of fit, do not be surprised if readers fail to see this as ‘consequential’. *Ceteris paribus*, papers that are motivated by the identification of unclear, misleading or incorrect understandings in the existing literature are more consequential than those that point to merely ‘incomplete’ understandings because the former causes us to revise (that is, to ‘look at again’) rather than merely supplement our current understanding.

So far, we have been seeking to identify violations of expectations that are consequential

for our understanding of the world, but one might also place a priority on consequences that are more practical. One way of asking the ‘so what’ question is to ask, ‘if you were successful in explaining your anomalous observation, how would the world be different?’ Unless one is entirely naïve, this is a very tough question to answer. But since most of us became political scientists and international relations scholars because we wanted to make the world a better place, it is still worthwhile. One reason to think about the ‘normative’ implications of the questions we ask is that an even passing familiarity with the literature in political science and international relations is enough to unearth a seemingly endless supply of unclear, misleading or incorrect understandings. In light of this, it is not unreasonable to try to tackle first those that are tied to issues about which we care deeply.

Nobel laureate Robert Lucas, in his Marshall lectures at the University of Cambridge, said: ‘Once you start thinking about economic growth, it is hard to think about anything else.’ (Ray, 1998) I suspect that is because it is not hard to see the real world, stick to your ribs, consequences of economic growth. Likewise, immigration, environmental regulation, political violence, economic inequality, government corruption, racial and ethnic discrimination, financial instability, authoritarianism, gender bias, illiteracy, failing schools or a host of other policy issues are of interest because of their impact on matters of justice and human well-being. Explaining observations that violate our expectations can be quite consequential when doing so sheds light on these and other social problems.

Marx’s last and most famous thesis on Feuerbach is that ‘the philosophers have only *interpreted* the world, in various ways. The point, however, is to *change* it’, and it is interesting that this is etched on his tomb despite having never been published while he was alive.<sup>7</sup> It captures the frustration of many scholars who would like to ‘make a difference’. It certainly captured my romantic

heart when I first read it as a young man (not much younger than Marx was when he wrote it) at the start of graduate school. But I was not in graduate school long before I realized the complexity of ‘interpreting’ the world and the dangers that could result if one sought to change the world without having interpreted it correctly. Understanding the world is a prerequisite for changing it in a responsible manner.

While it is desirable – perhaps even noble – bridging the gap between studying the world the way it is and using this information to improve social conditions is difficult – particularly when people, and, therefore, politics are involved. One problem is that if social ills have political roots, even accurate explanations of their causes are likely to be insufficient for mitigating them. One reason for this is the fact that the hallmark of politics is conflicting values. Explaining to prisoners confronted with plea deals that reward them for incriminating each other that they collectively benefit by keeping mum will not solve the prisoner’s dilemma because they will still have individual incentives to rat on their co-conspirators.<sup>8</sup>

So, while understanding the world may be a necessary condition for (responsibly) changing it, it is not likely to be sufficient. And, conversely, changing the world can make it a lot harder to understand. One of the things that makes social science difficult is that the entities we study can read what we write and change their behavior in ways that make our models less predictively accurate.<sup>9</sup>

Something like this may have been at work in the writings of Marx. The phrase ‘workers of all lands, unite!’ also appears on Marx’s tomb. In contrast to his theses on Feuerbach, this phrase was published during his lifetime. Marx and Engels closed one of the most influential political pamphlets ever written with it, three years after bemoaning the irrelevance of prior philosophers.<sup>10</sup> In an 1890 appendix to *The Communist Manifesto*, Engels admits that few heeded the call in 1848 but suggests many eventually did so over time, including those who

were organizing in support of the eight-hour workday in 1890. It is not unreasonable to suggest that Marx's analysis of an internal logic to capitalism (that the inexorable immiseration of the proletariat would lead to revolution) helped fuel the formation of labor unions and the creation of social programs that improved the material conditions of workers. But in doing so, this made them less revolutionary – thereby reducing the probability of the revolution he predicted.

Another example of how it is hard to have both influence in the real world and predictive accuracy comes from the recent literature on 'the happiness curve' – the robust empirical regularity that reported life satisfaction tends to decline when people are in their forties and rise consistently starting in their early fifties (Rauch, 2018). One explanation for this empirical regularity is that because human psychology is biased towards overly optimistic forecasts, young people overestimate how much their lives will improve in their thirties and forties. This results in disappointment during their middle years even if individuals' lives have improved considerably, but not by as much as they had expected. This disappointment also leads people to update their expectations and make grim forecasts for the future. Consequently, when life in their fifties, sixties and beyond turns out to be not as bad as expected, they report high levels of life satisfaction. If this process is truly at work, people who read this literature might be inclined to make more realistic predictions about future life satisfaction. If they did so in large numbers, the 'happiness curve' could disappear.

Notice that to the extent that Marx changed history, it may have been in ways that frustrated both his predictive accuracy and his social desires (for revolution), but if happiness researchers turn out to have the same degree of impact on society they might be perfectly willing to trade predictive accuracy for tangible improvements in people's life satisfaction.

In sum, we would like to answer questions that, when answered, would prove

consequential. These consequences can be either for the way we think about the world, or for the way people behave. While, all else equal, we would like our research to lead to improvements in human well-being, the strategic nature of politics means that even when we provide good answers to questions that are important to us, it may not lead directly to improvements in social outcomes. That is not to suggest that we should stop trying.

### **Question 3: What Is the Explanation? (Theory)**

A good explanation will take an observation that is sufficiently surprising to justify your study, and turn it into something that, in retrospect, should have been expected all along. In what remains one of the few books I know of that attempts to teach people how to explain things, the authors of *An Introduction to Models in the Social Sciences* (Lave and March, 1975) describe explanation as a process in which one imagines a prior world such that, if it existed, the surprising fact(s) would have been expected. Technically, any set of statements that logically imply the occurrence of the anomalous observation constitutes an explanation. But good explanations have additional attributes, and we would like to produce the *best* explanation. A satisfying explanation will give the reader an understanding of the process or mechanism that is likely to produce the previously anomalous observation. Readers want to know how surprising events came about, and explanations should tell them. Good explanations are efficient – the ratio of things they explain (implications) to things they require you to believe (assumptions) is high.

There is an optimal degree of novelty to an explanation. An explanation should be interesting, yet sound. By 'interesting' I mean that an explanation should cause us to see the world in a new way. By 'sound' I mean an explanation should fit in with other things we know about the world. An explanation that

causes us to see everything in a new way is likely to be wrong. An explanation that does not require us to change our mind at all is probably just a corollary of things we already knew (and, by extension, our motivating puzzle must not have been much of a puzzle).

Finally, explanations must be logically consistent. I have had empirically minded political scientists and international relations scholars tell me that formal theory is not important because they are sophisticated enough to live with theories that contain contradictions. This is nonsense. It can be shown with elementary logic that anything follows a contradiction. Consequently, if your theory contains a contradiction, anything can be said to follow from it. As a result, a contradictory theory rules nothing out and, therefore, no amount of empirical information will be sufficient to falsify it. Since potential falsification is the hallmark of science, a theory that contains a contradiction is not a scientific theory.<sup>11</sup>

One way to increase the likelihood that your explanation is logically consistent is to try to capture it with a formal model. Formal models allow us to demonstrate that our explanation's conclusions follow from its assumptions – most importantly, that our previously puzzling observation is not surprising in light of the world that our explanation posits. Also, by making the assumptions of our explanation explicit, we are more likely to notice if they contradict each other.

While these benefits of formalization are undeniable, it does not follow that every explanation should be formalized. I typically encourage my students to first articulate their explanations as a story that reveals a process that produces the previously unexpected observation. Formalization is only necessary when one hears such a story and asks ‘why would people do that?’ or, equivalently, ‘that doesn’t sound like an equilibrium’, or ‘isn’t there a tension between this part of the story and that part of the story?’ When one is confronted with such questions, a good formal model can often

provide answers. Thus, I tell my students to learn how to write down formal models not because they will always need one, but because, like fire insurance policies, they are always at risk of needing one.

Another reason to begin with an informal statement of one’s theory is to avoid the trap of thinking that a game theoretic model will generate a theory for us. Formal models help us interrogate certain aspects of our theory; they do not produce the theory for us. We must start with some theoretical intuition about what explains the phenomenon in question before we can begin to model the process.

#### ***Question 4: If the Explanation Is True, What Else Should We Observe? (Research Design)***

If you offer a view of a theoretical world that has the previously puzzling observation as one of its implications, you have offered an explanation. And while there are various ways to evaluate that explanation, to be scientific your answer to your original question must provide an answer to the following question: ‘if your explanation is correct, what else ought to be true?’ Good scientific explanations provide lots of answers to this question. If your explanation only implies the facts that you set out to explain, then there is no way to empirically evaluate your answer. You cannot use the fact that democracies seldom fight each other, or the fact that there is a lot of corruption in presidential democracies, to evaluate your explanation of these things, because it was those facts that led you to develop your explanation in the first place.

This part of the research process is a stumbling block for many researchers when they are attracted to a subject rather than a question. I once had a student who visited Brazil, was shocked by the level of corruption in the government there and developed an explanation that pointed to aspects of the large

district magnitude proportional representation electoral system as a cause. The student was surprised when I said I thought the argument had merits, but that returning to Brazil to collect data was not a promising avenue for evaluating the argument: we already knew that Brazil fit the argument! Perhaps data on corruption levels in countries with different electoral laws (such as the United States) would be more useful, I suggested. The student, however, responded that he did not want to study corruption in other countries – after all, he was interested in Brazil!

A similar problem is found in a very famous book by Theda Skocpol, *States and Social Revolutions* (1979). In it, the author wishes to explain the occurrence of social revolutions, and argues that her subject dictates her empirical strategy. Given her definition, there are only five historical cases of social revolution. She argued that as a consequence of this fact, structured focused comparison (specifically, Mill's Method of Agreement) was the only possible method for evaluating her explanation. That is not true.

The chief problem here is that if an explanation for a set of rare events only has implications about those rare events, the author does not have a data problem, they have a theory problem. If an explanation for global warming only predicts the general rise in the temperature that motivated the explanation, then it is not a very useful explanation. Cosmologists have offered explanations for the creation of the universe, but they do not choose their methodology for evaluating their explanations based on the fact that the object of their study only happened once. Instead, they ask: 'if my explanation for this unique event is correct, what else ought to be true?' They then think about how best to carefully observe the implications of their argument.

The goal of empirical research, therefore, should be to examine as many implications of one's explanation as possible. Because many, many scholars restrict their attention to the empirical puzzle that motivated their

study to begin with, many important papers can be written by simply asking of existing explanations, 'if this argument is true, what else ought we observe?'

One reason why scholars often restrict their attention to the data that generated the question is that it can often take considerable creativity to think about the implications of an explanation. There is no cookbook-like approach that can be applied that will automatically reveal to the scholar that seemingly unrelated events might be instantiations of a single social process. But one practice that Lave and March recommend is to try to see your answer to a particular question as related to a more general process.

For example, in her critical review of Skocpol's book, Barbara Geddes (2003) suggests that one element of Skocpol's explanation of rare social revolutions had implications for the occurrence of peasant revolts. Geddes suggests that a statistical model examining the conditions under which peasant revolts do and do not occur would, therefore, be useful in evaluating the empirical relevance of Skocpol's explanation of social revolutions.

Notice that when we ask 'what else ought to be true', we separate the question 'what is the author's explanandum?' from 'what is the author's "dependent variable?"' The explanandum is a statement of what the author develops a theory to explain. The 'dependent variable' is the endogenous variable in a model testing one or more of the implications of the author's theory. There are times when these might be the same, but there is no reason to assume they will be. In fact, when they are, we should wonder if the author is engaged in post-hoc reasoning – 'have they observed the dependent variable and its covariates and constructed a causal story after the fact?' Doing so would constitute a 'test' of the theory only to the extent that the lion's share of the observations could be thought to have been appreciably different from those that were observed before the theory's formulation. Conversely, a theory that produces a lot of

novel implications helps assuage the reader's suspicion that the author is merely engaged in a curve-fitting exercise.

In sum, it is typically more helpful to think of empirical work as testing the implications of a theory, rather than testing the theory directly. One reason why this is true is that testing the theory directly can easily descend into more or less complicated versions of curve-fitting and post-hoc reasoning. Instead, spend time thinking about the implications of your explanation for observations other than those that motivated your question in the first place. The more varied those implications, the better, because it is only those observations that are made after the construction of your theory that run the risk of being false and therefore actually constitute an empirical check on your explanation. And remember: if your theory only has implications for a set of events too small to use standard inferential tools to evaluate, you do not have a data problem – you have a theory problem.

### ***Question 5: Do We Observe the Implications of Our Explanation? (Findings)***

Determining if evidence is consistent with one's theoretical expectations is the primary focus of research methodology, and is therefore the central focus of the remainder of this Volume. Here I will merely stress the following: many, many studies present, often in dizzying detail, reams of information that is either irrelevant to or inconsistent with theoretical expectations. Typically, however, it is presented in a manner that suggests that this information confirms the author's expectations. Distinguishing when this is the case is a large part of what is meant by learning to read critically.

As I said, all of the collective wisdom of research methodologists is relevant for becoming a critical reader and producer of knowledge, but I will focus on one

admonition: present clear estimates of the quantities of interest as well as a statement about the degree of confidence one has in those estimates.<sup>12</sup> There are a few ways in which this admonition is frequently violated, and I would like to briefly draw your attention to them.

At least in the social scientific papers I read, explanations typically produce claims about the association between variables. Even when one is engaged in what looks like a descriptive exercise, like Huntington's attempt to demonstrate rising political instability, one is engaged in demonstrating that variables are related to each other in a particular way. If one wants to demonstrate that a phenomenon is changing over time, one must look at the relationship between that variable and time. If one wants to demonstrate that a particular behavior or attitude is more prevalent in some places or among some groups, one must look at the relationship between that variable and group membership or spatial location. Consequently, most of our empirical claims are about the relationship between variables. In a linear model we think of this quantity of interest as a slope coefficient, so I will use that terminology here, though the term 'derivative' might be even more appropriate.

A common way in which scholars become distracted from presenting the quantity of interest is by presenting something other than an estimate of a slope, when that is the quantity they are concerned with. For example, it has become common for scholars to plot the predicted probabilities from a logit model on the y-axis with some variable of interest on the x-axis when the quantity of interest is the association between a change in that predicted probability and a meaningful change in some variable of interest. The problem with doing so is that it requires the reader to infer the slope of that relationship from the picture. While it is true that slopes are not constant in non-linear models such as logit, and therefore the quantity of interest does not reduce to a single number, it would be better

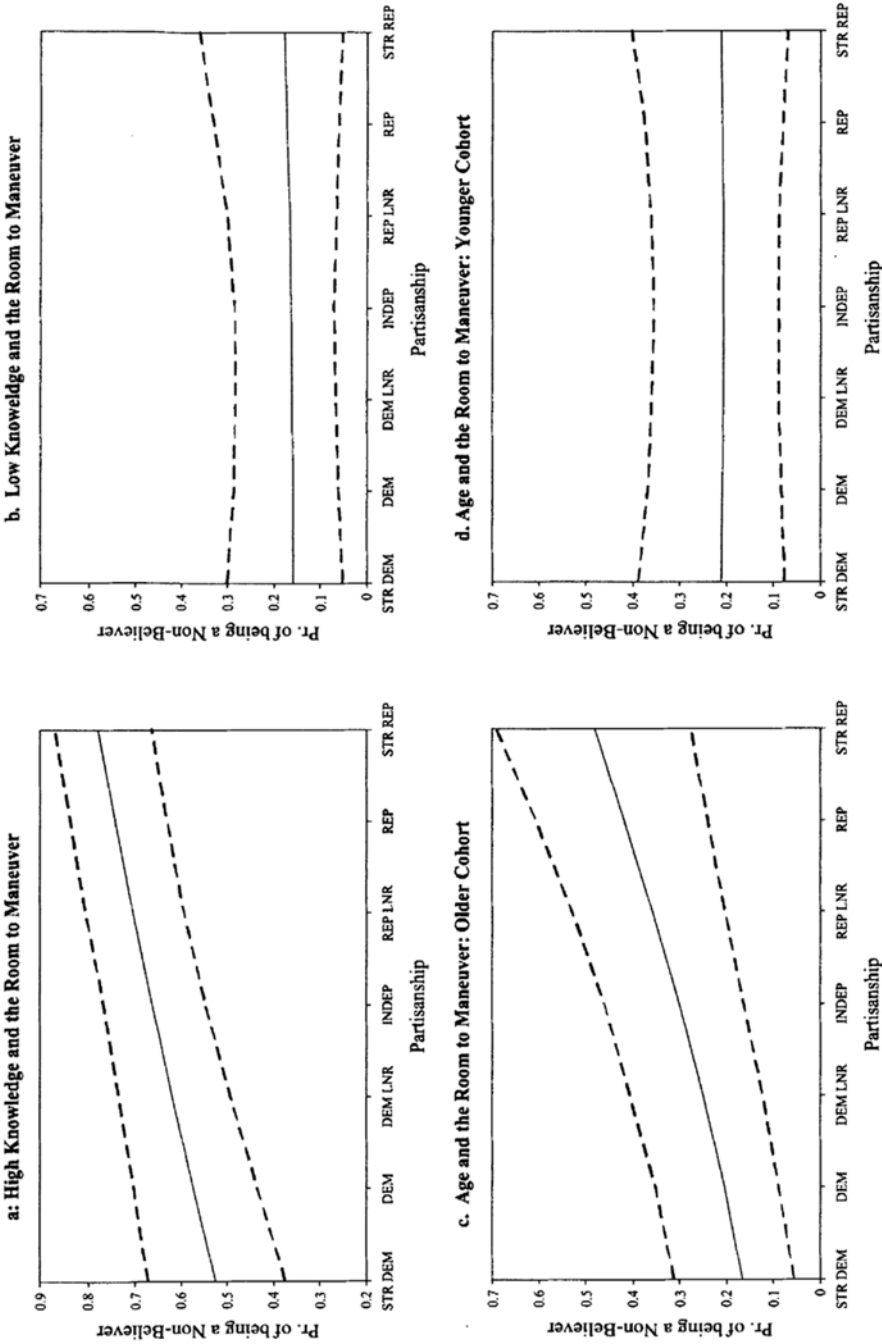

to plot the marginal effect of the variable of interest across a meaningful set of values of that variable of interest.<sup>13</sup> Adding confidence intervals around the predicted probability does not help because that tells the reader if the predicted probability is significantly different from zero, which is typically not the hypothesis being tested.

For example, Hellwig, Ringsmuth and Freeman (2008) present the graphs in Figure 1.2 as evidence for citizens' propensity to believe governments have little room to maneuver policy in a globalized economy. Each panel plots the predicted probability (and 90% confidence intervals) that a survey respondent said they did not believe the US government retains the 'room to maneuver' policy against the respondent's partisanship. The authors interpret the apparent difference between the slope of the plots in the left hand panel and the right hand panel as evidence that partisanship has an effect on respondent beliefs among respondents with college degrees (panel a) but not among those with high school degrees or less (panel b), and among respondents above the age of 59 (panel c) but not below the age of 40 (panel d). But what is the basis of this conclusion? The slopes on the right clearly look to be close to zero and, in comparison, the slopes on the left appear to be positive. But we are offered neither an estimate of the slopes for any degree of partisanship, nor an estimate of our uncertainty about that estimate. We can try to calculate the slope at different points on the line by estimating the 'rise over run' and we can kind of compare that estimate with the uncertainty implied by the error bars, but why make the reader construct a t-test from the picture rather than present that information for the reader by plotting marginal effects with their associated confidence intervals? Neither do the authors provide any evidence whether the slopes in the left hand panels are different from the slopes in the right hand panels. As a consequence, these pictures, and ones like them that appear frequently in

the literature, provide almost no *quantitative* evidence about the quantity of interest (under what conditions, if any, a change in partisanship is associated with a change in citizen beliefs about the government's 'room to maneuver').

Another common way of obscuring the quantity of interest is by presenting 'marginal effects' that are not marginal. It is commonplace for authors to say things like 'to gain some substantive understanding of these results, I note that a one standard deviation change in X is associated with a 0.056 change in Y'. The problem with this is that there is nothing typical or representative about a standard deviation – in data approximating a normal distribution, about two-thirds of all observations will be less than a standard deviation away from the mean. As a consequence, a change of a standard deviation in the variable of interest is not a particularly meaningful counterfactual to consider. This is particularly true where this practice is most frequently found – when interpreting the results of a non-linear model. Under this circumstance, the marginal effect of a variable is extremely sensitive to where it is being evaluated. The slope described by a 'marginal effect' the size of a standard deviation is likely to be very far from the slope of any estimated marginal effect within this interval. Another reason why this is not a particularly useful counterfactual comparison is that marginal effects are interpreted under a *ceteris paribus* clause where other factors are held constant – something which is not likely to be approximated in the real world when the variable of interest experiences an unusually large change the size of a standard deviation.<sup>14</sup>

Another common way in which scholars present information that is not the quantity of interest is when they have a hypothesis that is conditional in nature and either present results from an unconditional model or, equally common, estimate a conditional model but go on to interpret some of its results as if they were unconditional.<sup>15</sup>

**Figure 1.2 Partisanship and beliefs about 'room to maneuver': the conditional effects of knowledge and age**

## Summary

My claim, up to this point, is that a paper, book or dissertation that has good answers to the five questions above will be a useful paper, book or dissertation. It does not follow that a paper, book or dissertation must have an *innovative* answer to all five of those questions. Progress can be made as long as one of the answers is better than existing answers and none are worse.

Which questions are ‘most important’ and, therefore, which ones should be the focus of your efforts to innovate? It is hard to say, though I believe that it is probably not best to try to explain something that no one has explained before. This is an important point. I have had many graduate students inform me gloomily that someone has beaten them to their ‘question’. My standard reaction is to say, ‘well, I doubt they have come up with the definitive answer, so what are you worried about?’ Since any question worth asking is likely to be difficult to answer, it is highly unlikely that another scholar is likely to beat you to the punch and have the last word on a subject. Indeed, if you are asking a question that no one else has asked, it should give you pause. Maybe it is not a very interesting question, or maybe there is something about asking the question in that way that led other scholars to believe productive answers were not forthcoming. That said, the mere fact that other smart people have asked the question does not mean it is a great idea for you to try to answer it.

Graduate students are told that they need to make an original contribution, which leads them to believe that they must ask a question that has never been asked, or at least never been answered, before. That is not true. Rather, an ‘original contribution’ requires only that the student provide a better answer to at least one of the questions mentioned above. So, if a student at the prospectus stage is going to attempt to offer a novel explanation, then part of their answer to question 2 should contain a statement about what they

bring to the table that might allow them to make progress where others have failed. What theoretical insight, methodological advantage or historical knowledge puts the author in a position to simultaneously recognize that ‘things have gone wrong’ with existing explanations and offer a solution that pushes the field in a promising direction?

Since ‘theoretical innovation’ is often thought to be the most prized contribution a political scientist can make, scholars often believe that a good paper should offer a novel explanation. I believe this comes, in part, from physics envy combined with the notion that theoretical physicists have a higher status than experimentalists. I believe that the idea that every important contribution must contain a theoretical innovation has greatly hampered the progress of our discipline. How is the accumulation of knowledge possible if, every time a scholar puts pen to paper, they have to offer a new explanation? Given frequently imperfect research designs and flawed empirical methods, I often think the opposite is true. We might be tempted to declare a moratorium on the development of new explanations until the discipline has reached consensus about empirical tests of the implications of existing explanations. As my critique of Huntington suggests, if we do not get at least some of the empirics right, how do we even know if our observations violate current theoretical expectations enough to warrant new explanations? One reason to resist such a temptation is that new theories do more than explain anomalies. For example, they also address conceptual and logical problems with existing explanations.

## PRACTICES THAT ENCOURAGE GOOD QUESTION ASKING

Following Kuhn’s line of reasoning above, it is worth asking what is likely to promote the skill, wit, and genius capable of recognizing when things have ‘gone wrong in ways that

may prove consequential'. Of Kuhn's three desiderata, 'skill' seems the least constrained by natural ability and, therefore, the most responsive to the environments we create. While artistic creation involves many aspects, a degree of craftsmanship is typically involved and craftsmanship is derived largely from practice. Extensive training in game theory and statistics is now commonplace in most graduate (and some undergraduate) programs in political science and international relations, and this is what is typically thought of when scholars evaluate the 'skills' of job applicants. These skills are important because without them scholars might ask questions based on faulty reasoning based on formal or informal fallacies such as the ecological fallacy, ad hominem attacks, hasty generalization, confusing correlation with causation, ignoring strategy induced selection effects, and failing to recognize the presence of confounds.

But while methods training is extremely helpful, it is not sufficient to produce scholars who ask and answer interesting questions. The problem sets typically assigned in quantitative methods and formal theory classes do help build the skills necessary to execute sophisticated research, just as playing scales and arpeggios builds the techniques necessary to execute sophisticated music. But there is more to training a musician than playing scales and arpeggios, because as important as scales and arpeggios are, they are not music. I have heard musicians criticized for having sufficient technique that they 'know how to say things on their instruments, but they do not seem to have anything to say'. The analogous criticism is frequently leveled at newly trained political scientists and international relations scholars.

So, what is to be done? To play good music, students have to listen to good music and they have to have a lot of experience making good music. Most graduate programs provide students with the equivalent of listening to music. When I was a newly minted PhD I heard Bruce Bueno de Mesquita give a lecture

at the Hoover Summer Program in Game Theory and International Politics at Stanford University. He built a game theoretic model based on the assumptions of hegemonic stability theory – seemingly on the fly, based on comments shouted out by my classmates. I had an epiphany. Of course, if developing social scientific explanations is an art, then it must be taught as the arts are taught! I was watching the master at the easel – engaged in the very craft I was trying to learn. It suddenly occurred to me that much of my graduate training amounted to the equivalent of sitting in a room listening to recordings of music, and then when it was time to write my dissertation it was as if a door had been flung open and I was handed an instrument I had never played (I imagined a cello) and pushed out onto a stage where I was expected to perform. Most graduate programs in political science teach people the equivalent of playing scales in methods classes and music history or appreciation in substantive classes, leaving them to figure out on their own how to put this together to make music.

The missing piece in most of our graduate education is what musicians call *etudes*. These exercises are designed to be music-like (so students can begin to think about interpretation and expression) but are artificially designed to allow for a degree of repetition of particular techniques (articulation, vibrato, dexterity) that allows those skills necessary for musical expression to seep into the student's muscle memory. Many doctoral programs emphasize that students should write publishable papers, but I believe that success is unlikely if this is attempted before students have engaged in many repeated attempts to explain things or think about what observations are implied by their explanations. Students need to practice asking and answering the five questions outlined above, and writing a single paper in each seminar does not give them the 'reps' to develop muscle memory. Virtually no skill worthy of the name can be developed after a dozen or so attempts.

Consequently, I have argued that problem sets in 'substantive classes' can help students become proficient at asking and answering the questions that will make for innovative research. An analogy to the visual arts might be useful. When students are learning to draw, they are not handed a blank sheet of paper and told to 'think of something interesting to draw, that no one else has drawn'. Rather, a bowl of fruit, or perhaps a wooden model of a human figure, is placed on a table. Then, everyone in the class draws the same thing, after receiving instruction from the instructor about how to do so. In contrast, many political science departments do the equivalent of handing their students a blank sheet of paper and telling them to 'draw something interesting'. Problem sets in substantive classes can be the equivalent of a bowl of fruit. The instructor can assign students to a question related to a particular research area: 'Explain why X occurs under Z circumstances.' 'If P explains Y, what else ought we observe?' 'Why is Q an interesting question?' 'Does Figure 2 count as confirming or disconfirming evidence for hypothesis 2, and why?'

Students need a lot of experience 'making music' before they 'have something to say'. If the analogy to the arts does not resonate with you, consider the following. Political science and international relations can take a lesson from the so-called bench sciences, where students work on many projects as members of large teams before they are tasked with the responsibility of deciding on the topic of the group's next project. Experience and repetition helps students learn what works and what does not.

While graduate pedagogy is important for stimulating creative question asking and answering, the broader climate and culture that we create in our departments and research centers is equally important. In particular, it is extremely important to create an environment where it is safe to play with ideas and challenge orthodoxy. I once had a colleague who, while walking down the hall, read a passage from a book that he

thought was incorrect and loudly declared the author an 'idiot'. Creativity and risk taking are not encouraged by a culture that suggests that only stupid people say stupid things. Instead, it is important to create the idea that the smartest among us are capable of error and that there is a big difference between *saying* something that is stupid and *being* stupid. To that end, I think it is extremely important for senior scholars to be transparent about the errors they have made. Young scholars need to learn that if they have made a mistake, they are in very good company, and if the requirement for admission was never making a mistake, the building would be empty.

While a culture of support for individual risk taking is vital to any scientific or artistic community, there is an optimal degree of individualism behind scientific discovery. If you don't read what everybody else reads and fail to train like everyone else trains, you will ask naïve questions that the rest of your community knows the answers to. But if you only read what everyone else reads, and only train like everyone else trains, you are unlikely to experience that moment when you see something that has gone wrong which no one else has seen.

Jazz bassist Scott LaFaro started playing the bass in 1954, when he was 19 years old, and in the few short years before he was killed in a tragic car accident in 1961, he completely changed the world's conception of what could be accomplished on a double bass and what role the instrument could play in a piano trio. Prior to playing the bass he had played the clarinet and saxophone for years, and many have attributed his phenomenal technical prowess to the fact that he practiced the bass by playing *etudes* composed for the clarinet by Hyacinthe Klosé in the 19th century (LaFaro-Fernández, 2009). The lesson LaFaro taught the world, in addition to the general benefits of interdisciplinarity, was: 'if you want to sound like everyone else, practice like everyone else; but if you want to sound like no-one else, practice like no one else'.<sup>16</sup>

Just as there is an optimal degree of individuality that is likely to produce scholars with the skill, wit and genius to determine when something has gone wrong in ways that may prove consequential, communities that strike the right balance between conformity and diversity are likely to encourage the habits that lead to scientific breakthrough.

On the one hand, it is important for a scientific community to share a commitment to the growth and dissemination of knowledge and a common understanding of the logic of inference and the standards of evidence. Without this shared understanding, criticism is likely to fall on deaf ears. But on the other hand, it is important for a community to be as diverse and eclectic as possible. People from different cultural, class, linguistic and religious backgrounds are likely to see the social world differently because they are likely to have had different experiences. These different experiences are likely to lead to diverse moral, political and social intuitions that lead them to raise questions that a more homogeneous group might not consider (Page, 2007).

In addition, diverse groups are less likely to fall prey to what I call ‘strategic confirmation bias’. Confirmation bias occurs when an individual embraces an idea uncritically because it conforms to their prior beliefs. When confirmation bias is at work, people are less likely to scrutinize the research practices that produced the claim in question. They are less likely to look for confounds, to ask about the details of data collection or to think critically about either the micro-foundations or the moral implications of a claim because the results confirm what they have long suspected about the world.

Strategic confirmation bias occurs when an individual is able to overcome first order confirmation bias and think critically about the claim being made, but is deterred from voicing the criticism because they believe that others are refraining from criticism as a result of confirmation bias. Under such circumstances, critically engaging the claim in public might signal to others that the critic does not share their beliefs on the matter.

Strategic confirmation bias is most likely to be a problem in communities where ‘everybody’ shares particular beliefs. In such an environment, thinking critically about a result that confirms the community’s beliefs could result in ostracism, or, at the very least, fewer dinner invitations. A community composed of individuals from diverse educational, class, religious and ideological backgrounds is less likely to produce the kind of monolithic views that encourage strategic confirmation bias. Individuals are more likely to say something when they see something wrong that may prove consequential because the set of taken for granted shared beliefs is likely to be smaller. Diversity is most likely to be helpful in this regard when the multiple dimensions of identity are relatively uncorrelated. If gender, race or ideology are heavily correlated, then dissent on one dimension can be seen as defection on another. Thus, in ideal circumstances, communities would have as much within group diversity as between group diversity.<sup>17</sup> Of course, diversity has to be sufficiently developed to give individuals confidence that speaking up under such circumstances will not simply confirm that one is an ‘outsider’. If a community promulgates the norm that in a multidimensional space we are all, on one dimension or another, outsiders, the cost of revealing that one ‘thinks differently’ about something is likely to be less costly. The daunting thing about strategic confirmation bias is that it is mostly likely to occur around issues about which scholars feel passionately. As a result, there is a danger that a research community will be least scientific about the matters that it cares most deeply about and most scientific about matters which its participants view as largely inconsequential.

## CONCLUSION

Good scientists ask interesting questions and are unsatisfied, even impatient, with bad

answers. I have argued that most work in political science and international relations can be understood through the lens of five questions and that contributions can be made to the literature by improving on a research community's answer to any of the five questions.

Since coming up with better answers to questions is as much art as it is science, I have argued that the best way to train good social scientists is to learn from the way in which artists are trained. Musical and visual artists learn their crafts through structured repetitive practice. The implication of this insight for the social sciences is that scholars should be given materials to work with that allow them to engage in the daily practice of asking and answering the five questions outlined in the first section of the chapter. I have suggested that the best way to encourage this is through the use of problem sets in our substantive courses. I have also hinted that there are great benefits to interdisciplinarity. By bringing habits, techniques and insights that are normal in one discipline into a setting where they are rare, individuals are more likely to recognize when something has 'gone wrong in ways that may prove consequential'. Finally, I have argued that diverse communities are more likely to produce good question askers, in part because they are less likely to fall prey to strategic confirmation bias.

## Notes

- 1 The author wishes to thank Branislav Slantchev and Laurie Clark for thoughtful comments and useful suggestions on an earlier draft of this chapter.
- 2 The fad around 'clever identification strategies' is but the most recent instantiation of this phenomenon.
- 3 In the words of Branislav Slantchev (in personal communication), 'theoretic innovation does not have to begin with an empirical observation but with a potential flaw in the logic, inconsistency of the assumptions, or an insight about a general claim (e.g., the impossibility results)'.
- 4 It is fashionable in many top graduate political science programs for faculty to say that 'substantive courses' are a waste of time and enterprising students should have an almost single-minded focus on methods training. It is also commonplace for professors to complain that their students are not adept at identifying interesting questions. I suspect that these phenomena are not unrelated.
- 5 The questions would have to be adapted to serve this purpose for literature reviews, methods papers and purely theoretical papers.
- 6 The scatter plot is based on data from an example from Pearson and Lee's (1903) examination of the correlation between the adult heights of fathers and sons.
- 7 Marx (1950 [1888]).
- 8 In contrast, if the only problem is a co-ordination problem then the mere dissemination of information is likely to be sufficient. But such problems are about as political as getting drivers to stay on their side of the road.
- 9 Though sometimes this works in the opposite direction. For example, experiments have shown that students who take economics classes behave much less cooperatively, and therefore more in line with the models learned in these courses.
- 10 *The Communist Manifesto* (Marx and Engels, 1996) had little immediate impact on embryonic socialist movements, but its long-run influence is undeniable.
- 11 In the possibly apocryphal words of theoretical physicist Wolfgang Pauli, it is 'not even wrong'.
- 12 King, Keohane and Verba (1994).
- 13 In the language of calculus: if the quantity of interest is  $dy/dx$ , then plot  $dy/dx$  against  $x$ , not  $y$  against  $x$ . The former tells the reader what they need to know. The latter makes the reader try to infer what they need to know from the picture.
- 14 See King and Zeng (2006) on 'the Dangers of Extreme Counterfactuals'.
- 15 See Brambor, Clark and Golder (2006) or Kam and Franzese (2007) for a fuller discussion.
- 16 At the same time, nearly every innovative jazz musician learned their craft by memorizing performances of musicians that came before them.
- 17 The connection between 'intersectionality' and cross-cutting cleavages should be explored further.

# From Questions and Puzzles to Research Project

Adam McCauley and Andrea Ruggeri

*Nam placuisse nocet*  
(Perfection brings destruction)  
*Metamorphoses*, Ovid

Regardless of perspective, philosophy, approach or assumptions, strong projects require a good research question. The process can be laborious, and the researcher will likely spend significant time in draft, making the question clear and explicit before it emerges in its polished form in the research project. For this reason and those outlined below, a scholar will face many of the core issues discussed in this chapter and its companion Chapter 1. For the lucky ones, the chapters on different methods will be eye-openers – whether on case studies and process tracing (see Chapters 59 and 62), formal theory (see Chapters 3 and 11) or the exploration of estimators in multivariate statistics (Chapters 33–57). However, each of these journeys begins with a singular prompt: what are you going to study?

This is the vital query of academic life. Any researcher, reviewer or dissertation committee

member will wonder the following: what main question is this research aiming to answer? What is the relevance of the inquiry? What contribution will the potential answers make to the wider field? How conclusive can the answer be? The first three interrogations help scholars generate crucial research questions and phrase them most cogently. The final interrogation urges scholars to consider whether their questions are likely to lead to neat or complete answers. Potential indeterminacy should not dissuade the researcher, but should embolden her to explore and explain as much, as rigorously, as possible.<sup>1</sup> Thus, this chapter explores how we can approach, imagine and generate research questions in international relations (IR) and how our answers can open pathways to related research projects. Our mission is to explore the craft of formulating research questions. Adopting the position of the craftsperson, beyond the idealized realm of the scientist, this chapter provides insights from published work and offers ‘rules

of thumb' to think systematically about the puzzles that motivate academic inquiry. We stop short of discussing different philosophies of social science and how they relate to the discipline, as there are excellent works on the epistemology of IR (Hollis and Smith, 1990; Fearon and Wendt, 2002; Jackson, 2016). Further, while we do not aim to dismiss other styles of research in IR, space limitations have forced us to be selective, and we have settled on the styles with which we are most familiar.<sup>2</sup>

### **WHERE RESEARCH QUESTIONS MIGHT COME FROM**

While the research question is a prerequisite for any academic project, for all the time spent on methodological training, theoretical instruction and historical exploration in our field, we devote few formal resources to teaching the art of question development. In handbooks and courses on research design, 'there is rarely any mention [...] of the specific challenges students face when devising a research question' (Bachner, 2012: 2).

Some ideas seem to emerge at random or through communing with colleagues in one's field. Often, though, questions emerge as the net results of unseen processes of thought – a mind's work tying together different ideas (old and new). These ideas then inform research questions, which, like their subsequent answers, become a product of continual evolution. Scholars can find it difficult to explain the origins of their interests in topics such as sanctions, international organizations, military occupation or civil wars. Even if the origins of their interest remain unknown, we argue that the practice of question formation can be looked at systematically, and pay careful attention to how we refine, specify and clarify research questions. Insights emerge from the working (and reworking) of one's inquiries and, as Bertrand Russell (2009) put it, 'I do not pretend to start with precise questions. I do not

think you can start with anything precise. You have to achieve such precision as you can, as you go along.' This intellectual journey is as important as the destination.

To this end, patience and commitment are vital for the generation of knowledge.<sup>3</sup> Scott Berkun challenges the very notion of an 'epiphany' – a word which suggests that inspiration comes from supernatural forces or beings – and suggests ideas emerge from a lifetime of hard work and personal sacrifice. What might at first glance appear to be driven by intuition or creative accomplishment is most often the result of systematic commitment to scholarly review. In this way, real innovation emerges from 'an infinite number of previous, smaller ideas' (Berkun, 2010) – it is not produced in splendid isolation. Alex Pentland (2014) illustrates the importance of social context for idea generation and finds intellectual strength in numbers, particularly when these crowds involve free-flowing ideas and a community engaged in the process of knowledge generation. These characteristics are essential for innovative and productive societies – and these insights ought to hold for smaller epistemic communities as well.

Steven Johnson (2011) agrees: 'World-changing ideas generally evolve over time – slow hunches that develop, opposed to sudden breakthroughs.' He argues that ideas may be aided by our better, stronger communication platforms, which allow us access to real-time information in ways never previously thought possible. Our age of communication also facilitates connections between researchers – and these networks retain intellectual weight to be leveraged in search of evocative questions. Through studying the complexities of innovation, Johnson highlights the importance of collaboration while stressing the value of preparation. Scholars must 'do the work' if they want to be in position for good fortune to strike. Finally, Johnson knows the route to understanding is not carved by successes alone, but by the failures that lead to mid-range solutions, and often to

refashioning something old to create something new.

For our purposes, we find the ‘literature review’ serves as the tangible product of this systematic approach: it aids scholars in identifying extant claims in the literature and helps orient their question to explore where the potential cause and effect might be identified. By knowing as much as we can about what works and what does not, or how things are assumed to work and might not, we are better able to generate pressing and potentially catalyzing research questions.

Connecting previously under-appreciated insights, however, demands that a scholar engage deeply across the broad expanse of IR scholarship. These scholars should explore beyond their sub-field into political science more generally (Putnam, 1988), and beyond their discipline into cognate areas of sociology (Wendt, 1999), psychology (Levy, 1997a), the detailed accounts of history (Gunitsky, 2014; Levy, 1997b) and models born of the study of economics (Hafner-Burton et al., 2017). Scholars will also benefit from their appetites beyond traditional scholarship, looking to fiction, television and films to leverage these created worlds to their advantage. Each of these creative spaces can convey important insights or stimulate questions that one’s discipline might not. With this background – and a notebook filled with potential topics – researchers will be quicker to identify unexplored perspectives. The novelty of these topics will also be readily ascertained through participation in conferences and targeted (subject-specific) workshops.

Burkus (2014) also argues that creativity emerges when an individual can connect different types of knowledge. In the academic context, this creativity emerges when researchers incorporate relevant knowledge in parallel (but perhaps under-connected) disciplines in new and novel ways. Further, scholars also benefit from working between different *sub-fields* within their discipline, where insights and research puzzles are often found. Returning to the practicality of

accomplishing this, scholars should look to the literature review as a forum for this considered and engaged intellectual exploration.

To this end, there are important differences between using and writing literature reviews, and the best illustrate how critical this initial survey can be. We can break this down into two versions of the literature review. The *private* review is for the scholar’s own use. This survey connects assumptions, inconsistencies and insights, while highlighting possibilities for improvement. The *public* review is for the consumers of the finished scholarly product. This explains and situates the research project within the discipline. The private review can (and often should) be partially sacrificed for the latter, where only the critically important items are cited. All too often, early career scholars want to signal their commitment by adding extra entries to these public literature reviews, failing to distinguish between the logics that underpin the exercise: the logic of exploration and the logic of explanation.<sup>4</sup> The final literature review, which adopts the logic of explanation, should serve as a storefront display displaying only the essential and most compelling items: neither customers nor your readers should have to search through the storage room to find what they came for.

The literature review embodies our philosophy for idea generation. This initial stage often focuses on identifying potential puzzles, and these early queries must be analyzed, challenged and sharpened before they can be polished for use. This process of discovery, through systematic reading and questioning, does not preclude creativity or emotional investment. In fact, these features are assets, given ‘the role of curiosity, indignation, and passion in the selection and framing of research topics’ (Geddes, 2003: 27). It is possible to be systematic and analytic while being motivated by indignation and passion, but it takes practice (Blattman, 2012). All ideas benefit from intellectual clarity, and *good* ideas, specifically, are the product of intellectual clarity. These good ideas will

only be stronger if their discovery is motivated by inspiring research questions.

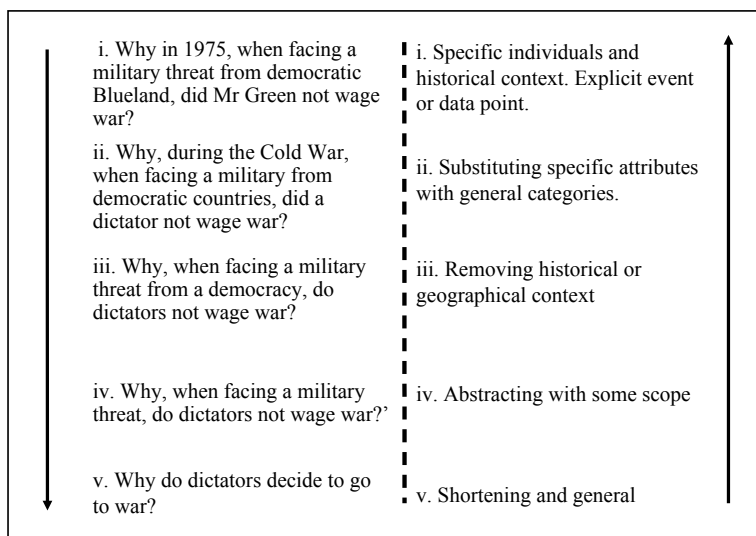

To this end, that clarity begins with simplicity.<sup>5</sup> Scholars should begin with the most basic and essential assumptions of how causes, effects and/or processes unfold, and construct their research queries in response. Consider this approach akin to Occam's razor: start from simple premises and proceed with the most basic explanation to build your initial theory. By removing all premises that are clearly incorrect, we are left with propositions that might plausibly capture elements of the answer. Simplicity distinguishes superior inquiries and research designs.<sup>6</sup>

## SPECIFIC AND GENERAL RESEARCH QUESTIONS

Academics often face the hedgehog or fox dilemma (Berlin, 2013): do you want to know a lot about one thing (hedgehog) or a little about many things (fox)? Are you interested in why the Mau Mau rebellion emerged in Kenya between 1952 and 1960, or are you interested in how civil wars begin? These

questions are related, and their relationship is important. While a scholar eager to explain why civil wars emerge might use the Mau Mau as a case of interest, a scholar focused only on the Mau Mau can generate lessons learned about this case alone. Solving the hedgehog and fox dilemma demands a scholar decide what questions she can answer, how comprehensive these answers can be and how she imagines her insights might apply to the wider universe of cases. Fundamentally, it requires that the researcher decide whether to privilege causal identification, which limits the questions she can ask, or whether to ask an unbounded question, while remaining cognizant of any methodologically imposed limits to the resulting answers.

Figure 2.1 presents a schematic of the process of abstraction for a research question. Although most scholars use this process intuitively and implicitly, visualizing the practice can be pedagogically useful. This process mirrors the form of Sartori's (1970) *ladder of abstraction* and provides a step-wise sequence for a researcher to explore alternative levels of inquiry that may emerge within the research agenda.

**Figure 2.1 From specific to abstract (and vice versa)**

Consider a fictitious dictator, Mr Green, who faced a military threat from a democratic country ('Blueland') in 1975 but decided not to wage war. The event is quite specific, as it focuses on only one person in a given year and within a single country. The second step calls for substituting the specific details of the case with more general categories.<sup>7</sup> We replace Mr Green with the general term 'dictator', change the specific date to a historical period ('the Cold War') and replace the country with the category of regimes to which it belongs ('democratic countries'). Of course, this process assumes that these different conceptualizations are possible, and, further, that their operationalizations are plausible. These issues (conceptualization, operationalization and measurement) should not constrain the question-generating process but should be tackled directly in later stages of the project. The third step up the ladder of abstraction sheds the temporal and geographical dependence. Not all research questions are ahistorical or devoid of geographical context. In fact, as Figure 2.3 will make clearer, we believe quite the opposite: historical and geographical contexts have complex interaction effects (Eckstein, 1998; Tilly and Goodin, 2006). However, developing a research question demands an early attempt to simplify by eliminating layers of specificity,<sup>8</sup> while recognizing that these layers can be added later when necessary. The fourth step focuses on the principal agent, the dictator, and drops the opposing regime type. In that way, we end up with a general research question and the project shifts from a study of interaction (dyadic type) that might explain war, to a study of a single regime type (monadic type) and its effects. This step retains some scope conditions by qualifying the circumstances that we are most interested in, namely, when the dictator is under a military threat. The final step reformulates the question so that instead of asking why something did not happen, we ask why it does. Although the puzzle was suggested by the absence of an event (i.e. the dictator did not go to war), posing

the question in positive terms provides clarity, especially when there might be a complex set of causal paths that explain the absence of any phenomenon.<sup>9</sup> This also echoes the preferred analytical posture of defining concepts in positive instead of negative and residual terms (Sartori, 1970). Thus, we settle on our final version: Why do dictators decide to go to war?<sup>10</sup>

Reading through case studies and historical accounts can be a useful starting point for exploring puzzles. Figure 2.1, viewed in reverse, illustrates a similarly valuable process of evolution, essentially 'stepping down' the ladder by adding specificity and context to the research question. This concentration of focus – shifting from the general to their specific elements – is a reflex of intellectual development and can be seen in many research agendas (see Figures 2.4 and 2.5 later in this chapter).

While ingenuity and originality are important for scholarly approach, all work lives within the ecosystem of extant scholarship. Researchers must not only motivate their specific question in the context of that scholarship but position their contribution among these existing studies. This means explaining how the findings clarify or qualify previous research; how their research remains relevant to the scholarly or policy communities; and – often overlooked – whether the aim of the project is feasible. One would do well to heed Merton's admonition from 1959 – still relevant today – that research agendas ought to: (1) focus on interesting and important phenomena in society; (2) lead to new studies of these social phenomena; (3) point to fruitful approaches for such studies; and (4) contribute to further development of the relevant research fields for these studies.

## RESEARCH QUESTION PILLARS

There are four 'pillars' that are often discussed in terms of framing and motivating a

research question: (1) a puzzle; (2) a gap; (3) a real world problem; and 4) feasibility (Figure 2.2).<sup>11</sup> Research does not have to speak to all of these pillars, but it is important not to overlook an important fifth pillar: passion for the topic. This final pillar can mean the difference between success and failure.

### **The Puzzle**

Most inquiries begin with a compelling puzzle. As Zinnes (1980: 318) puts it, ‘puzzles are questions, but not every question is necessarily a puzzle’. Gustafsson and Hagström (2018) propose a formula that succinctly captures what research puzzles look like: ‘Why x despite y?’, or ‘How did x become possible despite y?’, where x and y are two variables that can be isolated and studied. A puzzle formulated in this fashion is, admittedly, a research question, but one requiring much closer familiarity with the state of the art than the basic ‘why-x question’. Importantly, you will only discover such a puzzle by exploring prior research. During this exploration, scholars should remain open to the unexpected: did you find conflict where you expected cooperation, or order when you expected disorder? Most puzzles present after reorganizing prior arguments and findings, when this review begins to highlight the logical tensions and empirical contradictions. This, alone, ought to encourage systematic reading of the literature to ‘connect the dots’.

A puzzle that is particularly timely can be additionally appealing. Many scholars have been able to start new research agendas on ‘hot topics’ in contemporary politics. These scholars might gain a ‘first mover’ advantage, but the potential benefits must be weighed against the risks of investing in a research agenda with little systematic prior work. In the early 2000s, the ‘new kids’ on the academic block were the pioneers of the latest generation of civil war study (Collier and Hoeffler, 2004; Fearon and Laitin,

2003). Subsequently, those ‘new kids’ were replaced by the disaggregation generation. Today, the first mover advantage may go to scholars studying cyber security and artificial intelligence.

### **Filling a Gap**

As the second pillar in Figure 2.2 suggests, extant gaps in the literature present a clear starting point for new research projects. These gaps traditionally emerge at the weak points in previous theoretical frameworks or empirical designs. Researchers will benefit from challenging the assumptions that define either the piece of research or the related research agenda. For instance, this might include questioning how actors form preferences (Moravcsik, 1997) or whether actors adopt outcome-oriented rationality or process-oriented rationality (Hirschman, 1982). Perhaps extant research has focused too much on material incentives (capabilities, monetary aspects, etc.) and missed important dynamics associated with ideational aspects such as norms, ideas or emotions (Sanín and Wood, 2014; Checkel, 1998; Petersen, 2002). Perhaps there are stubborn, and under-analyzed, assumptions about the utility of specific strategies for a given outcome – e.g. that violence or force is an effective means of driving change. By challenging these assumption, scholars have developed pathbreaking work on the importance and influence of non-violent protest and its influence on regime change (Chenoweth and Stephan, 2011).

Challenging assumptions has a long history of sparking new research agendas in IR: where does action take place (Singer, 1961)? Where is the agency (Wendt, 1987)? Waltz (1959) wrote one of the core IR texts focusing mostly on this issue, asking: at what level should we analyze international politics – at the level of the individual, the subnational/local, the state/regime or international structure? Therefore, when we think about research questions and aim to formulate

What's the puzzle?	<ul style="list-style-type: none"> <li>• Are there contradictory findings?</li> <li>• Is an outcome unexplained?</li> <li>• Is the question puzzling per se?</li> </ul>	<ul style="list-style-type: none"> <li>○ clashing findings</li> <li>○ unexpected outcome</li> <li>○ question attractiveness</li> </ul>
Filling a gap?	<ul style="list-style-type: none"> <li>• What do you know?</li> <li>• How main contributions about this differ?</li> <li>• Strong/wrong assumptions in previous work?</li> <li>• Where is agency?</li> <li>• Is this gap due to non-interesting topic?</li> </ul>	<ul style="list-style-type: none"> <li>○ previous knowledge</li> <li>○ contradictions</li> <li>○ challenge assumptions</li> <li>○ level of analysis</li> <li>○ interesting</li> </ul>
Real-world problem?	<ul style="list-style-type: none"> <li>• How relevant is this?</li> <li>• Would a non-academic care?</li> <li>• Could it be translated into policies?</li> <li>• Are there ethical implications?</li> </ul>	<ul style="list-style-type: none"> <li>○ societal relevance</li> <li>○ audience reach</li> <li>○ policy implications</li> <li>○ academic ethics</li> </ul>
Methodological rigor?	<ul style="list-style-type: none"> <li>• Can you answer this question?</li> <li>• Ho can you answer this question?</li> <li>• Can you use new methods?</li> <li>• Are new data necessary?</li> </ul>	<ul style="list-style-type: none"> <li>○ scope</li> <li>○ method awareness</li> <li>○ method sophistication</li> <li>○ data awareness</li> </ul>
Will you enjoy it?	<ul style="list-style-type: none"> <li>• Is this topic 'yours' or imposed?</li> <li>• Can you add a creative twist?</li> </ul>	<ul style="list-style-type: none"> <li>○ autonomy</li> <li>○ creativity</li> </ul>

**Figure 2.2 Where good research questions come from**

new research agendas, it can help to identify whether the phenomenon can be scrutinized either at the micro level (i.e. individuals), at the macro level (i.e. structural features) or as an interaction between both. Increasingly, scholars have identified the value of an intermediate layer, called the meso level, where different organizational configurations (an identity group, the state and international organization) can connect both the micro and macro levels of analysis.

### ***Real-World Problems***

Enterprising research often aims to respond to 'real-world problems'. In part, this speaks to the utility of the intellectual practice: 'Our task is to probe the deeper sources of action in world politics, and to speak truth to power – insofar as we can discern what the truth is' (Keohane, 2009: 708). Karl Deutsch (1970), when discussing a new edition of Quincy Wright's *A Study of War*, wrote: 'War must be abolished, but to be abolished must be studied.' Pathbreaking research on security and strategy by Schelling (1960) clearly engaged with the

issues in his contemporary period. The researcher ought to ask whether their research question has consequences for wider society and what (or whom) might be influenced by their findings. Another way to orient our thinking is to explore whether, and what kind, of non-academic may find value in the work.<sup>12</sup> For non-academics, the incentive structure of publications and tenure-track preparation are replaced by a more tangible perspective of the work's value in terms of policy implications, implementation strategies, effectiveness and efficiency. These non-academics may be government analysts, politicians, practitioners employed by NGOs or civil servants at major inter-governmental bodies. These considerations ought to inspire scholars to avoid the crutch of academic jargon and to shy away from focusing on niche issues with unclear implications. In addition to crafting strong questions around specific themes or topics, researchers should strive for clarity in thought and communication. Empirical sophistication is no excuse for sloppy, senselessly convoluted style. Researchers would be well served to invest energy in crafting clear and 'economical' prose (McCloskey, 1985).

Despite perennial and contentious debates over the discordant responsibilities of the professional academic and the policy maker, students of IR have learned a few lessons. First, if authors are clear about possible policy implications, those policy makers will be more apt to read and incorporate their research. Second, clarity of argument and assertions should be considered a duty, particularly if your research resonates with contemporary policy challenges. If the policy implications are not made explicit, policy makers are likely to infer their own conclusions, potentially misusing the research. One debate around the 2003 invasion of Iraq focused on the Bush administration's misuse of the democratic peace literature in legitimizing the military intervention (Ish-Shalom, 2008). This point speaks to our question in Figure 2.2: what are the ethical implications of study? Researchers should be honest and self-reflective about potential challenges when it comes to the methodological approach and the practice of gathering evidence. Further, they should reflect on the effect of publishing publicly on findings with clear social costs: it is incumbent on the researcher to fully understand the consequences of their work, for themselves and everyone they have involved. Academic institutions have strict procedures and processes to assure that people who participate in a research project will not be facing any risks. Supervisors and senior colleagues should assist and advise early career scholars given the intrinsic dangers of studying certain phenomena in international relations.

### **Feasibility**

This pillar represents an important concern in political science and IR. Our first question is trenchant, though problematic: will you have the necessary data and methods to find an answer to your new research puzzle? This question is a necessary first inquiry, as it may

also be the last: supervisors and more experienced scholars are always concerned with the feasibility of the project and might try to refocus the core question if the answer demands resources and skills beyond what is currently available. It is possible that these individuals are wrong – perhaps they are not creative or visionary enough to see the potential – but one ignores this concern at one's own peril. It is difficult to know early in the process what methods and data will be most useful, and whether they will be available. Effective review of methods and existing data is a critical step (and one with which this *Handbook* is designed to assist). Scholars should find out whether the requisite data exist, but not despair immediately if the answer is unclear. A range of successful research projects involve data collection, sometimes exclusively so (Singer and Small, 1994; Sarkees and Schafer, 2000; Vogt et al., 2015; Sundberg and Melander, 2013; Tierney et al., 2011). However, one should be careful, as large data collection is quite demanding and expensive – most of the existing datasets are the product of years of research and were obtained by small armies of coders or through use of advanced automated data gathering tools. PhD students and early career scholars could face serious challenges if the data collection is not constructed carefully. Pragmatism is an asset in assessing the realities of obtaining the necessary data.

### **Enjoying Your Research**

Undertaking a research project comes with associated opportunity costs – time, energy and interest expended on any research project are resources a scholar cannot use elsewhere. Thus, it may matter whether the research project is strictly one of your choosing or one suggested (or even imposed) by someone else. Suggested topics may, at times, come from a supervisor or academic peers, and a particular approach may be imposed according to the availability of data.

You may also have stumbled into your research question through previous study or thanks to an essay or assignment you have already written. You need to ask yourself: does the topic continue to inspire you? Do you enjoy working on it?

In the end, a research project is 10 percent inspiration and 90 percent perspiration, and while a creative mind is an asset, the eventual result will depend on your commitment, hard work and effective time management. Further, scholars should also be aware that starting a completely new or novel research agenda is comparatively rare in an academic life – and perhaps a luxury, as well. However, understanding your personal interest and stakes in a project is important for deriving joy from your work and will be helpful in motivating scholars to finish their projects.

## DEVELOPING RESEARCH QUESTIONS

We now consider a range of possible research questions, as shown in Figure 2.3. This list is not exhaustive, but it does provide a starting point for crafting them. Broadly speaking, there are two types of research question. The first focuses on the main phenomenon to be explained (Y, the dependent variable, or *explanandum*). The second focuses on factors that can explain variations in that Y (X,

the independent variables, or *explanans*). Both types are legitimate queries for research, although they might involve different methods and approaches.<sup>13</sup>

The first ideal type – ‘what is Y?’ – is the most direct of the explanandum-oriented research questions. This question is highly theoretical, involves heavy conceptualization and is likely to produce typologies that might be useful for follow-up questions (Collier et al., 2012; Gerring, 1999). ‘What is Y’ queries also demand data to describe different trends and types (Gerring, 2012). Although we use ‘power’ as our example, we could easily have picked something else from a wide range of similar forms of inquiry in IR: security (Baldwin, 1997), human security (Paris, 2001), securitization (Buzan, 2008), or civil war (Sambanis, 2004; Kalyvas, 2005).

The second ideal type remains focused on Y, but instead of seeking to provide a conceptual definition, it tracks how Y has changed over time and space. Research agendas such as those charting countries’ Polity IV scores (Marshall and Jaggers, 2002) or calculating their position on the V-Dem spectrum (Coppedge et al., 2017) belong to this family of research questions.

The third type also starts with a definition of Y, but proceeds to provide potential explanations of the data-generating process while maintaining that definition. These questions are very useful for elaborating and studying

1. What is Y?	→ What is power?
2. How has Y changed?	→ How has trade increased?
3. Why Y?	→ Why war?
4. Under what conditions Y?	→ Under what conditions peace?
5. Do Y and X co-vary?	→ Do democracy and peace correlate?
6. Does X cause Y?	→ Do international organizations cause cooperation?
7. What is the effect of X on Y?	→ What is the effect of aid on civil war?
8. Is the effect of X on Y mitigated by Z?	→ Is the effect of democracy on war conditional on trade?
9. Why Y varies across G or T?	→ Why level of cooperation varies across regions?
10. Why X affect Y in T but not in T-1?	→ Why alliances influence risk of war differently over time?

**Figure 2.3** On research question types

mechanisms (Tilly, 2001; Hedström and Ylikoski, 2010). One of the most cited articles on processes leading to war, ‘Rationalist Explanations for War’ (Fearon, 1995), belongs to this style of research. What is an appropriate way to define war? What can account for the occurrence of war thus defined? The conceptual framing of the question and the provision of several tentative mechanisms that could answer the puzzle posed by the definition have made this article foundational in the study of war.

The fourth type is the natural extension of the third and involves starting with the classic phrase ‘*under what conditions...*’. This framing is useful because it pushes the researcher to think about variations of Y, their central variable of study, as well as the influence owing to variation of possible explanatory factors – the Xs. Hence, *under what conditions* suggests we should be conscious of co-variation.

The next three types of question seek to make this co-variation more explicit. Here, the choice of adjective or verb suggests the nature of that correlation. Specifically, in Figure 2.3 question type six outlines the *causes of effects*, while question seven refers to the *effects of causes*. This distinction is easy to state, but harder to distinguish in practice. Effects may have multiple causes and these causes inevitably give rise to a range of effects. Situating your research within this space is important and should be done consciously. Moreover, these ideal types are particularly important for our contemporary study of IR, and have attracted the attention of contemporary scholars (Van Evera, 1997; Samii, 2016; Lebow, 2014). Researchers should be cautioned against slipping into unfounded causal claims, however. Are democracies richer? Do democracies fight each other less than they fight other regime types? Do countries that are members in many IOs trade more than countries with fewer memberships?

For this, one could ask directly: does X cause Y? It used to be that quantitative scholars were less concerned about the differences between correlational and causal claims. Many incorrectly assumed that endogenous effects (those

that emerge within the phenomenon of study) could be suitably controlled by lagging (modulating the expected influence) the relevant variables, and that omitted causal effects could be discerned by imposing specific scope controls. The emergent consensus about the importance of causal identification has changed all that (Angrist and Pischke, 2008; Samii, 2016). Projects that had employed apparently solid quantitative causal identification strategies can now be challenged with qualitative and archival information that casts doubt on the supposed exogenous identification (Kocher and Monteiro, 2016). Qualitative scholars are also increasingly aware of the high bar for causality, which has led to the development of sophisticated approaches to methods such as process-tracing (Bennett and Checkel, 2014).

The last three ideal types of questions add layers of complexity. They ask whether the effect of X on an outcome is conditional on, or mitigated by, another factor Z. These queries tend to make research agendas more dynamic and expansive since they push researchers beyond studying X and Y alone. This can involve theoretical and methodological improvements. For example, quantitative scholars have been developing better ways of studying interactions between variables (Brambor et al., 2006; Franzese and Kam, 2009), while qualitative scholars have provided systematic approaches to conditionality and contextuality (Tilly and Goodin, 2006). The additional factors might also involve time (different historical periods or temporal moments) or space (regions or other appropriate geographical variables).

## EXAMPLES FROM IR: DEMOCRATIC PEACE AND CIVIL WAR

We now sketch some lessons learned by looking (briefly) at two research agendas in IR: democratic peace and civil war. Readers who are not specifically interested in the

topic of security in IR could seek to draw parallels with other areas of IR or more broadly in Political Science.<sup>14</sup>

Figure 2.4 sketches a (non-comprehensive) trajectory of research questions and topics about the democratic peace. This is one of the final IR debates in which paradigms remain in contention.

The research agenda began with a broad research question, with subsequent studies providing more stringent scope conditions and improved accuracy of empirical analysis. Subsequent debates have centered on how to make sense of the correlational findings: if democracies do not fight each other, we need mechanisms to explain why this might be the case (Maoz and Russett, 1993). In response, several papers, mostly from a realist perspective, challenged the pattern of causation and the conceptualization, while hinting toward possible omitted variable bias (Rosato, 2003). Given the rarity of the phenomenon (not just war, which is already rare, but war that involves democracies on opposite sides, which should be even rarer, as the central assertion

in this literature would have it), critics argue that it is difficult, and perhaps foolhardy, to make inferences from such a small sample. In response, scholars offered more elaborate explanations, finding cause for the seemingly pacific relations between democracies in variables such as trade or international organizations (Oneal and Russett, 1999; Russett and Oneal, 2001).

Subsequent developments adopted non-realist perspectives, and either attempted to shift the focus to variables other than regime type (e.g. capitalism (Gartzke, 2007), although see Dafoe (2011) for a methodological critique), or to dig deeper into the microfoundations of the proposed mechanisms (Tomz and Weeks, 2013).

Figure 2.5 offers a schematic of how research on civil wars has evolved. The study of civil wars has an established research pedigree but it experienced something of a renaissance in the 2000s (Kalyvas, 2010), as research became more systematic and publications more abundant (Fearon and Laitin, 2003; Collier and Hoeffler, 2004).

- Causes of war?
  - Specification : Are democracies more peaceful?
    - Further specification: Do democracies not fight each other?
- Mechanisms : Why democracies do not fight? Norms, structure, endogeneity
- Criticisms: Correlation no causation, conceptualization problem, omitted variable bias, rare event, non-representative sample
  - Reactions: larger samples, further controls, different methods
  - Extensions: international organizations, trade and democracies
- Alternative within: Is it capitalism or democracy?
  - Technical discussions : specifications, operationalization...
  - New methods: survey experiments...

**Figure 2.4 Stylized democratic peace research agenda**

- i. What does explain variation in civil war (cw) onset?
  - plethora of Xs
- ii. Refocus on cw facets: durations, intensity, civilians' victimization, outcomes, legacy...
- iii. Analytical and empirical refocus: dyad, transnational, groups, local data, leaders...
- iv. Refocus on actors' actions: governance, alliances, splintering, displacement, crime...

**Figure 2.5 Stylized civil war research agenda**

This period of academic exploration offered a range of arguments about the variables related to the onset of civil wars, moving beyond the traditional economic or ethnic factors. Many studies sought to explain the variation in civil wars with capabilities (of host states and non-state actors), countries' exports, domestic shares of natural resources and demographic patterns, among others. Scholars unpacked different facets of civil wars by looking carefully at their duration, intensity and level of violence against civilians (Kalyvas, 2006). Some proposed different levels of analysis to match the theoretical concepts and empirical operationalizations (Cederman and Gleditsch, 2009). This work has benefited from intensive data-collection exercises about the actors involved (Cunningham et al., 2009), the transnational linkages between these actors (Gleditsch, 2007), other relevant local features (Sundberg and Melander, 2013) and leader attributes (Prorok, 2016). Qualitative work has not lagged behind, either, with research on rebel governance (Arjona, 2016), systems of alliances (Christia, 2012), and their splintering and their influence on displacement (Steele, 2009). More recently, scholars have started to explore how the processes leading to political violence might be related. We now have studies of the substitution effects between civil wars and terrorism (Polo and Gleditsch, 2016), and between civil war and military coups (Roessler, 2016). The field of inquiry has also expanded to incorporate insights from the study of organized and transnational crime (Kalyvas, 2015; Lessing, 2017).

As both our brief examples illustrate, research agendas progress through systematic refinement. Scholars challenge each other's intuitions, assumptions and findings, and – in the process – reassess the models and methods being employed. Progress is built on failure, but it is failure forward, toward better understanding. The initial conceptual thought about the nature of a phenomenon ('what is security?') provides a center of gravity that attracts subsequent research that unpacks the

latent assumptions, alters the levels of analysis, and critically engages the conclusions reached. These improvements often come from leveraging new methods or specifying new mechanisms that connect the variables. These interventions often offer competing explanations of empirical patterns, which, in turn, pique the interest of new generations of scholars who jump in to analyze under-explored or emergent puzzles associated with these phenomena.

## CONCLUSION

Can you pass the 'elevator test'? That is, can you succinctly explain your research question and project aims in less than 45 seconds? The time limit is arbitrary, but the question helps sharpen the clarity of your work. If you cannot pose a short coherent question and provide the gist of the answer, then there is something amiss with your project. One often achieves this clarity after repeatedly writing and rewriting one's ideas until they are thoroughly understood. You cannot effectively communicate things you only dimly understand. All acquisition of knowledge relies on commitment, iteration and a significant amount of writing, thinking, and writing again. 'You do not learn the details of an argument until writing it up in detail, and in writing up the details you will often uncover a flaw in the fundamentals' (McCloskey, 1985: 189).

Clear communication is crucial because journal editors and book publishers ask reviewers to assess where a project fits between four categories: a relevant contribution to a relevant topic; an irrelevant contribution to a relevant topic; a relevant contribution to an irrelevant topic; or an irrelevant contribution to an irrelevant topic. While it is usually easy to avoid falling into the last category, careless write-ups and hidden flaws in the research process can often strand submissions in the second and third

categories. Depending on the patience of referees, this might also lead to outright rejection. Always be conscious of how to position yourself in that first category.

Thus, research projects are not simply assessed in terms of good or bad. They can be good or bad across a set of characteristics – from analytical rigor to methodological appropriateness – and should be evaluated across multiple dimensions.<sup>15</sup> It is also important to ask whether research can be ‘creative and inspiring in a swashbuckling way’, as scoring high on this dimension often signals that the research agenda can make a substantive difference. Of course, being rigorous and innovative is great, but every researcher should strive for intellectual humility, remaining cognizant of the potential costs and risks involved.

We conclude our chapter with a brief ‘Questions & Answers’ section that might be instructive to readers.

### ***How Specific Should a Research Question Be?***

From ‘why do civil wars start?’ to ‘why did the Mau Mau rebel against British rule?’, there are varying degrees of generality. However, as we emphasized in our discussion, scholars can ask general questions and explore them through specific cases or start with specific cases and build toward more general abstractions. The answer depends on what scope conditions you select and how generalizable you wish to be. There are tradeoffs on either end of this spectrum.

### ***Shall I Only Select Questions I Can Fully Answer?***

This is an important question and there might be disagreements about the answer. When discussing Figure 2.2, we stressed the trade-off between originality and feasibility. However, we also suggested that there are

myriad ways of assessing the potential and value of research agendas. Our advice is to be more curious than concerned in the exploratory phase, while rationally assessing the feasibility before you commit to the project over the longer period. Creativity and innovation are important features of any research project.

### ***How Useful Is a Literature Review When Posing a Research Question?***

Researchers with a thorough knowledge of previous research (in content and method) will have a demonstrable advantage over those without. Remember the distinction between a logic of exploration and a logic of explanation when writing literature reviews. The former is crucial for posing a proper research question; the latter is vital when writing in a piece of research and situating its contribution and relevance.

### ***Do I Need to Justify My Research Question?***

Researchers must do more than justify their topic – they need to situate their research questions. What previous research are you engaging with or challenging? What research streams does your project bring together? What is your intended contribution (what will we learn within IR or Political Science?) and how is it relevant (why should we care?)

### ***What Do I Need to Define in My Research Question?***

Definitions are central for research, but their importance varies with the type of research question that you are engaging with. If your question is a Y-focus query, most of the research will be about conceptualization, defining ideal-types and discussing typologies. X-focused research questions will also

require clear definitions, but this will likely occur at a later stage in the research design.

### ***How Many Research Questions?***

A good rule for any piece of writing or research is one paragraph, one idea. Applied to research, a reasonable rule of thumb might be one dominant research question for each paper, where a book or thesis might have more – though usually these questions are closely related. This predominantly takes the form of a large research question with different, but reinforcing, sub-questions that can improve the comprehensiveness of the project. Remember, the more research questions you pose, the harder it will be to answer them. Less is more, particularly if those questions are comprehensively studied and answered.

### ***Do I Need to Keep the Same Dependent Variable?***

Usually, yes. Switching among things you are trying to explain can be disorienting for a reader unless your central argument is about a selection process ( $Z \rightarrow X$ , then  $X \rightarrow Y$ ) or a recursive one ( $X \leftrightarrow Y$ ). Moreover, when you are formulating hypotheses, it is good practice to keep the Y consistent. Consistency improves project clarity.

### ***Do I Need Only One Main Explanatory Variable?***

Not necessarily. International relations, and politics in general, are complex, and several factors are often necessary to account for the variation of IR phenomena. However, scholars often mix main explanatory factors (what should be the core contributions of the research project) with controls (other factors that could be affecting the dependent variable). This is especially prone to happen in the

early stages of the research projects. Not all Xs should be placed under the spotlight. Focus on those Xs that make a contribution and remain essential to your research question.

### ***Can I Change My Research Question?***

There are two ways to interpret this question: as a change of topic, or as a change of the specific question being asked. The former is beyond our scope, as it comes down to the individual researcher or to their relationship with the supervisor or PhD advisor. The latter, however, may simply happen as you read more of the literature, strengthen your theoretical argument and advance your empirical analysis. Not all change is bad, but be conscious of why you are doing it.

### ***Do I Need to Specify Actors, Preferences, Strategies and Other Relevant Components of My Theory in the Research Question?***

Not necessarily, but they can assist in formulating the research question and project directives. Understanding at which level the analysis is being conducted, where agency is located, what preferences are involved and how they are formed can be crucial. These details help us explain the strategies actors adopt and help identify the structural constraints and ideational factors that might influence them. This information is essential for theorizing and can help refine your research question.

### ***When Should I Ignore Your Advice?***

We, like everyone else, are limited by our own subjectivity. In any domain where creativity is central and where the routes to

knowledge are many and varied (and sometimes deeply personal), there is a risk of dissuading researchers from following their own intuition and insights. We have tried to be systematic and egalitarian in our treatment of differences, but we cannot possibly account for all situations. We hope that our advice highlights common issues and potential solutions, so take our advice as formative, not conclusive.

## ACKNOWLEDGMENTS

We thank Branislav Slantchev, Juan Masullo, Francesco N. Moro for their comments on this chapter. With this chapter we want to remember the tragic loss of Giulio Regeni in Cairo. He was a graduate student conducting field research.

## Notes

- 1 The authors would like to thank Juan Masullo for his comments on this distinction between conclusiveness and rigor.
- 2 As Rob Franzese's saying goes: we summarize and report the best we know without implying that it is the best out there.
- 3 Procrastination and perfectionism are its enemies.
- 4 We owe this helpful distinction to a conversation with Monica Duffy Toft.
- 5 As Kristian Skrede Gleditsch would put it, simplicity is the simpler version of the term parsimony.
- 6 Bruno Munari (1981) compares the passages of research design building to the steps of cooking.
- 7 In this way, our proposed strategy is consonant with that of others who advocate taking inspiration from a specific event or actors before formulating the wider research question (Kellstedt and Whitten, 2018).
- 8 Here the parallel is with sculpture – getting to the gist of it. Hence, the research question-generating process should be similar to the craft of sculpture.
- 9 This could be labeled the 'Anna Karenina problem', where all happy families are alike and all unhappy ones are unhappy in their own way.
- 10 Weeks (2014) studies this very question.
- 11 King, Keohane and Verba, 1994; Gustafsson and Hagström, 2018; Bachner, 2012.
- 12 There is a difference between the 'grandma test' and the 'policy-maker test'. The former is about clarity and communication of a research project; the latter is about its implications and its answer to the non-trivial question 'so what?'
- 13 Stathis Kalyvas, in a personal communication, suggests that there are Y-focus and X-focus research projects, and often scholars stick to this divide in their careers. It is the case that certain methods work more effectively for Y-focus questions and others – qualitative methods and quantitative methods – for X-focus questions. Again, though, this only serves as a rule of thumb and is not a law.
- 14 Keohane (2009) points out, however, that '[t]he study of world politics begins with the study of war' before turning to the vital question: 'Why is war a perennial institution of international society and what variable factors affect its incidence?'
- 15 Personal communication with Brian Burgoon, whose elaboration is from Charles Sabel's categorization.

# The Simple, the Trivial and the Insightful: Field Dispatches from a Formal Theorist

Branislav L. Slantchev<sup>1</sup>

This advice begins with a disclaimer. I have a view of formal modeling that – while being shared by many fellow modelers and philosophers of science – is at variance with what seems to be the prevalent one in the discipline. All my thoughts on the use of formal models in research are bound up with that view, and are probably not useful if one does not share it.

Contrary to popular opinion, the biggest hurdle to effective modeling is not the absence of advanced mathematical skills. Instead, the problem lies with a hazy conception – shared by both proponents and critics – of what models are supposed to accomplish. The received view in the discipline seems to be that the primary purpose of (formal) models is to make predictions that are then ‘tested’ empirically.<sup>2</sup> On this account, models are hypothesis-generating machines – insert assumptions, crank through solutions, spit out predictions – and the benefit of formalism is to make the process more rigorous, and thus more scientific.<sup>3</sup> Since ‘research practice

in political science currently revolves around theory testing’, the sole value of the model is nearly always taken to lie in its ability to withstand empirical scrutiny.<sup>4</sup>

This view is incoherent in logic and unimplementable in practice.<sup>5</sup> It offers an impoverished interpretation of the role of models in research by denying outright their *raison d’être*: efficient and effective communication. Overcoming the fundamental hurdle to modeling requires one to recognize that models are merely specific arguments.

## MODELS ARE ARGUMENTS

A model is not evaluated if its predictions are not analyzed, regardless of how true the assumptions of the model are believed to be.<sup>6</sup>

Models are closed deductive systems, which simply means that their conclusions follow from their premises. Given these premises, the conclusions are true irrespective of

empirical referents. Models cannot be incorrect when their inferential rules are followed. No amount of ‘testing’, no matter how carefully designed, can alter this basic fact. The notion that hypothesis-testing somehow confers validity on a model or that it constitutes the core element in scientific practice has been roundly debunked.<sup>7</sup>

Moreover, all premises in these deductive systems are almost invariably false, in the sense that they do not correspond exactly to anything in the real world. This is true of any argument that purports to explain any social or natural phenomenon, not just models, and certainly not just the formal ones. For example, one might criticize a formal model for having the ‘unrealistic’ assumption that uncertainty over a parameter is represented by, say, the uniform distribution. But the non-formal argument that relies on the concept of uncertainty is not ‘more realistic’ because it does not make that assumption. It is exactly the opposite: without being specific about the concept, it might be impossible to evaluate as an argument. The virtue of the modeling exercise is that it can establish that the claim holds for the uniform distribution, which in turn could be used to establish whether it holds for a class of distributions or even arbitrary ones. Being non-specific and vague does not make an argument more general or ‘realistic’. If one is going to critique a model because of ‘unrealistic’ assumptions, one might as well give up any attempt to explain anything.

The proof of the model is not in its empirical consummation.<sup>8</sup>

If one thinks of models as arguments, then it quickly becomes clear what their role in research must be: give specific expression to a line of thinking, communicate it effectively and persuade the audience of its usefulness. It is the ability to perform these tasks well that defines a good formal model, so let us unpack them a bit.

First, formal models force one’s argument to be *specific*. That is, in order to represent abstract concepts with the mathematical

formalism of a model, one is invariably forced to define more or less precisely a specific representation of that abstract concept. For instance, we often use the rather abstract concept of ‘power’ in our research. In international relations, the term is ubiquitous, and yet it is never quite clear what it means. There are hundreds of articles about what ‘power’ could mean, and how it is to be understood in different contexts, and it is nearly impossible to evaluate research that deploys this concept (theoretically or empirically) because its meaning is protean. And yet we feel quite confident that something called ‘power’ is important in understanding international relations, not the least because policy makers seem so concerned about it.

When one writes down a formal model that wishes to use ‘power’, the abstract must become concrete. In the standard models of crisis bargaining, for example, ‘power’ is related to an actor’s expected payoff from war. It could remain undifferentiated – the higher the payoff, the more powerful an actor is – or become even more specific, relating to particular other concepts. For instance, it could be modeled as relating to the *costs* of war (the lower one’s costs, the more powerful one is), to the *probability of victory* (the more likely one is to win the war, the more powerful one is) or to the *valuation of the stakes* (the higher the stakes, the more powerful one is). Each of these specific formalizations of ‘power’ is subtly different from the others even if they all affect the expected payoff from war. For example, the *costs* only determine an actor’s own war payoff and nothing else, whereas the *probability of victory* determines the war payoffs of both actors (if one becomes more likely to prevail, the other one must be less likely to do so). *Valuation*, on the other hand, still relates to one of the actors, but determines both its war and peace payoffs.

At first blush, it appears to matter little how power is formalized: some of the most basic results in the crisis bargaining literature have been derived with each specification.

However, research soon showed that the specific formalization does, in fact, matter for many important conclusions. Uncertainty about the opponent's 'power' is a very common ingredient in theories of war, but once we have specified a precise formal definition of power, we are forced to adopt a precise formal definition of uncertainty as well. Thus, one could distinguish among uncertainty about the costs (independent private value), the probability of victory (interdependent value and uncorrelated types) and the undifferentiated value of war (correlated types). Fey and Ramsay have shown in a very general framework that the different sources of uncertainty have very different implications for the probability of war and the possibility of war-avoiding mutually acceptable settlements in crisis bargaining.<sup>9</sup> In other words, it matters very much what specific conceptualization of the abstract notion of 'power' one uses for one's argument.

Thus, contrary to the oft-repeated allegation that models are 'too abstract', models are in fact quite specific. They force us to give a particular expression to our line of thinking. The resulting clarity reduces the definitional burden of arguments and enables sharper communication.

Second, formalization lays bare the *structure* of the argument, which ensures its internal validity and simplifies communication. Consider the canonical crisis bargaining model used by Fearon to identify the risk–return trade-off as an important cause of war.<sup>10</sup> Amid its myriad of simplifying premises, the model assumes that one of the actors can make a take-it-or-leave-it demand, whose acceptance ends the game peacefully but whose rejection leads to war. Ultimatum games are quite popular in both economics and political science not because they are particularly representative of real-world situations but because modeling a bargaining situation opens a Pandora's box of additional assumptions about time horizons, discounting, inside and outside options, sequencing of moves, timing of offers and responses and

many others. (These usually remain rather buried in non-formal negotiation models where they are often tacitly assumed.)

One problem is that strategic bargaining models (ones where the analyst specifies the structure of the interaction; e.g., only one actor makes demands or the two alternate) that incorporate uncertainty tend to produce infinitely many solutions, as opposed to the ultimatum game, which usually yields sharp unique results. Because of that, the results of Fearon's analysis had to be tentative because it was not known just how dependent they were on that assumption. Powell extended the model to an alternating-offers bargaining framework and showed that, unlike the common models of that type, his also yielded a unique result that mirrored exactly the risk–return trade-off identified by Fearon's ultimatum game.<sup>11</sup>

This appeared to give us a stronger warrant to accept the argument until Leventoglu and Tarar showed that both the result's uniqueness and its risk–return trade-off aspect were dependent on another structural assumption: a proposer whose offer gets declined is not permitted to attack (only an actor responding to an offer could do so).<sup>12</sup> This premise is inconsistent with the standard assumption in international relations – that any actor can take military action whenever it chooses to do so – and relaxing it wipes out the canonical result. Their model shows that crisis bargaining can involve significant delays without escalating to war, and so the risk–return trade-off mechanism is less robust than previously thought. By varying only specific premises, scholars have been able to gain a much better understanding of how a particular argument works.

Third, formalization forces one to confront one's own demons of *unstated assumptions*. I have often heard the breezy dismissal of formal models with 'you can always concoct a model that yields any result you want', an assertion with the Schrödinger quality of being apparently both true and false at the same time.

It is true that anything can be described by some model when there are no restrictions to the premises one is permitted to make. It is also true that nothing in the modeling technology itself restricts the premises except perhaps to ensure that they are not mutually exclusive. The supposed (but famed) 'rigor' of models does not extend to the definition of the system itself or to the interpretation of its parameters and results.<sup>13</sup> Models can readily produce conclusions that are absurd (these are usually easy to spot) or trivial (because the premises assume them). This happens most often when people try to reverse-engineer an argument by working from the desired conclusion to the premises needed to generate it. So, the charge is correct, at least when it describes sloppy modeling practices.

The charge, however, is almost comically wrong when leveled against models designed from first principles and with careful attention to detail, as any formal theorist worth their salt would tell you. Constructing a valid argument that does not beg the question can be surprisingly difficult; the analysis can often be startling, and the entire process quite edifying. There is much to be learned from attempts to formalize one's intuition. There is a lot of trial and error involved in getting the argument right (meaning, to have a model that is both non-trivial and solvable), and often the conclusions are not the same as the ones the analyst expected to obtain. Models are great disciplinarians, and they can teach us when our intuition has gone astray or when our 'straightforward' argument turns out to require a small army of auxiliary premises to sustain.

My favorite example of the process in print (in addition to my own trials and tribulations) comes from Schelling.<sup>14</sup> He was dealing with the problem of surprise attack and reasoning from an intuition about an armed burglar surprised by an armed homeowner whose house he has broken into. Presumably, both prefer that the burglar just leave quietly, but the problem is that neither is sure whether the other might shoot. If he thinks that the

homeowner might shoot, the burglar becomes more likely to shoot first. But the homeowner knows that and now becomes even more fearful about getting shot, so he becomes more likely to shoot first. But the burglar also knows that his own fears are compounding the homeowner's, which makes him even more trigger-happy. This escalating spiral of mutual fears causes one of them to pull the trigger, ending the interaction with an outcome both would have preferred to avoid.

Schelling's intuition is compelling, but he decided to formalize it to see how such a 'multiplier effect' could arise. He then proceeds through a series of different formalizations, none of which yields the desired result. The failure in each iteration teaches him something about the problem that he had tacitly assumed without knowing how crucial it was for the inference he was making.

Even if his resolution leaves something to be desired from a modern standpoint, the exercise was clearly useful.<sup>15</sup> Not only did the author learn a lot about the subtleties of his intuition, but the exposition of the unsuccessful attempts to formalize it has great value for scholars who wish to build upon the insight. Knowing where the blind alleys are is crucial to progress.<sup>16</sup>

It is for these three main reasons that I almost invariably ask graduate students to formalize their arguments. Even the practice of constructing a model without solving it can be enormously beneficial, as it forces one to at least identify the basic premises and overall structure of its logic. Sometimes this is enough to expose a fatal weakness, as even rudimentary models can identify problematic lapses in reasoning.

Because models are correct by definition, specifying the premises and working systematically through their implications toward the conclusion has many benefits. We can tell whether a specific conceptual definition is consistent with a set of inferences, whether a collection of premises really does yield a claimed consequence and whether seemingly disparate arguments share a common

core. We can easily agree on what a definition means, on what the precise assumptions are and on how the results are obtained. This means we can build on each other's work more effectively and transmit that knowledge with a smaller chance of miscommunication.

None of these benefits are unique to formal models. People can make, and have made, arguments that are specific, well-constructed and non-trivial without formalizing them. What I am saying is that formalization facilitates the process for the analyst and democratizes it by making the argument instantly accessible to anyone with a modicum of training. To give an analogy, it was not formal musical notation that made Beethoven's Ninth possible. But it was this notation that allowed him to transmit what was in his mind efficiently, that has permitted generations of composers to build on his approach and that has enabled audiences to enjoy the results.<sup>17</sup>

Think of your model as an argument, and of yourself as a persuader.<sup>18</sup>

## WHEN TO MODEL, OR HOW TO GET INSPIRED

Although every argument can be modeled, formalization can be especially appropriate for certain kinds of arguments. Since published work almost never describes the inspiration behind the models and the evolution of the arguments before they end up in print, in this section I will give examples from my own experiences. In general, I resort to formal modeling when I have some intuition about a phenomenon of interest but find myself asking, 'How does this argument work?' Here are several instances of that question that produced formal models.

### *The Puzzling Case*

Logic, especially when human beings are involved, is often no more than a way to go wrong with confidence.<sup>19</sup>

I teach US foreign policy to undergraduates. One of the lectures is about the Korean War, and I never felt I understood why the US and China ended up in a war over North Korea. Political scientists who have tackled this question usually frame it as 'Why did the US miss clear warning signals from China and extend the war beyond the 38th parallel?' My reading of the history, however, indicated that the signals were anything but 'clear' – the Chinese chose an Indian intermediary dismissed by its own government as biased, they failed to intervene when it would have made most sense militarily (right after Inchon) and, perhaps most critically, they appeared to have failed to prepare for war.

The last of these was crucial: nobody will take you seriously if you threaten war but do nothing to get ready for it. Assured that the Chinese were bluffing, the Americans forged ahead, only to run into a vast mass of Chinese troops who swept them back south. Unbeknownst to anyone, China had entered North Korea with enough strength to shatter the UN advance and eventually stalemate the war despite reinforcements sent by the United States. If the Chinese had been serious about their threats, why not show that they were preparing to fight? This would have been a clear signal, but they chose not to make it, which in turn misled the United States into invading the north. Neither side wanted to fight the other, and yet war is what they got. Why?

This case was specially puzzling considering existing crisis bargaining theory. According to all our models, an actor who is willing to fight should make that preference known by some sort of costly diplomatic or military move. This is the only way to convey resolve and hopefully convince the opponent to make war-avoiding concessions. The Chinese behavior ran contrary to all these models, as they had deliberately concealed the one move that could have conceivably had a deterrent effect on the Americans. Why would they do this?

I was reading a science fiction novel by David Weber at the time, and there was a

scene in it where a very powerful military vessel on patrol detected a pirate ship in the distance. The captain's problem was that if she chased the pirates openly they would probably have the time to make their escape. So, she disguised the engine emission signature to mimic a merchant ship and lured the pirates into coming close enough for her to attack them. This was a fictional scenario, but one could think of any number of historical episodes involving such an ambush, so I wondered if the Chinese behavior had such an element to it.

The key was the possible self-denying aspect of revealing military strength: what if doing so gave the opponent an opportunity to do something that eroded your advantage? In the fictional story, the pirates would run away, thwarting the purpose of the patrol. In the Chinese case, the United States could use the information to target the troops with devastating effect because of its superior firepower and control of the skies (as it happened, Mao was still wrangling with Stalin over Soviet planes, since the Chinese air force was non-existent). Thus, if one believed that the encounter was likely to end in war, it could make perfect sense to conceal one's strength and gain the advantage of surprise.

This now presents a dilemma that the fictional captain did not have, but an actor engaged in crisis bargaining would: failure to reveal strength makes it more likely that the opponent would not offer significant concessions, which in turn would make war more likely. So, while feigning weakness could potentially be useful in war, it might not necessarily be optimal if it also made war more likely. This is the kind of problem – with incentives pointing in opposite directions – that is especially well suited for game-theoretic modeling.

I started with the canonical ultimatum crisis bargaining model and merely modified it so that after the initial demand was rejected, both actors chose how much to mobilize for the war, with their mobilizations being costly but also improving their chances of victory. Since a strong actor (one with low costs of

arming) would mobilize more aggressively, it could cause the other to respond with similarly aggressive mobilization. This, in turn, would weaken the incentive to reveal one's strength through the initial demand. The analysis revealed that this was indeed the case: there were circumstances in which a strong actor would not make a risky but revealing high demand but would instead pretend to be weak by mimicking the demand of the weak type. The cost of that was a lower peace payoff but the benefit was improved war payoff. The dilemma could produce behavior contrary to the canonical models but consistent with what the Chinese had done.

The analysis also showed that the assumption of two-sided incomplete information was unnecessary: it complicated the math without changing the basic insight, which could be obtained under asymmetric information about the actor making the demand. When I sent the revised version to the journal, a referee pointed out that the fundamental result might be had with an even simpler setup. He/she was right, and the published version centers on a much simpler model where only the informed responding actor can mobilize additional resources at a fixed cost.<sup>20</sup>

The model also yielded several surprises. First, there was the unexpected application: Jeff Ritter pointed out to me after a presentation that the mechanism could explain the puzzle of secret defensive alliances – they enhance one's fighting potential but deny one any deterrent advantages, the precise dilemma that could end in a feint. Second, there was the implication about the venerable explanation for war as being caused by mutual optimism. If an actor holds optimistic beliefs about the expected payoff from war, then it would be loath to make concessions, which in turn would make war more likely because it would weaken the opponent's incentive for peace. The crisis signaling literature had suggested that this optimism could be reduced by costly signals of resolve. One's apparent will to fight should lead the opponent to revise their estimate about war,

and if they are still willing to fight, then this in turn should lead the original actor to lower their estimate as well. The feigning weakness argument showed that a strong actor could deliberately foster false optimism in the opponent, which short-circuits the inferences: this actor could not use the opponent's willingness to fight as evidence to lower their own estimates about war since that willingness is based on the wrong inference induced by the feint. This would strengthen mutual optimism and make war more likely than the signaling literature would suggest.

Thus, my inability to offer a coherent explanation of a historical case to my undergraduates, coupled with the coincidental reading of a science fiction novel, led to novel insights about crisis bargaining.

I find history both fascinating and often puzzling. It offers a tremendous menu of opportunities to not understand something and is a fertile source of inspiration for research. I teach an entire graduate course on the history of international relations that is designed to puzzle students and generate ideas for study. It is important to realize that historical episodes (and empirical patterns) can only be puzzling considering existing explanations: one must know enough to understand that one does not understand something.

Being puzzled productively requires quite a bit of preparation, which is why it is often difficult for scholars tackling unfamiliar areas of research. Sometimes one's puzzlement is due to ignorance of existing work and is easily resolved by a literature review. This is why I am not a big fan of advice that tells scholars to avoid the literature review until after they have clarified their ideas. In fact, searching the literature with a particular idea in mind can be especially productive and efficient.

### ***The Inconsistent Assumption***

Varian contends that academic journals 'really aren't a very good source of original

ideas'.<sup>21</sup> I think what he means by that is that it is hard to get inspired by academic work to create something 'original'. I am using scare quotes because I never quite understood the emphasis on originality in the profession – sometimes there is a very good reason an idea did not appear in print before you had it, and it is not because you are a genius. Be that as it may, here is an example motivated by published research.

The study of crisis bargaining and escalation has relied on stylized models neatly summarized and analyzed by Fearon.<sup>22</sup> He distinguishes between behaviors that involve sunk costs (paid irrespective of the outcome) and those that involve audience costs (paid only if an actor backs down after making a threat). As an example of the former, Fearon gives 'building arms or mobilizing troops'. He is very careful to note that these actions 'may affect the state's expected value for fighting' (p. 70) and that it would be 'more realistic to have the probability that the defender wins in a conflict depend on  $m$  [the level of mobilization]' (p. 72). He opts not to do this in order to keep sunk costs and tying hands analytically distinct.

I wondered whether this distinction was distorting. It was very difficult to conceive of a military move that did not alter the distribution of power between the actors. This meant that any such move would alter not only the incentives of the actor making it but also those of its opponent: tying one's hands might simultaneously untie the opponent's, affecting the overall probability of war in the crisis in ways not anticipated by the original models.

To check this intuition, I modified that standard escalation game so that both actors could choose their mobilization levels during the crisis, with the probability of victory dependent on these allocations.<sup>23</sup> Sure enough, there were important differences in the inferences. For example, in contrast to Fearon's results, the military threat model (MTM) shows that bluffing is possible. It also undermined the long-established result

in the crisis bargaining literature that militarily stronger actors are likely to obtain better deals but must run a higher risk of war in order to do so.<sup>24</sup> In the MTM, these actors still get better deals, but their risk of war might be *lower* because they can compel the other side by a more aggressive mobilization (the untying hands effect). The MTM also showcased the importance of considering the costs of maintaining peace through mutual deterrence with high military allocations, which led me to another paper.

### ***The Tacit Assumption***

An essential, but often overlooked, assumption in the canonical crisis bargaining model is that peace is costless.<sup>25</sup> The high mobilizations without war in the MTM alerted me that this assumption might be problematic. I should have known this from Powell's earlier contribution that showed how the possibility of an armed peace depended on the long-term costs of deterrence, but since the point had been peripheral to the goals of his article, I had missed both it and its implications for crisis bargaining.<sup>26</sup>

Clearly, if peace were to be costlier than war, then the bargaining puzzle would fall apart: actors would fight because war was preferable to any negotiated outcome for at least one of them. This would shift the focus from the now trivial problem of war under these circumstances to the unexamined problem of how actors would create these circumstances in the first place. In other words, if they knew that making peace too costly would lock them into war, would they pursue strategies that do so anyway?<sup>27</sup>

I took the direct approach: since arming is costly irrespective of the outcome, I decided to look at how actors paid for military power. Since I had been reading a lot about the emergence of centralized government in early modern Europe, my head was full of examples of kings who could not tax very effectively but who borrowed a lot and sometimes

failed to pay back their debts. War finance through borrowing instead of taxation also seemed appropriate because funds would be instantly accessible (unlike tax proceeds), and this appeared important considering the fact that the vast majority of interstate wars only last for a few months.<sup>28</sup>

As usual, I started with the canonical model, allowed both actors to determine the distribution of power through their military mobilizations and merely allowed one of the actors to borrow to increase the resource base, thereby permitting larger military allocations. I assumed that the actor was committed to repaying the debt if the bargaining ended peacefully or if the war ended in victory, but that the debt was repudiated if the war ended in defeat.<sup>29</sup> The analysis then revealed conditions under which the actor would incur a debt so high that the other would not be willing to concede enough to enable its peaceful repayment, and as a result the interaction would end in war under complete information. Further analysis revealed the importance of the actor's efficiency in converting financial resources into military capability, a topic never explored formally before.

The review process beefed up the article substantially, since the referees wanted me to allow both sides to borrow and wanted me to account for interest on the debt that was somehow related to the risk of default. These analyses took several months to complete and showed that the fundamental insight was not dependent on these simplifying assumptions in the original. And so the article conveyed a new, and different, argument about the causes of war.<sup>30</sup>

### ***The Unsatisfying Argument***

Among the most fertile sources of inspiration are attempts to explain your arguments to others. Teaching students, discussing with colleagues and sometimes even just chatting with friends and family have all, at one point or another, stopped me dead in my tracks in

the sudden realization that my argument does not quite work, either because there seem to be missing steps or because it is making potentially distorting assumptions that themselves need to be explained. Being puzzled on one's own by reading is much harder than being stumped by someone's question. There is probably no limit to the inanity of ideas I can come up with if I work in isolation, and the healthy skepticism of others is a crucial corrective. That is why I advise students to talk about their ideas as much as they can, to anyone who will listen. Instead of becoming defensive about criticism, look at it as an opportunity to develop a better argument.

My first example is a model that came about from an offhand comment during a lunch break while I was still in graduate school. I was working through the literature on audience costs for a course assignment and was chatting with a faculty member (I cannot recall whom) in the lounge while waiting for the microwave to warm up my lunch. He had asked me what I was working on, and I was explaining the idea behind audience costs – that leaders who escalate a crisis are punished if they back down – when he interrupted me by asking: ‘why would they do that?’ As I was giving the usual ‘national honor and prestige’ answer, I began to realize that it involved an uncomfortable amount of hand-waving and that a good explanation would require these costs to arise endogenously in the model. In other words, there should be a reason for the audiences to be willing to impose costs on leaders for backing down. At this point, the microwave pinged, and the conversation shifted to something else. But the question bugged me.

The problem was that it was not actually at all clear to me why someone would punish a leader for avoiding war, especially if bluffing was an optimal strategy. I did not do much with this because I had to finish my dissertation, but a few years later I was discussing the importance of leaders with Hein Goemans and suddenly recalled the puzzle. We had a back-and-forth about this, and I searched the

(very small) formal literature on the topic only to find a couple of scholars asking the same question. I was not satisfied with the answers, so set out to model the problem myself.

My model stripped away all detail – like the presence of a foreign actor – that did not seem pertinent to the analysis of the interaction between a leader, a policy being implemented and the domestic audience.<sup>31</sup> I found a model developed by Dur to deal with the persistence of bad policies, and adapted it for my purpose, reasoning that a legitimate reason for punishing a leader (and thus imposing audience costs) would be the audience realizing that the policy implemented is bad and so preferring a more competent leader.<sup>32</sup> The nuance of the argument was that the imposition of costs had to happen with positive probability during the interaction, rather than being assumed as a hypothetical threat with the leader then taking action to avoid it. (If the imposition of costs remained a zero-probability event in the model, then the purported explanation of audience costs would amount to an assumption.)

As I developed my intuition, I realized that since the argument hinged on the asymmetry of information about the policy quality between the leader and the audience, the model might be useful in exploring other potential sources of relevant information, such as a political opposition and a possibly biased media.<sup>33</sup> Consequently, the model expanded to include these actors (along with the entailing auxiliary structural premises), and generated some surprising insights. Among them was the result that in the absence of a robust and unbiased free press, democracies were no more likely to generate audience costs for their leaders than autocracies. This was in contradiction to Fearon's working hypothesis in the original paper that claimed the opposite. Moreover, the argument helped explain why mixed regimes could be especially sensitive to policy failures.

My second example is a model that came about from a discussion with Christina

Schneider, who had been researching decision-making in international organizations (IOs). We were dog-walking and sharing what we knew about the literature on the topic when she mentioned the problem of compliance with IO decisions. When would actors abide by collective decisions without an exogenous system of enforcement? This quickly led to another question: how would actors agree on such collective decisions? Since most organizations involve voting, the answer seemed easy. But then we realized that the insights about voting come from models that assume that the outcome is enforceable and voters who disagree do not get to work to overturn decisions. Moreover, almost all such models assume that voting is sincere, which is not an issue in the setting they were developed in (secret votes) but that could be quite problematic where votes are public, as they are in many IOs. Indeed, many empirical studies implicitly rely on public votes being sincere when they use them to measure preference similarity of member states.

Thus, we ended up with a question: what makes voting in IOs meaningful in the sense that actors are likely to reveal their preferences with their vote and abide by the collective decision even if they disagree with it? We began formalizing the problem that very evening, and several months later had an answer.<sup>34</sup> The modeling exercise here also led us to some more fundamental issues such as conceptualizing of international cooperation not merely in terms of the free-rider problem, as the widespread reliance on repeated games with Prisoner's Dilemma preferences does, but also in terms of a conflict of interest between groups of like-minded actors with resources to pursue divergent policies. The introduction of this competitive element in the cooperation problem brought the original puzzle into sharper focus but also opened up a host of related issues for research.

In both examples, the impetus behind the model arose from the feeling that the existing arguments were not quite right because they relied on a premise that was itself in

need of explanation. This premise might have appeared for modeling convenience or because of the adoption of a model developed for an apparently related but in fact quite different context. In neither case was the empirical validity of the assumption relevant.

### ***Some Bad Ideas***

As I indicated above, thinking about published research could give one insight that begs to be formalized. For this to work, however, one needs to know enough about the substantive phenomenon being studied to understand which premises in the existing argument might be distorting the conclusion, and thus warrant change. Without this 'inductive' step, modifying existing models for the sake of 'relaxing assumptions' and 'making them more general' could turn out to be of interest only to a handful of modelers, or could prove a pointless exercise altogether. Do not formalize merely for the sake of formalization.

One unfortunate consequence of the misguided 'scientism' in the social sciences is the insistence that hypotheses be derived from a formal model. Somehow, this is supposed to imbue them with rigor and validity, never mind the fact that almost all such models are concocted after the fact and are absurdly trivial. I have argued at length about the supposed 'rigor' of formal models elsewhere,<sup>35</sup> so here I will limit myself to the following injunction: do not formalize just to give a formal gloss of your hypothesis (or to pretend that you are getting some precise point estimates).

As I will argue below, a good first step in building a model is to use an existing one and modify it as little as possible to adapt it to the problem under consideration. Thus, someone interested in crisis bargaining might start by looking at models of strikes or pre-trial negotiations: in all these settings the actors possess a power to hurt each other in the absence of an agreement, and in some there is also

uncertainty about who is going to prevail in a costly ‘fight’ if negotiations fail.

This sort of importation must be done very carefully, though, because there might still be very important differences between the contexts, and if one borrows the idea without accounting for them, the result could be worse than useless: it might in fact be harmful to subsequent research. Political scientists are especially prone to borrowing models from economists without due consideration of the different context or the fact that the economists themselves very often neglect crucial political considerations in their own models. It is very easy to end up with a very ornamental model and pages of equations that amount to no insight whatsoever. Sometimes all you need is a small change in a premise to adapt the model, but sometimes you might as well build your model from scratch. Do not attempt to shoehorn your intuition into an existing framework.

### HAVE PUZZLE, WILL MODEL

Most of my research time is spent thinking about puzzles and trying to make persuasive arguments that resolve them. When I decide to formalize something, I also tend to spend considerable time on what the model should look like. Understand that this is almost never the unidirectional process suggested by how the idea appears in print: idea → model → solution → interpretation. Instead, one should expect to make several attempts to formalize the idea, sometimes along with full or partial solutions to the models, and sometimes one might even have to modify the original puzzle in light of what the analysis uncovers. The process looks like this: simplify → model → solve → realize either model or question were not quite right → change appropriate premise → iterate. This goes on until one is satisfied about the match between the question and the model.<sup>36</sup> It is worth keeping a record of the failed attempts

to avoid having to repeat going down blind alleys and to assist with the write up and responses to referees (who often suggest things one has tried already).

When building the model, be aware that there is no guide that can tell you whether the model is going to be useful. Do not strive for ‘realism’. Keep it simple, and realize that all models, even the most ‘realistic’, are false. Utterly and irredeemably so. Strive instead for minimalism and elegance. Remember, you are going to be making an argument, so it pays to be clear, precise and concise, and to have as few moving parts as possible to convey your intuition. Resist the temptation to show off modeling chops with complex math. Any real mathematician is going to laugh at such a folly anyway. Unnecessary bells and whistles do not make the model ‘more realistic’; instead, they make it harder to solve and even harder to follow. Proliferating parameters and premises decreases the warrant to believe the robustness of the result: how can one be sure that it is not entirely dependent on one of these myriad assumptions or some unlikely combination of them?

Scholars are often tempted to make things unnecessarily complex (which is why impenetrable jargon is always *de rigueur* in seminars), mistaking incomprehensibility for profundity. The same is true for formal models: one can easily build a formidable-looking thicket of Greek letters and numbers without realizing that no flower of an idea survives in the forest of equations. Sometimes the authors themselves do not understand how these models work – having plowed to a solution in a mechanical fashion – let alone the audience, who might be duly impressed by the math fireworks but leave scratching their heads and quickly forgetting about the idea. One might hope that diligent scholars would pore over one’s brilliant but obfuscated work to tease out the intellectual gems concealed amid the baroque ornamentation, but most of us are neither Plato nor Aristotle, so what are the chances of that? Most likely, the work will perish in the scholarly wilderness

for lack of citation sustenance. If you want your ideas to make a difference, you need the audience to understand them, which means it is your responsibility to make them as clear as possible. Models should be as complex as they have to be, but no more.<sup>37</sup>

How can this be done? For starters, relating the model to something known can be helpful. This is why I talked about beginning with an existing model, especially one that the audience is likely to be familiar with. Building on previous work is not merely good scholarly practice (acknowledging the contributions of others should be the *sine qua non* of research), but also a valuable aid in fleshing out the argument – how similar is it to others, and what makes it different. It also helps communicate the ideas efficiently and effectively – the audience is more likely to grasp something that is not too far from what it already knows, and since it can then evaluate your argument better, it is more likely to be persuaded of its merits.

If an existing model is not readily adaptable, then you must build one from scratch. Begin by specifying who the actors are, what they want, what they think they know, what their constraints are and what they can do. There will be many tough choices to make here, and it is not at all obvious initially which are better. Should you limit yourself to two actors? If the interaction is dynamic, should it be just two periods or some sort of infinite-horizon game? If there is incomplete information, should you use two types or a continuum? If the latter, should you use an arbitrary distribution or something convenient analytically, like the uniform or normal distributions? Is the action space discrete or continuous? How many opportunities to act will the actors have, and in what order will they move?

The problem here is that when you are building a model from scratch, there is always the temptation to make the argument more general and the model more ‘realistic’. You might not know what assumptions are going to make it intractable and what assumptions

might make it trivial. So, there will be trial and error here. Build a model and try solving it. This will give you some intuition about its moving parts and how they interact. It will also give you some ideas about how to improve the model.

I cannot stress enough how important the process of building a satisfactory model is, how messy and iterative it can be, and how long it might take. Published papers make it look like the model sprang from the mind of the author fully formed and perfectly adapted to the task, like some sort of mathematical Athena from the head of Zeus. In my experience, nothing could be further from the truth. Coming up with a model that is an adequate representation of your argument is hard work, full of trial and error, over a very uncertain timeline. It has on occasion taken me months of trying different specifications and sets of premises to arrive at a model that is a reasonable approximation of my intuition while simultaneously being solvable.

This is where minimalism and elegance become crucial. By minimalism I mean trying to come up with the simplest non-trivial model you can think of that formalizes your intuition. Your goal is to expose the structure of your argument as cleanly as possible, so any unnecessary parameter or detail should be mercilessly pruned.

I have taken to writing a paragraph in my papers, right before the model specification section, where I enumerate the essential features the model should have in order to represent the puzzle the argument is going to address. This paragraph comes very naturally after the literature review, which has situated the puzzle in the relevant literature and shown why current research has not answered the question being posed. This review identifies gaps in existing arguments and points to premises that need to be incorporated into or omitted from the new argument. This paragraph also ‘sells’ the model to the audience by justifying its premises explicitly. Anything that cannot be justified in this paragraph should be removed from the model.

Elegance is an elusive concept. It is something that one recognizes when one sees it, but that cannot be defined very precisely. Minimalism certainly helps, but there is more to it. Does the model seem ‘natural’ for the question being posed (this is where that paragraph also helps)? Or does it incorporate some odd premises that artificially constrain the actors in their choices? All assumptions are false, but some are beyond silly and are likely to make your argument unacceptable despite its deductive rigor.<sup>38</sup> Always remember that the strength of your argument will rest not on the idea that your agents are optimizing but on what you have them optimizing over: their preferences and constraints.<sup>39</sup> Do the payoffs reflect reasonable preferences or do they appear contrived and complicated? Anything with more than a few parameters or with very specific functional forms begins to look suspicious to me. Is the notation intuitive or clunky? There is no standard notation in game theory, so here it is best to adopt the notation used in well-cited articles or textbooks such as *Game Theory* by Fudenberg and Tirole.<sup>40</sup> Here it is best to emulate the specification of prominent and well-cited models that you admire.

The build → solve → build again → solve again → build again → etc. sequence suggests that one could benefit from being smart about the analysis. Instead of trying the most general case, go through a few simpler variants first. Use numerical examples to get a handle on what might be possible in the model, and some intuition about the parameter space where it can happen. Simulations and graphs are an excellent way of exploring the model before you begin solving it analytically. Plot the payoffs and vary the strategies of the other players to see what form the best responses might take. You might notice a pattern. For example, some relationship between payoffs from two choices seems to persist no matter what values you assign to some parameter. Try to prove analytically that the optimal choice is independent of that parameter. You might see abrupt changes in the optimal solution. Try to

prove that it changes form at some threshold value. Once you derive the best responses, program them and then explore the comparative statics. You should use whatever programs you are comfortable with.<sup>41</sup>

When you start discovering analytical results, it is time to write them down in your draft paper. This is where the first lemmas and propositions will make an appearance. There might not be a lot connecting them yet, but the skeleton of the argument is being constructed as you learn from your model. I also like to typeset them in LaTeX immediately because the math looks beautiful, the proofs are easier to read and the text is readily useful. (It is also easier to make global notational changes.) I also write explanations of the intuition behind these results as if I am talking to an audience unfamiliar with the model. These often make it in some form into the final draft and are particularly useful to keep the argument running in my head.<sup>42</sup> Do not wait until the analysis is complete to write – write as you go along. You will end up with multiple drafts of various models and partial solutions as the record of your research endeavors, and you will have the basic draft of the formal exposition ready when you complete your analysis.

Throughout all of this, you must be ready to be taught by the model. Or, rather, you must understand the intuition behind the results you are getting, and you must be willing to either jettison the model if it does not represent your argument properly, or accept that your original intuition might have been incorrect or incomplete. In the end, learning from your model is the largest payoff from formalizing your argument.

## EXPOSITION: LEARNING FROM YOUR MODEL AND TELLING OTHERS

Now that the analysis is done and you have your main results, what next? If you followed the advice to write the intuition behind each

step in your argument, you have an excellent handle on how it works. Your goal now is to convey this to others and to persuade them.

Your final draft will not track either your research progress or the complexity of the argument itself. Instead, the paper should focus on how your results answer the question you posed (which may have been restated several times as your thinking has evolved while solving various models), and it should convey that connection efficiently and intuitively. The paper must lead the audience to your conclusions, not rely on it making its own inferences. This means exposing all necessary steps in the argument without getting bogged down in technical detail. It might be painful to relegate 50 pages of hard-won mathematical results to an appendix very few will ever read, but this is what you must do. The body of the paper should include just enough mathematical detail to carry the argument in plain prose.

If you cannot explain the behavior of your agents without reference to equations, you have a problem. You are telling a story, which means that your agents should have intuitive (given incentives and constraints) behaviors. Nobody will care about uninterpreted statements that refer to impenetrable mathematical conditions, no matter how correct they are. Nothing should remain ‘counterintuitive’ after you have presented your argument. Presenting the paper to colleagues is a very effective way of fleshing out the rough spots in the write up. What is obvious to you might be totally opaque to others. What you think is trivial might be crucially important to others. It is very difficult to put yourself in the position of an audience that has not spent any time on your research, so do not do it. Instead, go with a real audience for that. I never miss an opportunity to present ideas and have never turned down an invitation to do so, especially if the audience is not academic.

Word count limits prevent me from spending more time on advice about crafting the paper. Fortunately, there are excellent books about how to write elegantly and concisely.

Some of them are even specific to formal work.<sup>43</sup> Follow their advice. Read widely and emulate writers you admire. Like any skill, writing is made perfect with practice. And do not default to the dry, pedantic and, frankly, boring tone characteristic of academic papers.

Remember, your model is an argument, and persuasion hinges on how it is presented, on rhetoric. Strive for readable prose. Do not be afraid to be slightly imprecise when the alternative is a detour into technical detail. Use historical cases to illustrate your points (but do not pretend that they are some sort of ‘tests’ of your results). It is fine to be entertaining. It is you who must provide the justification and the interpretation of the model. It is you who must explain the argument. It is you who must hold your audience’s attention and persuade it. Leaving any of these steps to others is a guarantee that your modeling efforts will be for naught. And we would not want that, now, would we?

Johnson, 'How not to criticize rational choice theory: pathologies of "common sense"', *Philosophy of the Social Sciences*, 26 (1996), pp. 77–91.
  - 8 One might wish to keep in mind the distinction between models (which is what I am discussing here) and a theory (which I will not discuss). Think of models as the building blocks of a theory: useful (or not) specifications of concepts and ideas that comprise a theoretical explanation. Theories can, and should be, subjected to empirical testing in a way that models cannot, and should not, be.

  - 10 James Fearon, 'Rationalist explanations for war', *International Organization*, 49, Summer (1995), pp. 379–414. The trade-off arises because actors are unsure how much they must concede to each other to make peace mutually preferable to war. Conceding a lot makes the other actor more likely to accept a settlement but also forces one to forego some of the benefits of peace. Conceding too little, on the other hand, risks pushing the opponent into a fight. Generally, an actor that is uncertain about what the other one's minimal acceptable terms are would make an offer that carries some risk of rejection but that yields somewhat better terms if accepted.

  - 36 This reality also makes a mockery of the idealized notion that one constructs a deductive model in some pristine analytical void and then 'tests' its conclusions. The process I am describing is a mix of induction and deduction, all informed by the researcher's knowledge of empirical patterns, other models, and cases.
  - 37 For a discussion of what model complexity is and isn't, see Catherine C. Langlois, 'Are complex game models empirically relevant?', *Conflict Management and Peace Science*, 35, 1 (2017), pp. 1–15. She also critiques Allan and Dupont's assertion of a 'tendency toward theoretical elegance to the detriment of empirical correctness' that supposedly plagues formal models. I leave it to the reader to decide what to make of an assertion that uses 'empirical correctness' as a criterion to evaluate models.
  - 38 An example from economics would be the notion that unemployment represents the workers' free choice of leisure without a job over working at previous pay, as the real business cycle theory would have one believe. See Robert Lucas and Leonard A. Rapping, 'Real wages, employment, and inflation', *Journal of Political Economy*, 77, 5 (1969), pp. 721–54.
  - 39 Robert Solow, 'The state of macroeconomics', *Journal of Economic Perspectives*, 22, 1 (2008), pp. 243–9.
  - 40 Drew Fudenberg and Jean Tirole, *Game Theory* (The MIT Press, Cambridge, MA, 1991).
  - 41 I use *Mathematica* for the analytical derivations (I prefer doing them by hand and checking the result), and I use *Gauss* for simulations. The only reason for these choices is that these are the programs I learned in graduate school. The numerical exploration approach is advocated in Catherine Langlois and Jean-Pierre Langlois, 'From numerical considerations to theoretical solutions: rational design of a debtor-creditor agreement', *Peace Economics, Peace Science and Public Policy*, 22, 4 (2016), pp. 403–12.
  - 42 Keeping notes for yourself is not as strange as it sounds. If you stop working on a model for a few weeks, by the time you come back you will have forgotten all the details. At this point, I usually have to re-derive everything from scratch, so it really helps to keep extensive notes and not rely on memory for anything. This is a practice I inherited from my days as a computer programmer, when staring at my own code a couple of months after I wrote it taught me to document it as if I was addressing a partially lobotomized monkey.
  - 43 I have found two very useful for general prose: Helen Sword, *Stylish Academic Writing* (Harvard University Press, Cambridge, MA, 2012); Francis-Noël Thomas and Mark Turner, *Clear and Simple as the Truth: Writing Classic Prose* (2nd ed.) (Princeton University Press, Princeton, 2011). For formal writing, one is indispensable: William Thomson, *A Guide for the Young Economist: Writing and Speaking Effectively about Economics* (The MIT Press, Cambridge, MA, 2001).

# Evidence-Driven Computational Modeling<sup>1</sup>

Ravi Bhavnani, Karsten Donnay  
and Mirko Reul

## AGENT-BASED COMPUTATIONAL MODELS

Computational modeling is a powerful, versatile tool for the analysis of complex social phenomena. Historically, scholars used computational modeling to investigate abstract causal relationships in artificial settings, highlighting simple but counter-intuitive dynamics. Seminal examples include work by Thomas Schelling on the drivers of segregation (Schelling, 1971), Robert Axelrod on the evolution of cooperation (Axelrod, 1984), Joshua Epstein and Robert Axtell on artificial societies (Epstein and Axtell, 1996), and Palmer et al. on artificial stock markets (Palmer et al., 1999). These early applications influenced subsequent research, including notable studies on the formation and dissolution of nation-states after the end of the Cold War (Cederman, 1997), the dynamics of ethnic violence and genocide (Bhavnani and Backer, 2000), and more recently civil violence in Baghdad and Jerusalem

(Bhavnani et al., 2014; Weidmann and Salehyan, 2013).

In contrast to *consolidative models*, which typically involve the development of ‘model’ systems to represent ‘real-world’ settings with measurable physical characteristics (for weather forecasts, see Gneiting and Raftery, 2005; Skamarock and Klemp, 2008), *exploratory* computational models stop short of formalizing the complexity of social systems (Bankes, 1993). Given the difficulty of fully observing, theorizing and validating processes in social and natural systems, our approach builds on work that is exploratory, not consolidative, in nature. One class of exploratory computational models used in the social sciences is agent-based computational modeling (ABM) (for an overview, see de Marchi and Page, 2014).

A key property of ABM is the specification of simple rules from which complex outcomes *emerge*. As such, an ABM may be specified as a non-linear function that relates combinations of inputs and parameters to

outcomes. ABMs are typically composed of agents, decision-making heuristics, an interaction topology and a non-agent environment (Epstein, 1999). Agents in an ABM can represent individuals (Bhavnani et al., 2008; Epstein, 2002), groups (Bhavnani et al., 2009; Kollman et al., 1992) or institutions (Cederman, 1997), to name a few possibilities. In this regard, the approach provides a high degree of flexibility or *granularity*, given the ability to integrate phenomena specified at different scales. ABMs are process-oriented and lend themselves well to studying dynamics, in contrast to approaches that tend to be more equilibrium-centered.

In most formulations of ABM, agents are endowed with a range of characteristics and decision-making heuristics. Individual agents may learn or adapt their behavior based on their own experiences, driven by heuristics or imitation, or change may be effected for a population of agents by means of evolutionary selection (Kollman et al., 1992; Laver, 2005; Mitchell, 1996). The interaction topology specifies how agents interact with each other and their environment, the latter being composed of physical features such as geography or topography (Axtell et al., 2002; Epstein, 2002) or various states of the world (Axelrod, 1984; Nowak and May, 1992; Tullock and Campbell, 1970). These elements constitute the key components of an ABM, which is run repeatedly to identify causal mechanisms, observe relationships, patterns and emergent outcomes, and explore counterfactual scenarios.

ABMs lend themselves well to the analysis of complex social phenomenon, in particular where ostensibly simple decisions have unexpected consequences (Epstein, 1999). Yet, while agent-based models have notable strengths, they are not immune to criticism (Richiardi et al., 2006). A notable weakness of ABM is the tendency to include too many factors and interactions, given the ease with which these may be specified. As a rule of thumb, a model becomes too complicated when comprehensive exploration

of the comparative statistics for each model parameter is infeasible (see Lustick et al., 2004). Under these circumstances, it is virtually impossible to determine what is driving model results. Yet another flaw is the lack of relevant theoretical and empirical anchors, which result in unrealistic or even arbitrary model specifications. These anchors are essential to address the *identification problem* – the notion that multiple plausible mechanisms may explain a given outcome (Fisher, 1966). This chapter provides practical advice for designing, implementing and using computational models that are evidence-driven and designed to address these shortcomings.

## EVIDENCE-DRIVEN COMPUTATIONAL MODELS

The evidence-driven modeling (EDM) framework rests on three methodological pillars: agent-based modeling (ABM), contextualization using geographical information systems (GIS) and empirical validation. EDM harnesses the strengths of ABM in capturing both social complexity (e.g., the heterogeneity of actor beliefs, preferences, attitudes and behaviors as well as the characteristics of specific institutional settings and local environments) and causal complexity (including questions about who interacts with whom, when, where and with what effects), while simultaneously achieving a high degree of real-world correspondence and resonance. The combination places EDM squarely at the intersection of theory and empirics.

Notable examples of EDM include studies about civil violence in Jerusalem and Baghdad (Bhavnani et al., 2014; Weidmann and Salehyan, 2013), neo-patrimonial networks (Geller and Moss, 2008), social inequality in pastoralist societies (Rogers et al., 2015), the rise and fall of the Anasazi people in what is now the Southwestern United States

(Axtell et al., 2002), social capital and civic culture in Italy (Bhavnani, 2003), legislative politics (Laver et al., 2011), party competition (Laver and Sergenti, 2011) and the occurrence of burglary (Malleon and Birkin, 2012). The diversity of research demonstrates the utility of combining computational models with rich empirical data – data that are spatially and temporally disaggregated – to analyze the links between micro-level dynamics and emergent, macro-level outcomes.

Where other, more aggregate analyses yield inconclusive results, EDM enables researchers to adjudicate between alternative explanations and reveal complex, conditional relationships and inter-dependencies that would otherwise be difficult to detect (Camerer, 2003; Kim et al., 2010).<sup>2</sup> In particular, EDM makes it possible to specify causal mechanisms in ways that are sufficiently intricate, conditional and, thus, ultimately realistic, while maintaining the ability to go beyond purely exploratory modeling by means of rigorous empirical testing. And in contrast to experimental approaches that control for contagion and spillover, EDM explicitly incorporates these ostensible threats to validity as part of the causal chain, for example by endogenizing the effects of geographical proximity and the heterogeneity of covariates across spatial units. The more specific benefits of EDM include the following:

- 1 *Model Topography*: The ability of EDM to harness GIS, in conjunction with empirical data, enables realistic topographies to be substituted for the abstract grids characteristically used in ABM. As such, the landscapes used in EDM more closely represent actual physical or social inter-dependencies, capturing complex, often endogenous relationships among adjacent units, rather than controlling for these relationships statistically or by means of experimental design.
- 2 *Agent Granularity*: EDM can simultaneously accommodate data of different spatial and temporal resolution, whereas other methodologies are often wedded to the use of specific, fixed

units. In contrast to ABM, these different units of analysis correspond to empirical observations and capture dynamics at meaningfully interlinked levels, e.g., individual decision-makers interacting with groups.

- 3 *Data Imputation*: EDM is typically used in data-rich contexts but also excels in data-poor contexts, where information on relevant indicators suffers from incompleteness, a lack of synchronization, mismatched units of observation, and differing levels of detail. Imputation in EDM works by seeding a model with potentially sparse empirical data, and then permitting model dynamics to evolve endogenously. The closer simulated outcomes are to empirical trends, the better the imputation. The estimation of different parameters across contexts, using the same model, is one way to increase model robustness.
- 4 *Identification*: As with ABM, EDM can be used to explore relationships between or adjudicate among competing micro-level explanations, relying on methods for data construction, such as participant observation, expert or field interviews. Insights from these methods help ground a model, ensuring that researchers 'get the story right' and tailor the model to the specificities of a given context.
- 5 *Counterfactual Analysis*: Once a model is calibrated and empirically validated, counterfactuals can be devised by adjusting values of certain parameters, including those capturing micro-level dynamics and the empirical context, or by introducing new parameters. The results, produced under an assortment of 'what-if' scenarios, offer an indication of what the world could look like if empirically observed trends were to change. In essence, this option enables experimentation through simulation. Short of true out-of-sample forecasts, counterfactual experiments make it possible to undertake evidence-driven forecasting.

In the remainder of this chapter, a step-by-step discussion guides the reader through the use of EDM in the *Modelling Early Risk Indicators to Anticipate Malnutrition (MERIAM)* project. We provide further detail on the building blocks for EDM, as well as on the choices and practical challenges of using the approach. Our discussion is

intended to serve as a point of departure for conducting research with EDM.

## EVIDENCE-DRIVEN MODELING OF MALNUTRITION

The MERIAM project illustrates how the EDM approach can be applied, from initial conception to final, policy-relevant application. MERIAM is a four-year project funded by the UK government, which brings together an inter-disciplinary team of experts across four consortium partners: Action Against Hunger, the Graduate Institute of International and Development Studies, Johns Hopkins University and the University of Maryland. MERIAM's primary aim is to develop, test and scale up models to improve the prediction and monitoring of undernutrition in countries that experience frequent climate- and conflict-related shocks.<sup>3</sup>

In 2017, the number of undernourished people was estimated at 821 million; this is closely associated with the spread of armed conflict (FAO et al., 2018). Regions across Nigeria, South Sudan, Somalia and Yemen face severe food insecurity, related in no small measure to their exposure to conflict as well as a host of other characteristics that increase vulnerability to famine. The gravity of these situations and high interest among stakeholders serve as inspiration for devising effective means of forecasting risks to better anticipate crises and guide appropriate responses.<sup>4</sup>

The research team at the Graduate Institute is tasked with the development of an EDM to analyze the effect of household-level decisions on nutrition-related outcomes (e.g., acute malnutrition and resilience), accounting for variation in household characteristics; local, contextual factors; and more macro- or aggregate-level covariates. How households adapt their behavior, changing or diversifying sources of household income in response to stressors and shocks, may serve to improve

or worsen a household's resilience to food insecurity over time. We develop and validate our EDM based on the case of Karamoja, Uganda, and subsequently expand our model framework to other cases in sub-Saharan Africa.

We use this project – and, in particular, the application of our approach to study malnutrition in Karamoja – as an example of applying cutting edge computational modeling techniques to a highly relevant policy issue. The 'entry-point' for the use of EDM is an abundance of theoretical knowledge on the issue, the complexity of interactions of the numerous factors that influence malnutrition outcomes at the household level and the need for a systematic, reliable and transparent forecasting technique. At present, practitioners and policymakers tasked with anticipating changes in the risk of acute malnutrition need to combine expert knowledge on malnutrition, including a deep understanding of its causes in particular cases, with statistical analysis of data from various sources on a regular basis. A prominent example in the context of sub-Saharan Africa is the Famine Early Warning Systems Network (FEWS NET), which classifies a country's risk of acute food insecurity, relying on expert discussions and analysis mainly of remote-sensing, market price and trade data. The outcome is an indicator for food insecurity on a five-point scale, ranging from 'Minimal' to 'Famine', with 'near'-term and 'medium'-term forecasting windows of up to seven months (see *IPC 2.0*<sup>5</sup>).

There are several potential weaknesses inherent to such an approach. First, the link between data and projected food insecurity lacks formalization (the scenario-building process is interpretive) and transparency (it is unclear how a particular prediction is made). In a related vein, expert discussions underlying the data analysis are undocumented for end-users, making comparisons of forecasts by different experts problematic should interpretations vary.<sup>6</sup> And finally, predictions of food insecurity by livelihood zone obscure the

relative weight of various risk factors and their effects at more disaggregated spatial units.

Our EDM approach attempts to address these weaknesses. First, we harness available expertise on food security and malnutrition, relying explicitly on expert surveys, to develop a theoretically grounded computational model. Second, we use existing, household-level data and household surveys conducted in the field to empirically contextualize and validate the model for a set of sub-national regions that vary in terms of their incidence and prevalence rates, livelihood zones, climate conditions and history of conflict. Third, we provide a tool that stakeholders can use to construct acute malnutrition scenarios across diverse contexts, exploring the relation between shocks and stressors, on the one hand, and more immediate and long-term outcomes on the other. In the section that follows, we provide an in-depth example of the EDM approach, beginning with why we believe this is an appropriate methodological choice. We then provide an overview of the model development process, data construction, model implementation, refinement and validation. Lastly, we discuss how the validated EDM can be used for scenario-based analyses and how its results can be presented to expert users and relevant stakeholders.

## A STEP-BY-STEP GUIDE TO THE EDM APPROACH

The MERIAM project seeks to identify how, in response to conflict and climate shocks, household-level decisions affect nutrition-related outcomes – effectively unpacking the ‘black box’ of household behavior. At the household level, our EDM analysis is motivated by a set of fundamental questions that link household characteristics and behavior to acute malnutrition outcomes:

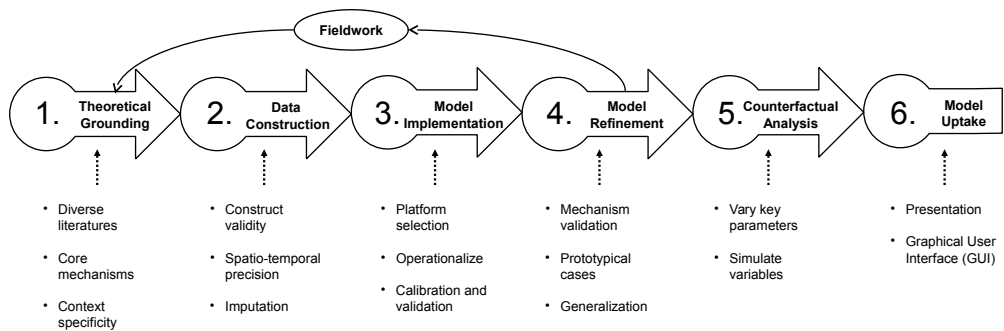

- Holding the context constant, why are some households affected by risk factors while others are not?

- To what extent do households within the same context react to risks in the same way?
- Is the same segment of a population recurrently affected, or is substantial flux observed?
- Do the risk factors for those affected remain the same year after year, or do they change over time?
- Does a given risk factor have the same effects across diverse contexts?

Our model uses *resilience*, the ability to cope with or adapt to various shocks and stressors, as a conceptual frame to investigate variation in nutritional outcomes in a manner that resonates with development stakeholders (e.g., Boukary et al., 2016; Food and Agriculture Organization of the United Nations, 2016; United States Agency for International Development, 2012; see Béné et al., 2015). In this particular domain, a resilient household – and in the aggregate, resilient communities, regions and countries – is better positioned to cope with the unfavorable effects of an exogenous shock, or has a greater ability to recover (say to pre-crisis intake levels of nutrition) in the aftermath of such a shock. Stakeholders may design interventions to boost endowments, moderate constraints, facilitate learning or strengthen systems for crisis management (Béné et al., 2015), all of which should contribute to greater resilience to nutritional crises.

The development of our EDM may be broken down into the six steps illustrated in Figure 4.1.

- 1 *Theoretical Grounding*: the EDM is grounded in existing theoretical and empirical knowledge of the subject matter.
- 2 *Data Construction*: relevant data to seed and validate the EDM are collected, analyzed and formatted.
- 3 *Model Implementation*: a preliminary version of the EDM is implemented as a computer simulation.
- 4 *Model Refinement and Cross-Case Validation*: the model is refined through expert interviews, fieldwork and out-of-sample testing.
- 5 *Counterfactual Analysis*: a valid EDM is extended by implementing counterfactual, ‘what-if’ experiments to explore how simulated trends are altered under different conditions.

**Figure 4.1 Model development process**

6 *Model Uptake*: suggestions to visualize and present EDM results are put forth in an effort to make the model accessible to relevant end-users and stakeholders.

In each of these steps, the researcher makes consequential decisions that affect the outcome of the EDM process. Yet by design, EDM makes these choices explicit and transparent. And while computer simulations are not as well understood among social scientists and policy makers, the basic intuition underpinning EDM is relatively simple, perhaps more so than a statistical model that addresses similar questions.

### **Theoretical Grounding**

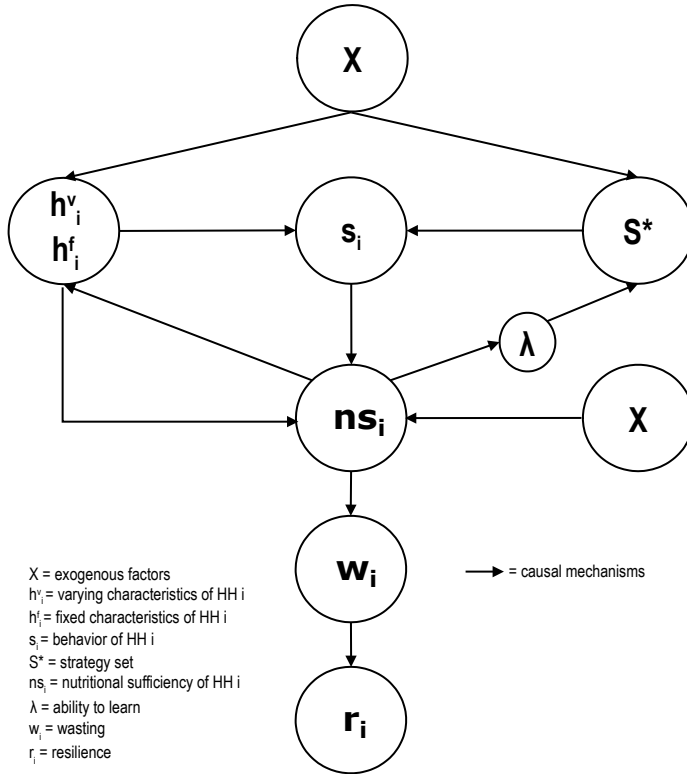

First, we surveyed a diverse body of research on malnutrition, including detailed qualitative case studies (e.g. Hatløy et al., 1998; Manners, 2014; Parker et al., 2009), comprehensive ‘broad-brush’ approaches that integrate a wide range of mechanisms to explain malnutrition (e.g., Young and Marshak, 2017) and statistical analyses (e.g., Ajieroh, 2009; Ehrhardt et al., 2006; Fotso, 2007). Like any computational approach, the internal validity of EDM depends, in no small measure, on prior, often qualitative work that describes social processes in their requisite complexity.

Second, we reviewed this work to map the relations between leading and underlying indicators, in an effort to identify the \*\*core

mechanisms\*\* that characterize malnutrition dynamics. The two defining categories into which these indicators fall are *shocks* and *stressors*. The first category of shocks includes the onset of a conflict, which usually has a sudden impact that is unanticipated by households. The second category of stressors accounts for the effects of longer-term or more gradual, recurring changes such as a lack of rainfall, which may vary in intensity, including its most extreme manifestation as drought.

Third, we examined *context-specific mechanisms*. In Karamoja, conflict has been endemic given the 20-year insurgency of the Lord’s Resistance Army (LRA), as well as more recent pastoralist conflicts that involved cattle raiding or rustling (DCAF-ISSAT, 2017; FEWS NET, 2005). This has had many negative effects on the Karamojong, including the loss of human lives, displacement, reduction in livestock, and the progressive spread of small arms used by herders for protection, indirectly contributing to an increase in violence (DCAF-ISSAT, 2017).

Our model evolved as we relaxed simplifying assumptions and improved our understanding of malnutrition in Karamoja. Moving beyond an initial specification of households endowed with an unbounded ability to adapt behavior, we defined households as boundedly rational actors (Arthur, 1994), focusing primarily on food provision. The latest version of the model is depicted in

**Figure 4.2 Flow diagram for MERIAM EDM**

Figure 4.2. In each iteration and for every household, we calculate nutrition levels (*ns*) based on previous actions, a set of health- and food-intake factors ( $h^{v,f}$ ), and exogenous constraints (*X*). Proportional to changes in *ns*, households adapt their behavior based on learning ( $\lambda$ ): if *ns* is stable and sufficient to feed household members, the household continues to behave the way it did before. But if radical changes occur, households adapt their behavior either (a) randomly, (b) by copying a locally optimal strategy from their neighbors, or (c) by combining existing strategies to create a new one (Holland, 1975; Kollman et al., 1992; Krakauer and Rockmore, 2015; Mitchell, 1996; Urbanowicz and Moore, 2009).

In the current formulation, sub-optimal behavior is the rule rather than the exception, and status-quo behavior is effectively reinforced if households attribute a worsening of

their situation to previous behavioral changes rather than exogenous factors (see ‘probe and adjust’ in Huttegger et al., 2014). The approach permits us to account for structural impediments to adaptation in a context like Karamoja, while still allowing for household-level change, e.g., from pastoral to agro-pastoral food production (e.g., Mercy Corps, 2016; see also Stites and Huisman, 2010). Note that the model, at this stage, may still be classified as an ABM. The next step is to construct the data necessary to enable the empirical contextualization of the model.

The process of theoretically grounded model development as is described here is prototypical, including the iterative refinement of model mechanisms and their operationalization as the modeler’s understanding develops. At this stage, choices are made based on the best available insights on the

case, bearing in mind the need for further refinement following fieldwork and empirical validation in the next stage.

### **Data Construction**

The EDM approach relies on data for empirical contextualization. The quality of the data – its accuracy, resolution and coverage – ultimately shapes our ability to seed and validate the model. A careful examination of data availability and quality is thus of paramount importance. In this section, we describe the main strengths and weaknesses of our household-level data for Karamoja, although our considerations may be generalized beyond the specifics of this case.

Our EDM is fundamentally about household characteristics and behavior, but it requires information exogenous to households as well, from district-level statistics about health facility capacities to more granular data at the grid or point level. Figure 4.3 presents an overview of the data we use to seed and validate the MERIAM EDM.

For our analysis of household characteristics and behavior in Karamoja, we utilize nutrition survey data provided by Action Against Hunger (2013). The dataset has two distinct advantages compared to other nutrition surveys. First, it contains behavioral variables at the household level. Second, the dataset is longitudinal: it consists of six survey rounds between August 2010 and May 2012, allowing us to validate and align the timescales of simulations against empirical outcomes repeatedly over this time period.

Our household-level data exhibits three principal weaknesses with respect to construct validity, spatio-temporal precision and completeness. First, some household-level variables do not measure the specific household attributes and behaviors we seek to model. For example, we use the variable ‘food source’ as a measure for how households obtain food. But only the ‘*most important*’ food source was measured in the survey,

which means that we cannot observe whether households use other means to obtain food.

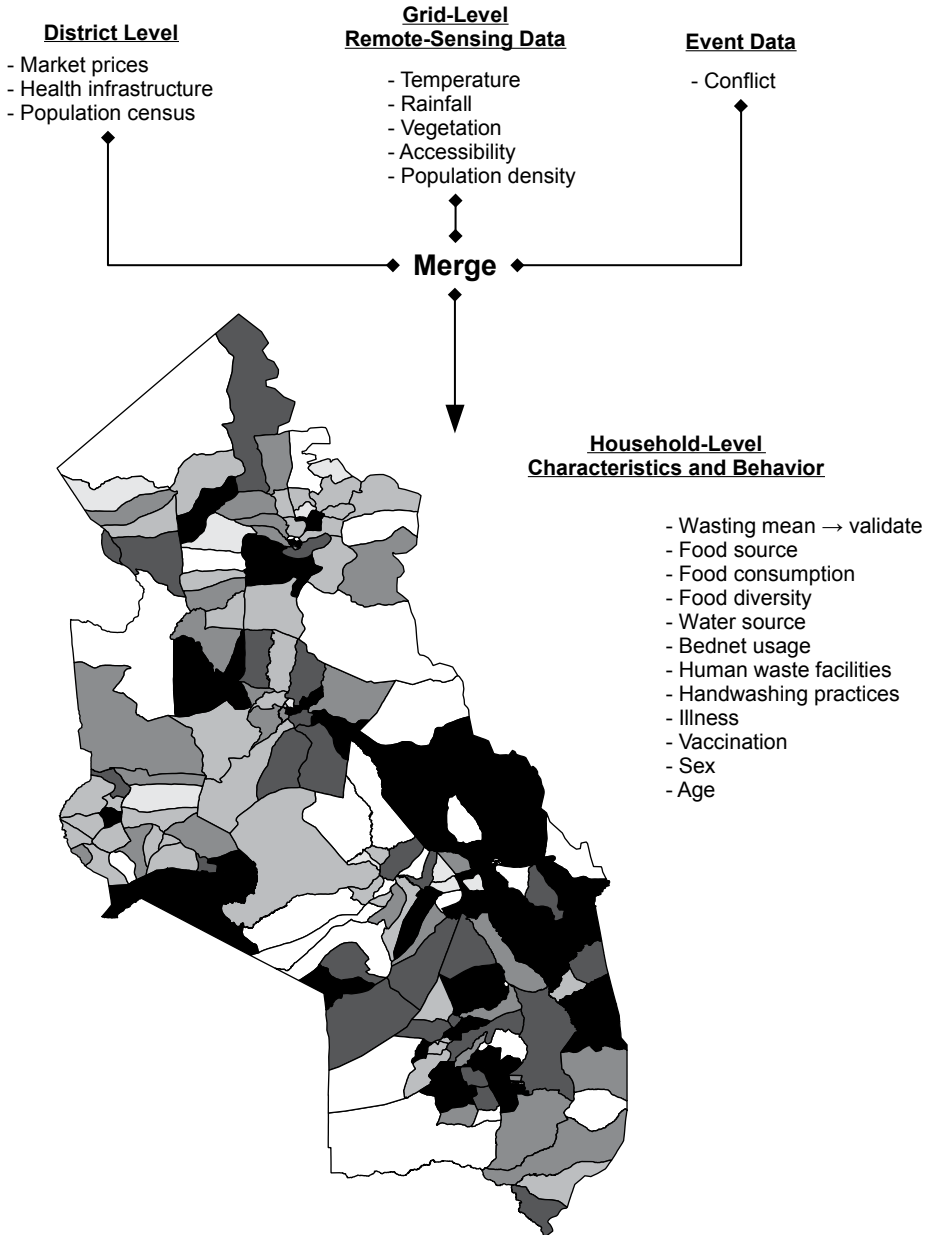

Second, the data are imprecise. They capture longitudinal trends, rather than following the same households over time. With panel data, we could seed and validate our EDM against the decisions and characteristics that each particular household makes over time. With trend data, this information exists at an aggregate level to the extent that we know, on average, households changed on the measured variables between samples.

In addition, our household data is spatially imprecise insofar as it is representative at the ADM1 district. Short of obtaining representative samples at lower levels of analysis, there are still ways to mitigate spatial imprecision using *imputation*. For Karamoja, census data is only available at sparse intervals – no census was conducted between 2002 and 2014, a period that saw a 2.4% population growth in Karamoja (Uganda Bureau of Statistics, 2017). An alternative is to use remote-sensing data to estimate population numbers at the grid level.

The challenges to data quality from construct validity, (lack of) precision and completeness recur across empirical settings and are by no means specific to the EDM approach. The ability to accommodate data at varying levels of granularity, though, is a strength of the approach. As such, we need not match empirical and simulated household characteristics at the same level of granularity, given that we measure other contextual factors related to conflict, climate and market prices (see Figure 4.3). Instead of joining data at the lowest common level granularity, each model component can be simultaneously specified/matched with empirical data at the maximal level of granularity permissible.

### **Model Implementation**

Several platforms are suitable for programming an EDM, with a trade-off between

**Figure 4.3 Data construction overview**

simplicity of use and performance, i.e., the ability to handle complex modeling setups. A popular and widely used solution is the NETLOGO platform (Wilensky, 1999), which is easy to learn but more restrictive in

its capabilities. At the other end of the spectrum are powerful libraries such as the Repast framework in Java (North et al., 2013) or MESA for Python (Masad and Kazil, 2015), both of which require greater customization.

The EDM discussed here uses a custom class-based implementation in Python. We note that the choice of programming language and framework do not affect model outcomes – only the ease of use and the ultimate runtime of the simulation.

In contrast, the *operationalization* of the model can have a profound impact. To operationalize model dynamics, it is necessary to specify the logical order of progression, sequence of actions and updates within the model – who does what, where and when and based on which information – paying close attention to attendant implications (Caron-Lormier et al., 2008). It follows that model heuristics can be universal or conditional, fixed or subject to change over time.

Consider, first, the problem of defining time progression within the model – the number of actions and updates that occur within a time step (e.g., an hour, day or year) to correctly reflect the timescales of the processes the model seeks to represent. A common solution is to make this correspondence explicit in the definition of a model time step, i.e., define time progression in terms of the fraction of possible actions or updates performed. For example, we consider a time step to have ended after updating the state of all households once. For the timescales of simulated and empirical outcomes to align, any time dependent parameters in the model that have empirical equivalents (e.g., the rate at which households adapt their strategies) have to be scaled such that their timescale aligns with that of the observed empirical process.

Second, EDM use geographical information for contextualization that ensures a high degree of correspondence between geography and the model topology. Exactly how space is operationalized within the model reflects an explicit choice to be made by the researcher. A common choice of implementation that reduces computational complexity is to discretize physical space. For example, in the model for Karamoja, household locations are defined on an underlying regular grid that is dynamically generated using

actual settlement locations and their associated densities. In order to account for both low and high population densities, we use data on population densities at the grid level such that the number of households in a grid approximates the population density in the corresponding area in Karamoja.

Choices related to model operationalization are by no means simple or straightforward. To avoid influencing simulation outcomes or unwittingly introducing errors and artifacts, competing operationalizations of the same model mechanisms should be tested to ensure that a specific operationalization is not driving simulation outcomes (see also Galán et al., 2009).

Analogous to testing in- and out-of-sample predictive power for statistical models, EDM are formally validated and calibrated to maximize the correspondence between simulation results and real-world outcomes. Figure 4.4 shows the full modeling cycle, from model operationalization and contextualization to enumeration and calibration. For the Karamoja case, we identify the degree to which households are able to adapt to changing conditions that, all else equal, best explain the observed patterns of malnutrition. The closer the calibrated model approximates empirical outcomes, the greater the validity of the model predictions. Yet, quantitative agreement is not the only important measure. The parameters that best predict empirical outcomes must also reflect plausible dynamics on the ground. Should this fail, further refinement and validation of the model are necessary.

The modeling cycle illustrated for Karamoja (Figure 4.4) serves as a template for identifying parameters that yield the closest correspondence to real-world outcomes, a process that constitutes the core of the evidence-driven approach: given a model specification that formalizes our theoretical understanding of a process and data to seed the model (possibly at varying levels of granularity), what is the model with maximal explanatory power for our outcome of

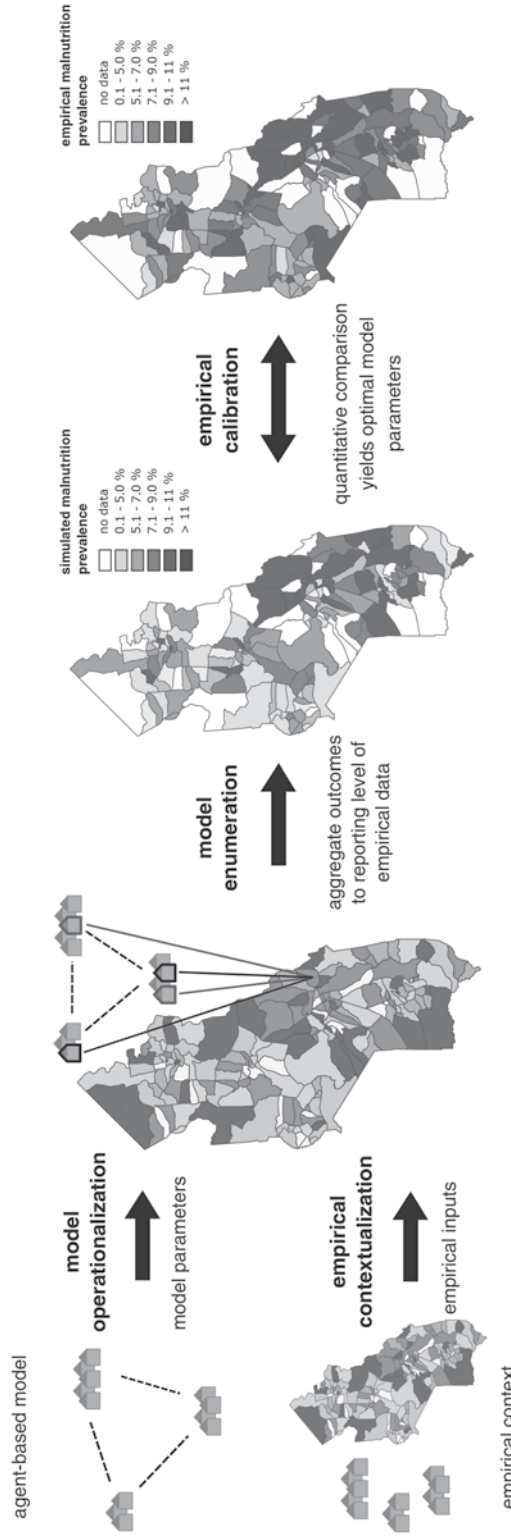

Figure 4.4 EDM modeling cycle

interest? The parameter constellation of the ‘best-fit’ model indicates which specific mechanisms in which constellation yields maximal agreement with empirical outcomes. Clearly, there is no guarantee that the constellation is empirically plausible, which makes the step of model refinement and validation an essential part of the process.

### ***Model Refinement and Cross-Case Validation***

While our model framework is derived from the existing literature, in addition to which we have undertaken a limited set of interviews with experts outside of the region, ground-truthing the model in Karamoja is an integral part of our EDM approach. Absent fieldwork, we run the risk of misrepresenting the dynamics at the core of our model, in particular, those that concern agent decision-making and behavior:

- Household decisions ( $ns, \lambda \rightarrow S^*$ ): Who are household decision-makers? To what extent are ‘households’ independent decision-makers? Can they make decisions in the way we envision them? Which household characteristics are adaptable? If household characteristics change, what is the time scale? If households learn new strategies, what strategies are learned and how?
- Nutritional sufficiency ( $ns, h^{iv}$ ): How do household decision-makers evaluate the nutritional intake of their children? What general knowledge/awareness can we assume? What factors explain why some households cope/adapt successfully, while others do not?
- Household and exogenous variables ( $h^{iv}, X$ ): Is the relative importance of household and systemic constraints in our model appropriately balanced? What amount of agency can we attribute to households?
- Resilience ( $r$ ): What types of resilience (coping vs. adaptation) can we expect in a context like Karamoja?

These and other questions pertain to core components of our model. They needed to be addressed with experts and government

officials working on the ground, and more importantly with Karamojong households whose nutritional situation we seek to understand.

The relationship between model development and field research can and should be treated as an iterative process. Multiple stages of model development can be interspersed with multiple rounds of field research. As such, the EDM approach is agnostic to the timing of fieldwork. A possible starting point is the development of a theoretically grounded model framework. A first round of field research can then be used to refine the model, identify relevant causal linkages and supply additional empirical input for the model. For MERIAM, we received some of our most valuable input through modeling exercises where we probed experts and households to make their ‘mental models’ explicit, through surveys and focus group discussions. Depending on one’s epistemological orientation and practical considerations, it is plausible to conceptualize a modeling framework inductively from preliminary field research.

Whereas ‘getting the story right’ in Karanoja was important, it is evident that an EDM initially developed and tested in one region need not be applicable to other contexts. Households may respond differently to the same exogenous shocks and stressors in ways that cannot be accounted for comprehensively in a single model specification. That said, re-building the entire model for each context analyzed is also unnecessary. Rather, a given model can be modified to incorporate contextual differences in a systematic manner, by identifying model *prototypes* that exhibit meaningful variation across key dimensions, and *validating and refining* the model for each prototype.

A necessary first step involves the identification of similar patterns across contexts, with respect to either (causal) drivers, mechanisms, behaviors or outcomes, as a means of building a set of computational model prototypes. For example, prototypes for malnutrition dynamics could be constructed to

account for similar patterns of incidence and prevalence in wasting across contexts. The selection of prototypical cases that exhibit consequential variation, both geographically and temporally, is essential to ensure that an EDM generalizes beyond the confines of a particular case. More specifically, a different case enables us to refine the model with a view toward maximizing external validity, while a similar case allows us to verify and strengthen the internal validity of the model in another context. For the MERIAM project, analyzing sub-national cases over finer-grained temporal units was preferable to selecting country-years as units of observation.

As a second step, case-specific grounding, data construction, and fieldwork are repeated for every model prototype to which the EDM will apply, building on prior work where possible, given that much of the data on exogenous factors is constructed uniformly across contexts (e.g., remote-sensing and conflict data). For our second prototypical case, West Pokot in Kenya, we assessed historical and cultural differences relative to Karamoja, as well as changes in salient causal mechanisms. Finally, we adapted the field survey used in the Karamoja case for the particularities of this context, making only the minimal changes required.

So while the classic trade-off between external and internal validity applies in no small measure, EDM can be systematically extended to produce valid results across contexts, while retaining internal validity for specific cases.

### ***Counterfactual Analysis***

Counterfactual analysis can be divided into two types of ‘what-if’ scenarios for EDM: those that relate to model parameters – determinants of model dynamics that have no direct empirical referent and were inferred from the model – and those that relate to model inputs specified by empirical data.

Counterfactual analysis for model parameters is equivalent to considering comparative

statistics. Here, one sets all model parameters to their optimal values, except for a particular parameter whose influence we seek to assess. For example, the effect of a household’s propensity to adapt could be analyzed, all the more tellingly if the effect is non-linear, i.e., if small changes in household behavior produce significant changes in nutrition outcomes.

Counterfactuals may also be conducted for model inputs. Instead of seeding all inputs with empirical data, one can use exogenously determined values for one or more inputs, treating them as equivalent to parameters. Examples include testing the impact of climatic and economic shocks, as well as the source, timing, location, type and scope of interventions (e.g., food imports, humanitarian assistance from international sources and education designed to shape household behavior) on household behavior and malnutrition. Stakeholders can then use these insights to understand the likely effects of different interventions under a variety of conditions across different contexts. While this type of counterfactual analysis is best constrained to the period for which the model was optimized – in other words, within sample – out-of-sample counterfactual analysis, including forecasting, is feasible when one clearly specifies how parameters and empirical inputs might change in the future.

It follows that EDM are well suited to providing data-driven, scenario-based analyses, with the caveat that underlying assumptions are transparently communicated. The EDM developed as part of MERIAM forms the basis for a tool to make scenario-based forecasts of malnutrition and explore the efficacy of various interventions in response to climate- or conflict-related shocks. A concern, then, is to develop an effective means to communicate the methodology beyond a purely academic or expert audience.

### ***Model Uptake***

The EDM approach requires a combination of technical knowledge and relevant domain

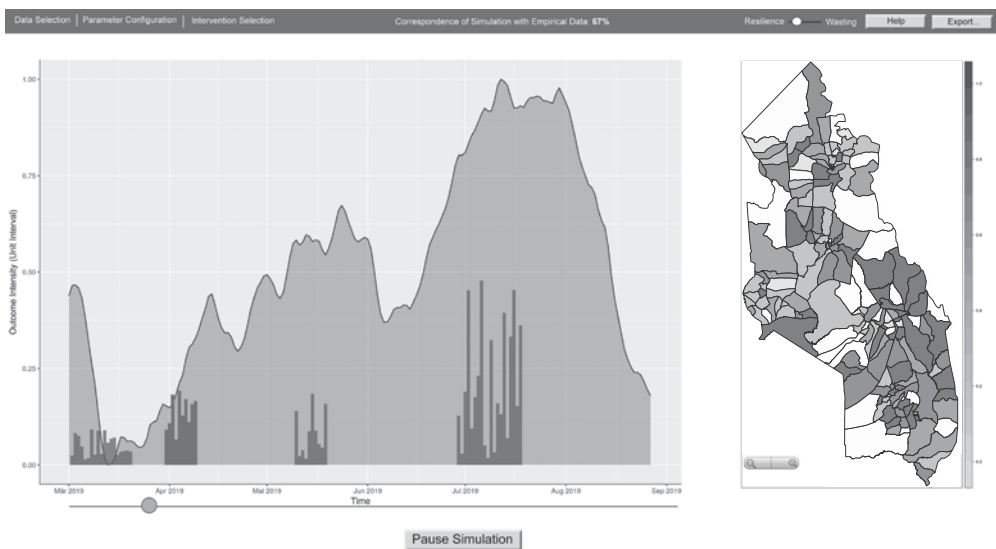

expertise. As such, the specification, contextualization, validation and refinement of an EDM is typically undertaken by academic researchers or trained experts. On the other hand, if done correctly, the kinds of scenario-based analysis for which EDM is suited may be of immediate interest to practitioners, subject experts or policy makers largely unfamiliar with the methodology. The question then concerns how the EDM methodology can be pitched to stakeholders beyond a mere visualization of results, to provide a ‘feel’ for the model, its specificity and generalizability, and its use as a tool for making evidence-driven policy decisions.

With an expert and practitioner audience in mind, we plan to complement an academic research paper with a policy brief written for a general, non-specialist audience. Rather than using technical jargon, a brief would explain the steps involved in model construction, much in the way that this chapter does, highlighting key policy-relevant insights. The brief would clearly communicate the limits and uncertainties associated with the EDM scenario-based

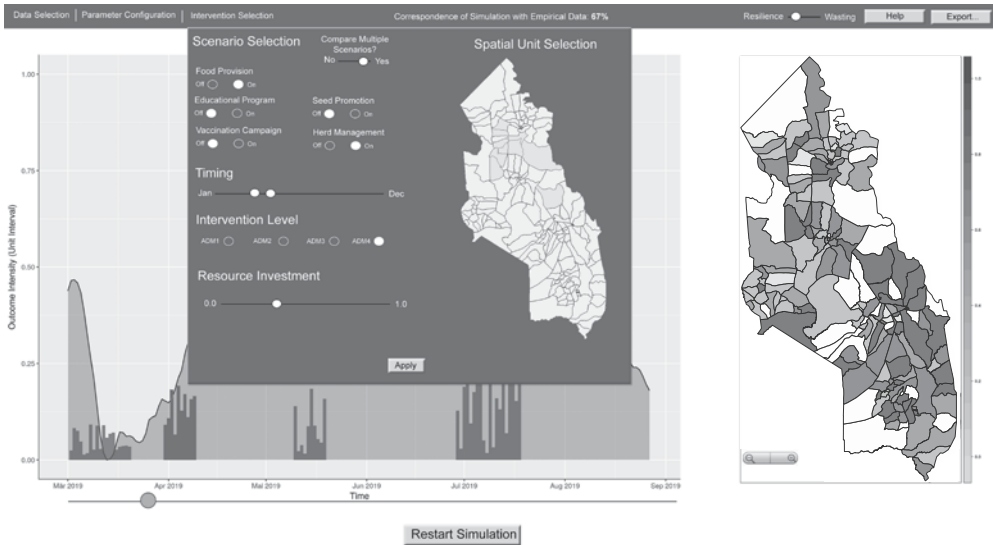

forecasts, considering the effect of specific interventions on malnutrition outcomes discussed above.

While a brief will certainly help communicate policy-relevant insights, it falls short of providing a true ‘feel’ for the EDM. The only way to achieve this is by developing a tool with an interactive graphical user interface (GUI). Such a tool would preserve the full complexity of the EDM while allowing non-expert users to easily engage with the model and translate output. The tool may also require an expert to revise a particular model specification for a new case, after which the GUI will perform its intended function.

Figures 4.5 and 4.6 depict a mock-up of the Simulating Acute Malnutrition Toolkit (SAMT). At the center of the GUI is a trend-based forecast and a map of the region being analyzed. Users can switch between outcomes (e.g., resilience or wasting prevalence) and select the time point for which outcomes on the map would be displayed. The heat map shows normalized levels of the selected outcome (here, resilience) at a fine-grained level of analysis for the selected time point, with the slider below the time

**Figure 4.5** Mock-up of SAMT (main window)

**Figure 4.6 Mock-up of SAMT (intervention configuration)**

series graph. Bars in the time series indicate the intensity of shocks and aid interventions, respectively. The degree to which the simulated results correspond to empirical data is specified at the top of the interface.

GUIs and software tools for decision support are generally starting to gain traction. These include a large array of domain-unspecific tools for data handling and visualization, as well as more specific policy support tools in diverse domains such as epidemiology (den Broeck et al., 2011) and public safety (Chooramum et al., 2016). Making EDM accessible to others requires this kind of explicit engagement with stakeholders, allowing them to develop a better intuition for the approach.

## CONCLUSION

Evidence-driven computational modeling effectively harnesses the strengths of ABM, while achieving a high degree of real-world correspondence and resonance. As our

discussion of the MERIAM project demonstrates, the EDM approach incorporates contextual knowledge and theoretical insight, captures complex spatio-temporal inter-dependencies, explicitly accounts for endogenous relationships, uses realistic topographies and harnesses data at varying levels of measurement. The combination places EDM at the intersection of theory and empirical work. For the MERIAM project, we harness the power of EDM to make scenario-based forecasts and undertake counterfactual analyses, developing a tool for policy makers tasked with addressing the high-stakes problem of malnutrition. The development of the MERIAM EDM has been elaborate, costly and time consuming, given that many of the standard elements of research design in political science – theory building, case selection, data collection and fieldwork – comprise the approach. We believe the contribution to evidence-driven decision-making is well worth the effort, and trust that the procedures and best practices outlined in this chapter will result in the development and use of EDM across diverse domains.

## Notes

- 1 The authors thank Alessandra Romani from the Graduate Institute, Geneva for helpful comments on draft versions of this chapter. This document is an output from a project funded by UK Aid from the UK Department for International Development (DFID). The views expressed do not necessarily reflect the UK government's official policies.
- 2 Take, for example, contact theory. Researchers have found empirical evidence to support the notion that increased inter-group contact leads both to higher and lower levels of violence. EDM have been used to explore the conditions that give rise to these divergent outcomes. For a detailed discussion, see Bhavnani et al. (2014).

# Taking Data Seriously in the Design of Data Science Projects

Mitchell Goist and Burt L. Monroe

## INTRODUCTION

In its broadest sense, every empirical project is a ‘data science’ project, so every chapter in this *Handbook* contains relevant advice for data science projects. Conversely, some might define ‘data science’ more narrowly, associating with particular approaches to inference from data (e.g., *machine learning*, *deep learning*, *Bayesian inference*), or with particular modes of data collection (e.g., *web scraping*) or with the set of methodologies and technologies that have emerged for drawing inferences from relatively new sorts of ‘nonrectangular’ data, ranging from data with complex structure (e.g., spatial or network data) to data with no obvious structure as social science data at all (e.g., text or image data). Most of these topics have one or more chapters devoted to them here as well. That is to say, we’re all data scientists now.

That larger context acknowledged, our focus here is on the data in ‘data science’,

especially in computation-intensive or data-intensive projects where data is<sup>1</sup> unusually complex or ‘big’ in some way and requires more than conventional attention to how it is handled and processed. We try to address common issues and challenges that arise as data moves through the workflow of data science projects in the social sciences, and direct the reader to possible solutions and useful concepts and tools.

## ***Workflow of a Data Science Project***

There are several frameworks for characterizing the ‘workflow’ or ‘pipeline’ of a data science project. The most ubiquitous are Mason and Wiggins’ (2010) semi-romantic characterization of data science as OSEMN (‘awesome’, if you squint) – Obtain → Scrub → Explore → Model → iNterpret – and the industrial data warehousing characterization of pipelines composed of individual, ETL

modules – Extract → Transform → Load (Kimball and Caserta, 2004). There are many others of varying levels of complexity, with various pieces of pipe named, conceptualized or ordered differently. These share some common elements and a general idea of a process that ingests some raw data, transforms the data in various ways and then provides some meaningful output at the end.

In the present context, we'll delineate four stages in a social scientific data science pipeline:

- Data Collection: Human Behavior → Raw Data
- Data Wrangling: Raw Data → Clean/Structured Data
- Data Preparation: Clean/Structured Data → Analysis-Ready Data
- Data Analysis: Analysis-Ready Data → Inference/ Interpretation

We note that these are the stages in a *replication* pipeline. Typically, each (and always some) of those stages can be instantiated in code, such that if given the same inputs any researcher using the code would get the same (or sufficiently similar) outputs.

We also note that each stage may have a more complex structure underneath. Any one step may be a series of consecutive transformations.<sup>2</sup> There may be multiple inputs that have to be merged in some way. There may be multiple types of analyses that require multiple outputs. There are almost always processes that benefit from a 'split-apply-combine' or 'map-reduce' conceptualization, under which data is split, each split has an identical sequence of transformations applied to it and the results are recombined (Wickham, 2011). We return to this concept below.

And, of course, such a pipeline does not describe the actual *workflow* of a social scientist conducting research and constructing the pipeline in the first place. When conducting the original analysis, creating the pipeline, each stage is embedded in a social science workflow that might be something like:

- **Anticipate:** What outputs are needed as inputs to the next stage? What could go wrong?

- **Theorize:** What do I expect?
- **Design:** How do I design this stage to provide valid outputs (at acceptable cost in acceptable time)?
- **Collect, Wrangle, Prepare, or Analyze...**
- **Store:** How do I save the output for use in the next stage or the future?
- **Validate:** Is the output what I think it is? Is it right?
- **Document:** What exactly did I do? What would I, or anyone, need to know, or have, to do it again?

In particular, theory and research design are the focus of other chapters in this *Handbook*, so we touch on these only lightly here. Finally, we note that given the extensive coverage of many approaches to the Analysis stage elsewhere in this *Handbook*, as well as many aspects of, and approaches to, the Collection stage (including experimental design, survey design and web scraping), we focus primarily on a somewhat idiosyncratic collection of remaining pieces of a data pipeline that the social scientific data scientist may need or wish to consider.

### A Basic Data Science Toolkit

The core of your data science toolkit<sup>3</sup> will likely be a *high-level programming language*, and there are two such languages that currently dominate data science: Python and R.<sup>4</sup> Python is generally perceived as better at the data manipulation processes that occur in the Collection and Wrangling stages of the pipeline, better matched with a machine learning approach – especially a deep learning/neural net approach – to the Preparation and Analysis stages, and better at scale. R is generally perceived as better at the Analysis stage, especially with a statistical inference approach, and better when visualization plays an important role in validation, analysis or documentation. That said, each has dramatically improved on perceived deficiencies in recent years, and there is not as much that one can do that the other cannot. Python is the more used in industry data

science; R is the more used in academic data science, at least in the social sciences. It's not unusual for a pipeline to involve both (ours typically do), and we discuss below some ways of communicating between them.<sup>5</sup>

It is also good practice to develop your code in an *IDE (Integrated Development Environment)*, such as Spyder for Python (and R) or RStudio for R. These integrate well with notebook systems such as R Notebooks and Jupyter, an important tool for 'literate programming', which we discuss further below under the topic of open science and reproducibility. Spyder and Jupyter are included in the open-source Python (and R) distribution, Anaconda, which comes with most data science oriented packages (including the 'PyData stack' of at least numpy, scipy, pandas and matplotlib) installed alongside a user-friendly Python package and environment manager, conda.

Most scientific computing environments, and essentially all university research computing clusters, require you to interact with a *Linux/Unix shell*, most commonly bash. It is easy enough to learn the bare minimum necessary to move around directories, manage files, start software and submit scripts for later processing, but we encourage some investment in learning a bit about data manipulation from a unix shell. You will be amazed at how handy it is for a data scientist to know unix commands like `head`, `tail`, `cut`, `split`, `count`, `sort`, `uniq`, `tr`, `ag/grep`, `sed`, `awk` and `curl/wget`.<sup>6</sup> These can be used for very efficient retrieval, cleaning, manipulation and management tasks in a surprising variety of settings. It is also likely that the easiest way to integrate diverse pieces of a pipeline containing modules in Python, R and other languages is with a shell script that evokes these modules in sequence.

You should also incorporate *version control* into your workflow, most likely using *git* and a git repository like github. The most immediate benefit is saving your work. Not only can you insure against inevitable computer crashes, but the ability to revert back

to older versions or to create tentative project 'forks' helps insure against your own mistakes. Git really shines when you need to work with a partner or team, as it smoothly handles conflicting changes made along different project branches. Moreover, github and similar offer convenient ways to code in the open, aiding reuse and replicability.<sup>7</sup>

The core data science programming tool that in practice seems least likely to be learned in passing by social scientists is *SQL (Structured Query Language)*. SQL is the language for interacting with conventional relational databases, by far the most likely database system you will encounter or yourself set up. SQL's core functionality is querying, extracting, filtering, aggregating, reshaping and merging data stored as tables in a relational database into output tabular data. Furthermore slight SQL variants are used by other database systems (e.g., Spark SQL or Apache Drill) and SQL concepts inform more familiar data wrangling and management formalisms in R (e.g., `dplyr`, `data.table` or `cdata`) and Python (e.g., `pandas`). We return to these concepts below.

## DATA

Our pipeline above imagines three major intermediate states that data can be in: *raw* (or *dirty* or *unstructured*), *clean* (or *structured*) and *analysis-ready*. Of course, whether data is raw or clean, structured or unstructured, analysis-ready or not is largely determined by context. Different analyses may call for different arrangements of the same data. For example, an effort to create political event data ('Group A protested against Government B on date C in place D') from news articles might require text input in full sentences with original capitalization (to help identify 'named entities') and punctuation (to help identify the subject and object of complete sentences). An effort to model the topics of those same articles might require

per article counts of words that have been stripped of order and punctuation and ‘normalized’ (e.g., ‘case-folded’ to lower case, or ‘stemmed’ or ‘lemmatized’ to root form).

Moreover, the clean data of one process may be the raw data of another. The Nexis database of news articles would be considered by information scientists to be highly clean and structured, able to respond to many simultaneous complex queries defined by search terms, outlet, date and so on, as well as incorporating and indexing new data each day. But from the point of view of an event data or topic modeling project, the output of such a query is something between raw data (What’s the text of the article vs. metadata like title, source, date? Are there duplicates or multiple versions?) and not-data (Am I actually allowed to download all the article content?).

### **Data in Memory**

Within any of the computational processing steps of the pipeline, the data being collected, wrangled, prepared or analyzed are held, at least temporarily, in a computer’s volatile working or cache memory. Sometimes all of the relevant data is in the memory of one computer simultaneously. Sometimes it is in pieces that pass through memory sequentially. (Even transferring a file from disk to disk involves pieces of the data passing temporarily through memory.) Sometimes it is in pieces that are distributed across the memory of multiple processors or computers. There are at least three levels at which a data science project might deal with data in memory: as bytes and primitive data types, as abstract data types and data structures or as specialized data objects including ‘tables’ and other analysis-ready data.

At a low level, data is what your cellphone provider means by data: sequences of eight-digit binary numbers, called *bytes*, that take up ‘space’ in memory, in storage or in bandwidth. That is, any digital information is,

by this definition, data. The ‘digital revolution’ has been enabled by the greater number of human activities that are born digital (e.g., social media posts, web searches), the improved technology for sensors and other technologies to convert nondigital activity to digital traces (e.g., optical character recognition, GPS devices) and our greater capacity to gather, store, share and mashup digital information.

The ways in which bytes can be directly interpreted correspond to the *primitive data types* of a programming language, defining what sorts of data a variable of a given type can hold and what operations can be applied to it. Loosely speaking, there are three primitive data types that essentially all systems have: integer, floating point (‘numeric’ in R) and Boolean (TRUE/FALSE, binary, ‘logical’ in R). Knowing how these work in your current computing setting can help you avoid some common problems. So, for example, in R, `sqrt(2)^2 == 2` returns FALSE, because floating point data (‘numeric’ in R) can represent real numbers like  $\sqrt{2}$  only to a certain level of precision. A vector of integer ones (like `x <- rep(1L, 100)`) takes about half as many bytes to hold in memory as a vector of floating point one-point-zeroes (like `x <- rep(1, 100)`), but exactly the same as a vector of Boolean ones (like `x <- rep(TRUE, 100)`), because Boolean data is just integer data interpreted differently (0 means FALSE, everything else means TRUE).

More important, these bear only loose correspondence to the way social scientists have traditionally thought of data as measures. The most basic social scientific understanding of data is commonly characterized by the Stevens (1946) *levels of measurement* hierarchical typology. Stevens asserted that scientific measures are on one of four types of ‘scales’ – *nominal* (often called *categorical* or *qualitative*; two observations can be equal or not equal), *ordinal* (two observations can be compared and one deemed greater than the other), *interval* (two observations can be compared – subtracted – for meaningful

difference) and *ratio* (two observations can be compared – divided – for difference in magnitude relative to a meaningful zero).<sup>8</sup> The integer data type can be mapped to the ordinal, but floating point does not distinguish between interval and ratio measures, and Boolean can represent nominal data directly in a single variable only when there are exactly two categories.

To represent multi-category data (in one variable), we need a new *composite data type*. We need to enumerate the categories, store the integers representing each observation's category *and* store the mapping from integers to category labels. In R this is the 'factor' data type. Python itself does not have a categorical data type, but the library pandas does ('category').

The notion of labels brings us to textual (in most languages *character* and/or *string*) data, which is also generally represented in a composite data type. Strings are particularly common in data science, but can be tricky. They are intended to be read by humans, but they must be structured and stored as sequences of bytes, using one of many possible *encodings*, systems that map specific characters to specific byte sequences. A common error results from software – you may have noticed this in a browser or Excel, if not in your scripts – encountering UTF-8 encoded (a Unicode encoding) characters and interpreting (*decoding*) them as if they were, say, 'Latin-1', 'ISO-8859-1' or 'Windows-1252' encoded. These character sets overlap for the 256 characters encoded with a single byte, so an English or Western European language text will look mostly right. But characters that require two bytes to encode in UTF-8 will be interpreted as two characters. So a Spanish word may mysteriously contain 'Ã±' instead of 'ñ' and a text enclosed in 'curly quotes' may instead conclude with 'â€' (the telltale signs are the random accented 'A' and 'a' characters). Those working with data from social media or cell-phones might be mystified by the four-byte '\U0001F44D' or b"\xf0\x9f\x91\

\x8d' if their font or environment doesn't include ☹.<sup>9</sup>

Composite data types lie on a fuzzy continuum between primitive data types and *abstract data types* or *data structures*. These are often base objects that can be used and manipulated in a given programming language, and include things like lists, tuples, sets, queues, stacks, linked lists, trees, graphs, heaps or hash tables. Conceptually, data structures are often paired with 'algorithms' (in book and course titles; e.g., Klein, 2016), and many industry coding interviews contain a 'data structures and algorithms' section), since efficiency of algorithmic tasks such as sorting or searching depends on the data structure.

To a social scientist, structured data often refers to data that is ready for analysis. For the vast majority of techniques this means *rectangular* data which can, hypothetically at least, be displayed in a spreadsheet-like format with rows corresponding to observations and columns corresponding to variables or features. These are typically referred to as *tables* or *data frames*.<sup>10</sup>

A table can have features of different types, but it is often the case that 'big data' is big because there are many features with identical primitive data types, levels of measurement and scale. That is, the cells of the table are all integer counts (e.g., of a given word), all Boolean (e.g., presence/absence of a relationship link), all on the same scale (e.g., ratings from one to five stars), or similar. In this case, these can be thought of – and generally benefit computationally – from being held and manipulated in *matrix* or (two-dimensional) *array* data structures (e.g., in Python a numpy array rather than a pandas DataFrame).

Further, it is almost always the case that such data are mostly zeroes (or missing), in which case there are often substantial computational benefits to storage in a *sparse matrix* format that stores only information about each nonzero.<sup>11</sup> There are some common pitfalls when handling data in sparse matrices, however. One of these is accidentally forcing

the conversion of the sparse matrix into a dense one by, for example, adding a floating point 1.0 to every element and then taking the log of every value. Now you still have a lot of zeroes, but you're storing them all. The other common pitfall has to do with whether the sparse matrix is *row-oriented* or *column-oriented*. Consider the example of a typical observation–feature matrix (like documents represented by rows, and words represented by columns). The row-oriented format will store values for each document together; the column-oriented format will store values for each word together. As a result, calculations on each document (like length) will be very fast in the row-oriented format and very slow in the column-oriented format, and vice versa for calculations on each word (like average frequency).

Ultimately, many types of analysis require data arranged in accordance with a social structure of interest, such as space, time, network or hierarchy. Some of these are specialized sorts of matrices (e.g., adjacency matrices representing networks, or images represented by grids of pixel intensities), but some are genuinely different (e.g., GIS vector structures that describe the shape and location of geometric objects in geographic space). This funneling into specialized data formats and tools is another source of friction in data science projects. Social media data or political event data or GPS tracking data all contain spatial, temporal and network structures. But we have only limited ways to represent and analyze the network information in a conventional geographic information analysis tool like ArcView, and limited ways to represent or analyze the spatial structures in a specialized network analysis tool like Gephi. In part because of this tool-dependence, we tend to technically specialize around these data structures, limiting our ability to conceive of the data along other lines. (Peuquet (2002) has an elegant discussion of this phenomenon in the context of incorporating time into the static spatial representations at the core of GIS systems.)

This is one motivation for a ‘team science’ approach, a concept we return to in our concluding remarks.

### **Data in Files and Streams**

Data science gets its reputation for being dominated by data cleaning largely because of data in files. Our ability to gather, store (or *persist*) and copy data far outstrips our ability to make sense of it. Your research project's needs do not typically inform how that data is stored or delivered to you; moreover, we need to persist and transfer our own data in a way that allows for replicability and future unknown use. We can't begin to address the full variety of possibilities here – for example, Wikipedia provides an idiosyncratic list of more than 2,000 distinct file formats<sup>12</sup> – so we concentrate here on a few of the more commonly encountered formats and a few general concepts.

Perhaps the most foundational concept for the design of data pipelines is *serialization*, the process of converting data objects in memory into a sequence of bytes (i.e., ‘serially’) that can be transmitted or stored and reconstructed (*deserialized*) later, potentially in a different computing environment. If you're going to construct data pipelines where the output of one stage is written to disk before being ingested by a subsequent stage in a (potentially) different computing environment, or even if you wish simply to save intermediate or final data for future unknown purpose, serialization formats offer the greatest portability and consistency. If you are ingesting data from an open data service and/or data API,<sup>13</sup> well-constructed ones will provide the data in one or more serialization formats. Serialization formats vary in their efficiency, their portability, their transparency and their universality.

Among the most familiar, because they are common formats in which data is delivered, are *JSON* (JavaScript Object Notation) and *XML* (eXtensible Markup Language). *JSON*

and XML are *human-readable text-based* serialization formats, both of them arranged around a hierarchical tree-like structure and human-readable ‘keys’. This is inefficient from a storage point of view, but makes these formats portable, searchable, editable and more or less *future-proof*.

XML is the older and less fashionable of the two, but is still fairly common in ‘open data’ settings. It can be constrained by a *schema* and easily queried, which has led to many specialized variants of XML for specific purposes. Examples include DOCX and XLSX (Microsoft Office files), ODF (Open Document Format, for Open Office files), XHTML (a formalized variant of the web page format HTML), KML (Keyhole Markup Language, a format for specifying geographic data for display in Google Earth and similar) and RDF/XML (a serialization of RDF, Resource Description Framework, the format for internet resources, including metadata and semantic web/‘internet of things’ objects). XML can get complex enough that its human readability can become questionable.

JSON is the newer of the two, and increasingly the one used as a data serialization format, particularly with data APIs. The Twitter APIs, for example, return search results in JSON. There are differences in what you can do with JSON and XML, but JSON is generally more readable, more compact and less memory intensive to parse. Although originally designed for JavaScript, it is now so ubiquitous that most programming languages, including R and Python, have dedicated JSON parsers that can be used to navigate JSON files. JSON also has some standardized variants, such as JSON-LD (‘linked data’), an emerging format for enabling interoperability of open data, and JSON Lines, a compelling record-per-line format (allowing, for example, parallel processing) that has been adopted by some APIs (e.g., plotly) and is the serialization format recommended by Python web scraping module Scrapy.<sup>14</sup>

At the cost of human readability and some future-proofness, binary serialization formats offer more compact storage, more efficient read/write operations and the ability to store more general classes of data objects. Python users will be familiar with the *pickle* and *cPickle* modules which provide serialization for Python objects. R users seem much less likely to be familiar with the *RDS* (‘R Data Serialization’) format for serialization of R objects. These are ideal for efficient passing and persisting of data between stages of a data pipeline, as long as human readability isn’t necessary for debugging or some similar purpose. (R users seem more likely to save collections of objects, or entire workspace images, in ‘Rdata’ files. This is useful for maintaining continuity across different R sessions, but considerably less useful for passing data objects across segments of a data pipeline, particularly from R to Python or another language.)

JSON has a binary variant called *BSON* (‘binary JSON’), used by the popular document-oriented data store MongoDB as a storage format, and can also be used in the relational database PostgreSQL. BSON offers more compact storage than JSON as well as the ability to store some additional data types. There are also multiple serialization formats designed to work with distributed big data environments such as Hadoop and Spark, with Apache Avro (developed as part of Hadoop), Apache Parquet (developed at Twitter and Cloudera) and Protocol Buffers (developed at Google) among the most popular.

Of course, much more common than any of these in standard social science practice are *flat files*, text files representing tabular, spreadsheet-like data. Each line of the file represents a row of the table (or maybe a header with variable names), with values for each column separated by a designated *delimiter* character. This is most often a comma, and such files are of course called *CSV* (Comma-Separated Values, or occasionally Character-Separated Values) files. CSV is both more familiar and more compact than

JSON or XML, taking about half the space. (A flat file can be stored in almost identical space as CSV in JSON Lines, however.) CSV is more or less human-readable, has standard read and write commands in Python, R and most languages, and can typically be opened directly in spreadsheet software like Excel or econometrics software like Stata. CSV is, however, as much bug as it is feature. The encoding assumed may be wrong, data types might be misinterpreted, strings might be truncated at a maximum length or any number of other errors might be introduced, changing your data when you only meant to look at it.

CSV is considered a serialization format, but an inconsistently defined one with many ‘dialects’ defining different encodings, string delimiters, escape characters and so on. Among other potential problems, raw string data, especially running text and numerical data represented as strings, contains ubiquitous commas or quotation marks that can cause havoc when the file is read in under different assumptions. The use of a tab separator rather than a comma – often given the extension TSV – or another character (ideally one that cannot occur in your data) can help make these problems less likely, but there is still no way within a delimited file itself to specify what data types the strings in the file are meant to represent. A format like JSON or JSON Lines avoids these problems altogether.

Arguably, the most frustrating file format the data scientist will regularly encounter is *PDF* (‘Portable Document Format’), known infamously as the format ‘where data goes to die’.<sup>15</sup> You will encounter PDFs *you* can read or print, but which are just scanned images of the original text. These require manual keying or OCR (‘optical character recognition’). You will encounter PDFs with OCRed text riddled with errors (99% accuracy at the character level can still leave a mistake every other line). Even if the text is searchable and there are no character level mistakes, PDF is a *display format* that arranges the characters

on the page to display correctly, but not generally in a semantically logical order. This can be particularly maddening when the page includes multiple columns, tables or characters from right-to-left languages such as Arabic or Hebrew. The best case scenario is often that a tool like xpdf, poppler, tabulizer, pdftools (R) or PyPDF2 (Python) can properly identify blocks of consecutive text, which still require some bespoke wrangling.

There are many further complications that can come with details associated with the generation and interpretation of a file. We have already mentioned encodings of text files, but there are even more complicated *codecs* (‘coding/decoding’) issues that arise with the handling of media data such as image, audio and video. You need to get these details right to make sense of such data, and to be sure others can make sense of yours. Moreover, such files tend to be large in their natural state, so they often undergo *lossy compression* when stored, and especially when streamed over a network. Many of the most familiar formats (e.g., JPEG for images, MPEG for video, MP3 for audio) contain only an approximation of the original data. This may be fine for watching a video on your phone, but problematic for training a model to learn from that video.

### **Data Stores and Databases**

To information science and database specialists, data is structured if it is in ‘normal form’ (or *normalized*) for a *relational database*.<sup>16</sup> Roughly, this means that every type of object has its own object × attribute table, and there are no duplications in data or dependencies in relations among those tables. So, for example, a relational database of individual campaign contributions to political candidates would have separate tables for (at least) contributions, donors and candidates. The donor table would have one row per donor, with, say, (donor id, donor name, address, zip code, registration) as columns. The candidate

table would have one row per candidate, with, say, (candidate id, candidate name, party) as columns. Finally, the contribution table would have one row per donation, with, say, (contribution id, donor id, candidate id, amount, office, date). The schema of the database would define data types of fields and the relevant relationships between the tables, namely that each contribution is associated with one donor and one candidate. To calculate, for example, the total contributions by zip code, one would first need to join/merge the relevant information from the donor table with the contributions table, creating an unnormalized table of the relevant columns of the contribution table with the matching zip code added as a new column, and then aggregating contributions by zip code. SQL is the standard language for executing queries of this sort.

The advantage of this is largely in limiting errors when data is entered or changed. If a donor changes address, we need only change a single record. The primary disadvantage is that our analysis step almost always needs the data unnormalized and these join operations become time consuming and unwieldy as our data grows. So, while it is certain that you will need to understand SQL concepts, if not directly use SQL, to query someone else's database, it's often not terribly useful for a social scientific data scientist to incur the overhead of setting up and maintaining a relational database and server.

Alternatively, we encourage you to look into nonrelational and *postrelational* database or data store options for management of unnormalized data at scale. First we note that our data now can easily get too big to store on a single node, which has led to the development of *distributed data stores* that spread and replicate data across different nodes of a cluster. The most well-known perhaps is HDFS, the Hadoop File System. Many postrelational databases can be deployed on Hadoop and similar data stores. There are also search and query engines that can be used to access data on such stores. Popular

pairings include Elasticsearch and HDFS, and BigQuery designed to work with Google Storage.

Second, the fairly dizzying array of options for postrelational data management is otherwise best distinguished by the data model it contains. One of the most popular, and one that has penetrated social science, is the already mentioned MongoDB, a *document-oriented* database that uses JSON as a model. Another important alternative model is 'wide column store', which stores data based on fields/features (columns) rather than by records/observations (rows). Much of Google infrastructure is run on proprietary column store BigTable, and there are several open-source spinoffs, with Cassandra currently the most popular.

If you need to store large 'unstructured' binary objects – image, audio and video are common examples – there is often little to be gained over simply storing them as files. A separate database can hold file pointers and any metadata, which is usually all you could execute a query on.<sup>17</sup> One option to consider, however, is an *object store*. This is similar to a familiar file system, except objects can have arbitrary and searchable metadata attached to them in the store. These are most commonly used in cloud storage systems like Amazon's S3 service and Microsoft Azure's Blob Storage. Another possible aid in the storage and exchange of complex collections of arbitrary binary data is *HDF5* (Hierarchical Data Format). HDF5 is actually a file format that can effectively contain an elaborate self-describing data store within a single file. It is not for serialization as such, but HDF5 files can be straightforwardly read into and written out from Python.

## DATA COLLECTION AND JINGLE-JANGLE FALLACIES

One of the main promises of data science is the almost endless array of data that is now collected and available: digital records of all

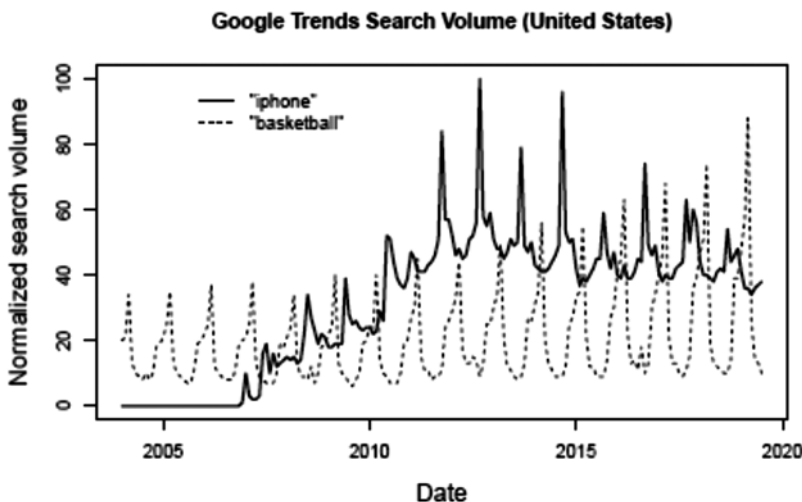

shapes and sizes, from governments and companies, from individuals through social media and distributed sensors, through innovative experimental designs, through innovative uses of human-in-the-loop computing and citizen science platforms, and in forms – natural language, images, audio, video, etc. – that have only recently begun to be exploited in the social sciences. There is almost endless room for creativity (see Salganik, 2017 for discussion of dozens of examples).

By far the most exploited class of new data is *data exhaust*, the digital traces of contemporary life from social media, cellphones, shopping, online searches and so on, which appear ripe for interpretation as *unobtrusive measures* (Webb et al., 1966) of human and social behavior. The key characteristics of data exhaust are that it is more or less always being passively generated, it is often proprietary and generated by proprietary processes and it is typically too big to use or quality check in its entirety.

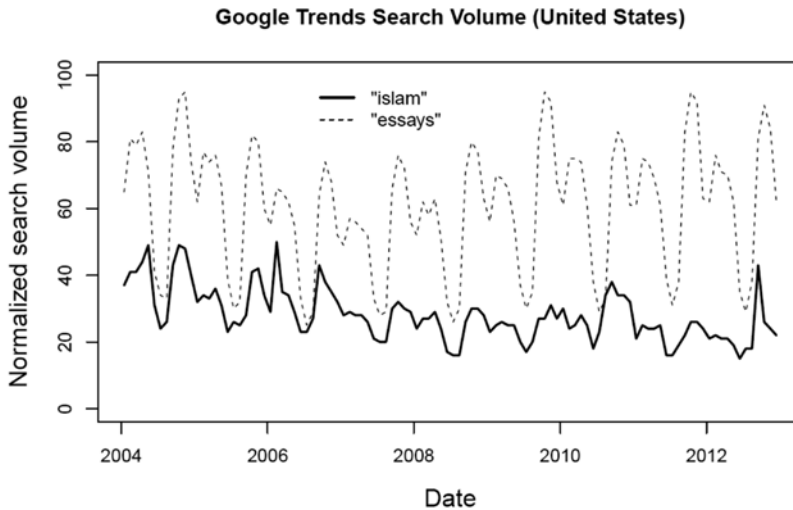

In this section, we discuss some subtle issues when such data are taken at face value as more or less direct measures of

underlying behaviors. Measurement theorists have warned us for many decades to beware the *jingle fallacy* – that two things with the same name are the same thing (Thorndike, 1904) – and the *jangle fallacy* – that two things with different names are not the same thing (Kelley, 1927). We seem particularly inclined to these fallacies in the context of data exhaust.

Consider, for example, the use of Google search data as an indicator of general public interest in a subject, and in turn, particular drivers of that interest. It seems almost tautological that searches for ‘word’ should indicate interest in the subject of ‘word’, and generally speaking this seems to have face validity. For example, Figure 5.1 shows plausible dynamics in searches for ‘iphone’ and ‘basketball’. This type of approach has been used most famously, and infamously, in the ‘Google Flu’ project (Lazer et al., 2014), in which searches for terms like ‘flu symptoms’ were (initially) shown to predict traditional, but slower, influenza outbreak data reported by doctors through US Centers for Disease Control. Political scientists have used search

**Figure 5.1** Searches for ‘basketball’ have the expected seasonality and a plausible pattern of growth. Searches for ‘iphone’ do not appear until the iPhone is invented, display expected spikes around model release dates and suggest a plausible decline in interest from a peak reached with the iPhone 5 and 6

**Figure 5.2** The prominent dynamic in searches for ‘islam’ is the same as that in searches for ‘essays’. US internet search for some topics is dominated by the academic calendar and the demands placed on high school and college students in common courses

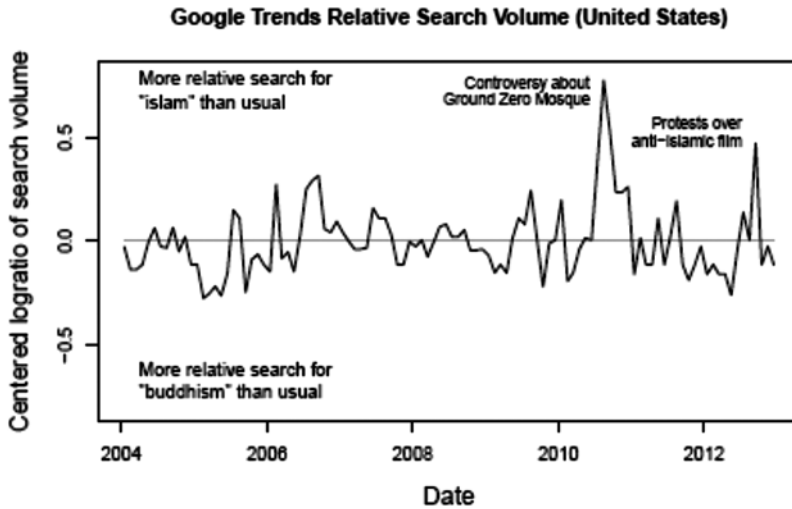

data as well, e.g., in searches using racially charged language as an indicator of spatial variation in racial animus during the Barack Obama presidential campaign (Stephens-Davidowitz, 2014).

Consider, however, Figure 5.2, which shows search volume for ‘islam’, occasionally used as an indicator of salience of Islam-related issues among the general public (e.g., Smith, 2013). The annual seasonality is mysterious<sup>18</sup> until you see a similar pattern in a term like ‘essays’. It appears that internet search volume in the United States for topics that might be covered in common courses such as western civilization or world history – especially before 2012, as depicted – is dominated by college and high school students.<sup>19</sup>

Similar phenomena have been found in the Google Ngrams data built from Google Books. One of the most telling is the apparent exponential growth since 1900 in use of the term ‘Figure’ relative to the term ‘figure’ (Pechenick et al., 2015). This reflects, of course, the growth in the percentage of university library holdings – the source material

for Google Books – that are composed of scientific journals. Someone researching the history of internet abbreviations might be alarmed that the terms ‘lol’ and ‘wtf’ reached their peak usage around ... 1660. This is a consequence of OCR mistakes being particularly egregious in older texts, and these mistakes being amplified by there being a trivial number of texts with 17th-century dates in the first place.

Perhaps even more pernicious with commercially created data exhaust such as this is *algorithmic confounding*. The relationship between the phenomenon of interest and its digital traces are a function of proprietary and changing algorithms, and those are driven by commercial motivations rather than utility for your research. Lazer et al. (2014) discuss, for example, *red-team/blue-team dynamics*. The blue team identifies changes in an algorithm that provide commercial value, such as click-through or purchases. The red team defends the algorithm from manipulation and malicious attack. A plausible blue-team culprit in Google Flu’s decline was the introduction of search auto-complete suggestions, which

**Figure 5.3** Comparing to a reference term captures more relevant shifts in attention

made search more helpful for users but likely changed the natural tendency of ‘flu’ to be extended to ‘flu symptoms’, or ‘bird’ to ‘bird flu’. Both red and blue teams, in any case, have an incentive to obfuscate changes and their impacts. As a result, the outside researcher cannot count on digital exhaust to carry consistent conceptual meaning over time.

There are a couple of strategies one can use to mitigate these problems. The first is to calibrate your big/cheap/noisy/biased data with small/expensive/precise/accurate data that you believe in, if possible. A parallel in traditional design is ‘double sampling’, where you might, for example, estimate the age of trees of a given species in a forest by (a) estimating their height by eye from the ground and then (b) cutting a small number of those down and counting the rings, using those to determine the relationship between your height guesses and their actual age (Thompson, 2012). In the context of surveys, Salganik (2017) calls this ‘amplified asking’, in which a small subset of individuals in a large imperfect data source are surveyed about the exact concepts of interest. These are then linked statistically to convert the large data into estimates of the concept for everyone in the larger source.

As with Google Flu, however, algorithmic confounding can make it difficult to confidently generalize your calibrations beyond the original time or context.

The second is to think of such measures with this question in mind: *relative to what?* Is there a sensible ‘control term’? For example, Figure 5.3 shows the relative Google Trends data for ‘islam’ vs. ‘buddhism’. This removes the shared content (world religions, etc.), and reveals spikes that seem to be associated with the summer 2010 stir up about Sharia law and the ‘Ground Zero Mosque’, and the September 2012 worldwide protests over the anti-Islam film *The Real Life of Muhammad*. Also, one need not have discovered the ‘essays’ phenomenon to identify ‘buddhism’ as a plausible control term.

Similarly, it is often useful to track ‘placebo’ terms, which aren’t expected to display any pattern at all. The reader is invited to search on the Google Books Ngram Viewer<sup>20</sup> ‘the’ since 1650. This provides us with warnings about the early noisiness, as well as a mysterious (to us) decline that began about 1850 and accelerated around 1970. This can be even more useful in your own bespoke data collections, as placebos can be diagnostic

of things like scraper and server errors that might otherwise cause drops in terms of interest to be interpreted substantively.

Another practice that can ‘jingle’ in our ear misleadingly is the use of specific terms to identify a relevant subset of impossibly large data for one’s analysis. Consider, for example, the dataset created by Mohammad et al. (2016). This has been used as a gold standard test bed for the NLP task of ‘stance classification’, identifying whether a text (in this case a tweet) is ‘favorable toward’, ‘against’, or neither, with respect to a target concept (in this case, ‘atheism’, ‘climate change is a concern’, ‘feminist movement’, ‘Hillary Clinton’, and ‘legalization of abortion’). A tweet got into this dataset in the first place by ending with one of a manually selected set of hashtags thought to be about the target and favorable (e.g., #GOHILLARY), against (e.g., #HillNo), or ambiguous (e.g., #hillary2016). For the ‘climate change is a concern’ target they were unable to identify a hashtag they considered clearly favorable (#climatechange was considered neutral), but nonetheless ended up with a dataset so skewed the *other* way (fewer than 5% were hand-labeled ‘against’) that the classification task was effectively impossible. At a minimum, the chosen hashtags did not have the filtering properties the researchers thought they had. Recent work on keyword expansion (King et al., 2017; Linder, 2017) provides techniques for understanding and tuning the precision and recall of your search terms.

## DATA WRANGLING

The received wisdom in data science is that most of your time will be spent in the data wrangling phase. It seems to also be widely held that data wrangling is entirely *ad hoc*. There are, however, theoretical frameworks, common wrangling tasks and relevant tools that can help make this process more principled. The most well-constructed theoretical

frameworks for data science come embedded in particular software, with prominent current examples including tidyverse/dplyr (R), data.table (R), cdata (R), pandas (Python) and Trifacta Wrangler. These each come with quasi-religious adherents and opponents, but we have found each of them useful both for practical projects and for framing our thinking on wrangling.

First, the big picture. What’s the goal? What would clean data look like for you at the end of the pipeline? It’s almost definitely some sort of table or matrix, or a set of them. We often find we are aiming for something of a hybrid, often a matrix (think document-term or donor-candidate), usually sparse, with an additional data frame of relevant data or metadata for the rows and one for the columns, consisting at least of labels.

Next, think of your input as tables. For all our discussion of new forms of data as ‘non-rectangular’, it is always possible and usually useful to think of even raw inputs of a data wrangling pipeline as tables. The main necessary abstraction is allowing that the ‘cells’ of these tables may contain complex objects, including other tables. So, near the beginning of a pipeline, your ‘table’ may, for example, be of dimension  $n \times 2$ , with one column a list of  $n$  raw data objects (e.g., documents, images, audio files, websites, adjacency matrices, shapefiles, JSON files) or even *pointers* to such objects (filenames, urls), and the second column a list of *metadata* associated with the objects (e.g., labels, source, date). Or you might have an unprocessed natural language text, which might be thought of as a single column of observations, each of which is a document, or page, or line, or word, or character – whatever is most useful. At the extreme, your input is a  $1 \times 1$  ‘table’ whose one cell contains all of your raw data in arbitrary form.

Now you’re just converting one set of tables into another. There are only so many things you can do to tables. The most straightforward things are actions that change at most one dimension – rows or columns – at

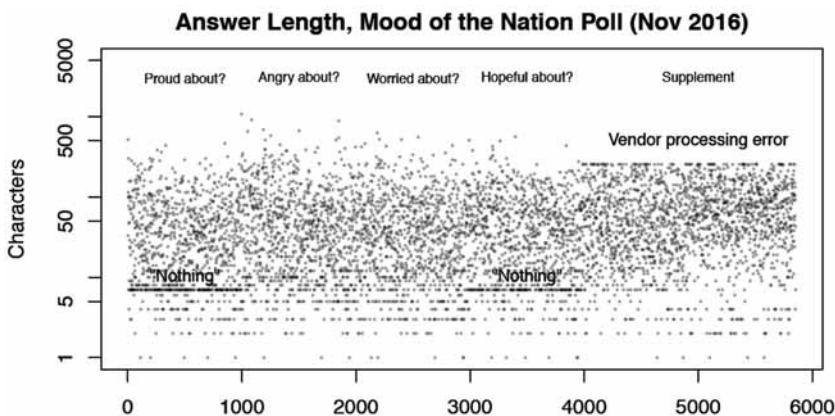

a time. You can delete some rows or columns, making your table shorter or thinner. You can use patterns to split some rows or split some columns, making it taller or wider. You can extract information from some rows or columns to create new ones. You can combine multiple rows or columns to create new ones. You can use patterns to change the contents of a row or column.

What do we mean by ‘use patterns’? In most instances, we mean the use of *regular expressions*, a sort of ur-language with slightly different dialects in different programming languages including R and Python, that is used to specify patterns in strings that you want to find, extract, or replace. Regular expressions push you into puzzle-solving mode, which appeals to some more than others. Computer scientist Jamie Zawinski is credited with an infamous quip: ‘Some people, when confronted with a problem, think “I know, I’ll use regular expressions.” Now they have two problems.’ Regular expressions can be frustratingly unwilling to do what you mean rather than what you say, but there are numerous graphical tools available online to visualize what your regular expression

is actually doing. We can also recommend Wrangler, which dynamically predicts and suggests patterns based on examples you show it (Ratterbury et al., 2017).

One set of exceptions to the ‘usually regular expressions’ advice is when the text in question is in a nested hierarchical format such as JSON, XML or HTML. It is often difficult and occasionally impossible to extract certain patterns from these with regular expressions. There are dedicated and well-built JSON, XML and HTML parsing libraries in both Python and R that make this task much easier.

It is also advisable at various stages to look for patterns that shouldn’t be in your data, and may be the result of errors. This process goes by many names, including *data profiling* and *data editing*. Some basic techniques include looking at the distribution of variables (or derivatives like length of strings) overall and sorted or plotted against other variables like time. Figure 5.4 shows an example we recently faced. Puts et al. (2015) discuss statistical and graphical methods for detecting and correcting errors in large scale datasets.

**Figure 5.4 Profiling of open-ended responses in the Mood of the Nation Poll (Wave 4), run by Penn State’s McCourtney Institute for Democracy, revealed three suspicious patterns, one of which was in fact the result of an error at the vendor (processing in Stata truncated the responses at 244 characters). (The lines at length seven are not errors. In every wave of the poll, the modal answer to ‘What recently in politics/the news made you proud?’ and ‘Looking forward to the next 12 months, what makes you hopeful?’ is ‘Nothing’.)**

Some wrangling changes the shape of your table in more than one dimension. Common variants of this include *pivoting* information from columns to rows, making your table shorter and wider, or *unpivoting* information from rows to columns, making your table taller and thinner. This is one of the more conceptually confusing aspects of data wrangling. We recommend the recent work by the cdata team on *coordinatized data* and *fluid data*, which offers among other things encouragement to worry about this less than we tend to do (Zumel, 2018).

Some wrangling involves using an existing set of tables to create a new table. This is almost always a *grouped summary* that involves some *split-apply-combine* logic, terminology generally attributed to Wickham (2011). In such a task we have, for example, a table with one or more variables we can ‘group by’ and one or more statistics we want to calculate for each group. Conceptually, we split the table into groups, apply our aggregate statistics function to the group, and combine the answers into a new table with one row per group. This is a core operation in SQL, pandas, data.table, dplyr and cdata, and you will see it repeatedly.<sup>21</sup>

Finally, you can combine two (or more) tables into one, merging records that match on some key variable(s). With clean data this is straightforward. With any ambiguity this is one of the most difficult and consequential problems the data scientist will regularly face. The most common social scientific term for the process and problem is *record linkage* (is ‘Angela J. Nunez’ on the voter registration list the same person as ‘A. Nuñez’ in this survey?) but there are variants of the problem called other things, such as *entity disambiguation* or *duplicate detection*. Getoor and Machanavajjhala (2012) provide a good overview of the sources and consequences of this problem. The state of the art (e.g., Enamorado et al., 2019) involves *locality sensitive hashing* and related concepts at the edge of computer science, statistics and social science methodology.

## DATA PREPARATION

While we may now have clean data, structured the way we need it structured, this still may not be exactly the data we want to analyze. There are a number of ways in which we might alter, reduce or expand our data, and a number of reasons we might want to do so. Some of these improve computational properties of models. Some of these improve the inferential or learning properties of models, including regularization, robustness and generalizability. Some of these improve the interpretability or domain relevance of our models. Typically, there are tradeoffs between these objectives.

### *Combining Observations*

Let’s consider the possibility of reducing observations by combining them, creating a new combined unit with a new aggregate statistic calculated from the component observations. In data conceived of as ‘signals’, such as audio and image, this is a form of *downsampling*. This could serve a variety of purposes. It might be a way to ease computation or a way to smooth our data across noisy individual observations. In the case of audio, image or video signals, it might filter out high frequency audio beyond human hearing or images of higher resolution than the phones being used to view them. In more familiar settings where the original observations are people, such aggregation might serve to protect privacy of individuals who could be identified from the disaggregated data.

We’ll use the famous photo of Abraham Lincoln in Figure 5.5a as a running example throughout this section. The raw data depicted in 5.5a is an intentionally low resolution ‘png’ (bitmap) version of the photo in ‘grayscale’. It is a matrix of pixels, 120 rows and 96 columns (96 × 120 in the convention of image descriptions) with each pixel

**Figure 5.5** Downsampling aggregates pixels (observations) into new pixels, reducing the resolution of the image. Vector quantization aggregates the intensities (features) into fewer possible values, reducing the depth of the image

defined by a gray level from 0 (black) to 255 (white).

As can be seen in Figure 5b, downsampling – in this case, combining groups of four pixels into one – can be thought of as lowering the *resolution* of our data. This is one form of *lossy compression*. It is compression, because we have used 1/4 as many numbers (2,880 pixels, down from 11,520), taking advantage of the grid/neighborhood structure of the pixels to approximate the original data. It is lossy, because we can't recover the original data from the compressed version. We now do not need to squint to see the distinct pixels.<sup>22</sup> Aggregation of nested units – as with geographic data nesting people in census tracts, counties in states, etc. – is similarly a sort of lossy compression, but with the added complication that aggregation units are generally not the same size, the same shape, or organized on a grid.

### **Adding Observations**

Conversely, let's consider the possibility of expanding our dataset. In the context of machine learning, *data augmentation* involves adding fake data to your training set.

How could this possibly be either legitimate or helpful? Consider our Lincoln image as itself one piece of a data in a face recognition training set. What if we rotate it clockwise a quarter turn? Wouldn't we want our image classifier to recognize this as Lincoln also? So, we add some rotated, translated and rescaled variants of our training images to help the model learn to recognize such changes.

To make your model robust to noise, you may also wish to introduce some to your training data. This form of data augmentation is now used in *adversarial learning*, where the idea is for the adversarial part of the model to try to trick the learner, making the learner harder to fool (Goodfellow et al., 2016).

An implicitly common, but often unacknowledged, type of regularization can be achieved by adding *pseudo-observations* to your data. A particularly common variant is 'adding one to all my counts before I take the log', often referred to in machine learning as *additive smoothing*. There is an explicitly Bayesian justification for how this works. Many regularization techniques have a direct analogue and interpretation as Bayesian shrinkage priors. The most

well-known are L2-regularization (if applied to the coefficients of a linear regression, this is *ridge regression*) and L1-regularization (if applied to the coefficients of a linear regression, this is the *LASSO*), which are equivalent to the use of a mean zero normal or Laplace distribution prior, respectively. In turn, *conjugate Bayesian priors* have a direct interpretation as pseudo-observations added to the dataset. So, equivalently, adding pseudo-observations is equivalent to (some) Bayesian prior. Monroe et al. (2008) demonstrate the use of this technique. A prominent implicit example from machine learning is the impactful word2vec model for word embeddings. Training involves a technique called *negative sampling*, which adds unobserved word non-cooccurrences to its training data as if observed (Mikolov et al., 2013).

## Altering Features

It is important to recognize that the features in our raw data, even if clean, may not be the best way to *represent* our data. There may be transformations of the data that make it easier for the model to learn, or for us to make sense of what it learns. Of course, even apparently trivial alterations can have a massive impact on what features and observations are similar to each other (Denny and Spirling, 2018).

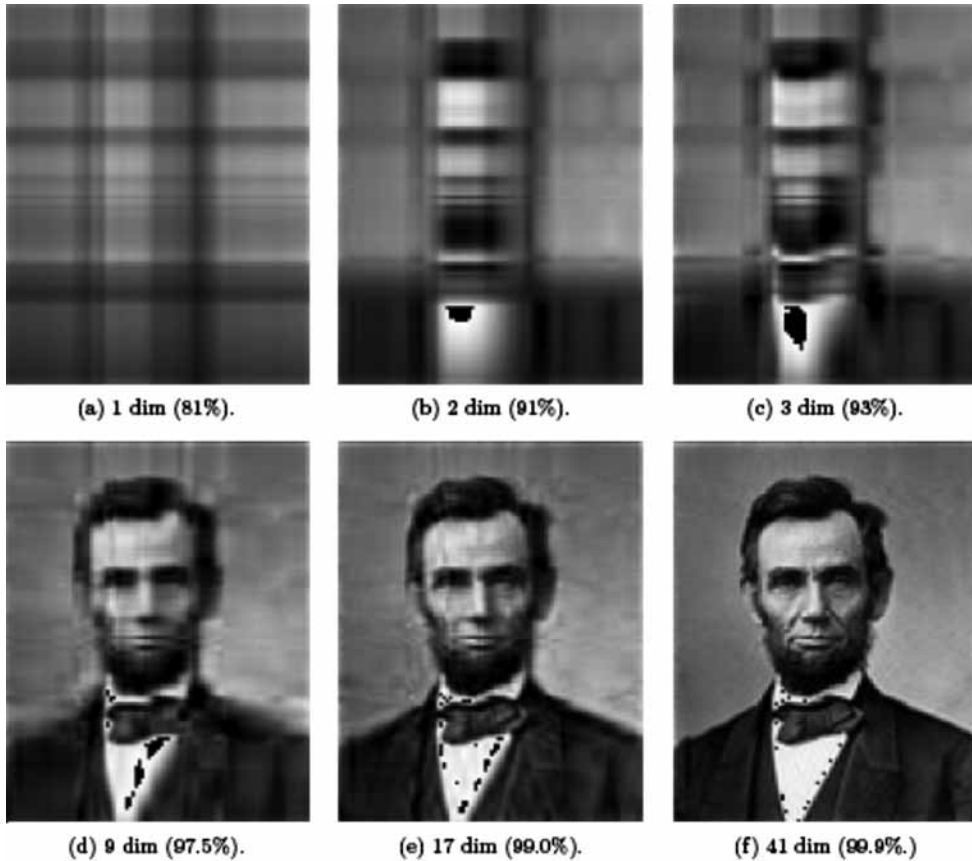

We may, for example, wish to reduce the dimensionality of our feature set, to find a smaller set of features that still provide a reasonable representation of our data. One approach might be *vector quantization*, in which we cluster our observations, summarize each cluster by its mean and then replace each observation with this cluster prototype. If we vector quantize our Lincoln image by a factor of four, we need to cluster the 256-pixel intensities into 64 representatives. The reduced image that results is shown in Figure 5c. The resolution is the same as the original, but now the *depth* has suffered, losing important detail.

An alternative is to decompose the data into a new set of features. One objective of this decomposition might be to reduce redundant information in the features. There are several possibilities for decomposing this matrix, including Singular Value Decomposition (SVD), Principal Component Analysis (PCA), Independent Component Analysis (ICA) and Nonnegative Matrix Factorization (NMF).<sup>23</sup> One characteristic of SVD (and PCA) is that the order of the new features reflects their importance in capturing variation in the original matrix, so we can take the first  $k$  new features to get the best  $k$ -dimensional recreation of the picture, in this sense. Figure 5.6 shows the quality of the representation at different levels of  $k$ .

If your data has some structure that implies connectedness among data points – such as sequential structure, as with time series, audio or natural language, or two-dimensional spatial structure, as with geographic or image data – you may benefit from the application of *convolution* to your data or in the structure of your model. The specific functional form of convolution applied or learned – the function that *is convolved with* your data – is referred to as a *kernel* (or in some application areas a *filter*). The math of convolution can be intimidating, but the idea is simple and you have undoubtedly encountered it before, whether you knew it or not, most likely as some form of *smoothing*.

A kernel is just a function; a smoothing kernel is just a probability distribution function, often a normal (Gaussian) distribution. An easy example is as in Figure 5.7, where we have a set of  $N$  integer-valued observations, in this case the 11,520 grayscale values of 0 to 255 in the original Lincoln image. Loosely speaking, to convolve a kernel with such data, you replace every data point with a  $1/N$  sized copy of the kernel and add them up. Essentially each observed data point melts into neighboring regions of the space, providing a smooth version of a histogram, or *kernel density* plot. You have probably seen the same idea applied for *kernel smoothing* of

**Figure 5.6** Effect of dimension reduction through singular value decomposition (SVD)

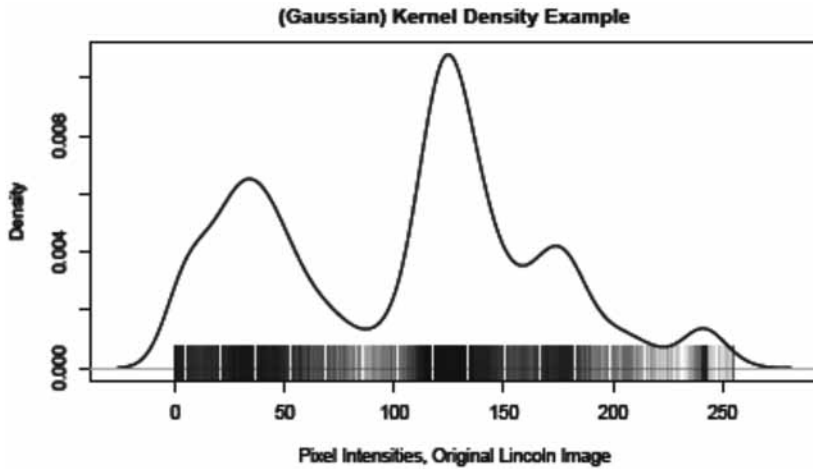

*Note:* Captions indicate the number of dimensions retained (from an original with 96 dimensions) and the percentage of variance in the original's pixel intensities that is captured.

geographic point data. Each discrete observation is melted across its (two-dimensional) spatial neighbors, providing a smoothed version of the data.

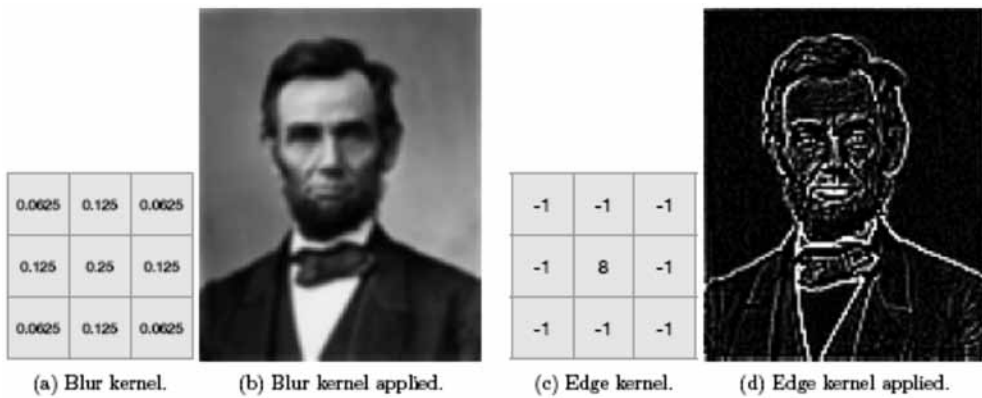

Convolution is much more general than smoothing, however – a point again most easily demonstrated in image data. We can define a simple *image kernel* or *filter* as a  $3 \times 3$  matrix of numbers like that in Figure 5.8a. We will take this kernel and slide it like a window over each  $3 \times 3$  block of pixels in the original Lincoln image (Figure 5.5a), for each replacing the central pixel's value with a sum of the nine pixel values in its window, weighted as defined by the kernel. This

particular kernel is similar to our Gaussian from before, smoothing neighboring values toward each other and creating a 'blur' effect as seen in Figure 5.8b.

Now consider the kernel in Figure 5.8c. This kernel brightens pixels that are brighter than surrounding pixels, where there is a sudden change in values. This makes it an edge detector, as shown in Figure 5.8d. Convolutional neural nets work, in part, by learning multiple such filters to apply to data like pixel values to infer, for example, different combinations of edges in different directions sufficient to distinguish faces or particular objects.

**Figure 5.7** A kernel density estimation of the Lincoln images pixel intensities convolves a Gaussian curve (normal distribution) over the observed distribution of values

**Figure 5.8** Effect of convolutional image kernels

**RESPONSIBLE DATA SCIENCE PROJECTS**

Data science is a new field that combines elements from many existing disciplines. One downside to this novelty is that scientific and ethical standards have not been clearly defined by the community. And, of course, there are broader public concerns about corporate and government practices in the collection of data, the protection of data and the social

implications of machine learning, artificial intelligence and other data science techniques. In this section, we discuss three considerations that arise when trying to design responsible data science projects: reproducibility, data privacy and algorithmic bias.

**Reproducibility**

Concern about the reproducibility of findings has become a defining feature of social

science and, indeed, science in general in recent years. This has produced laudable progress, accelerated by policies of journals and funding agencies, in the development of standards and mechanisms for things like study preregistration and public archiving of replication data and code. Against that background, the data-intensive projects pursued by data scientists present unique hurdles to transparent and reproducible research.

One might consider the bare minimum to be posting the data necessary to replicate your analysis on dataverse or a similar publicly accessible archive, but this can be impossible in many cases. First, the data may be too large for permanent storage with sufficiently low latency network bandwidth to be technically or financially feasible. Even more frequently, the data has inherent value to a commercial owner, and sharing it would violate copyright or other legal constraints, licensing agreements or terms of service. One reasonable way of working around this is by sharing *dehydrated data*, i.e., providing pointers and scripts that can be used by the replicating user to recreate and collect the full data themselves, given sufficient time and access. A very nice example of this is the Documenting the Now project (Clark et al., 2019), which archives collections of tweets around important social events (such as Black Lives Matter protests or the Women's Marches) and shares them as sets of dehydrated tweet ids. They also provide a variety of tools, easily incorporated into replication pipelines, for rehydrating these data consistent with Twitter's terms of service and other policies.

There are also emerging academic–industry partnerships designed to provide academic researchers with controlled access to, and scientifically acceptable mechanisms for both publishing and replicating with, proprietary data. Most notable is the Social Science One project facilitated by Harvard, the SSRC and eight foundations and currently partnering most prominently with Facebook (King and Persily, n.d.).

As we have seen, data science projects, almost by definition, do not consist of one tabular dataset and one analysis script. Instead, there is often extensive data wrangling and feature engineering performed just to arrive at a point where analysis is possible. These are consequential parts of a data science project and they should be subjected to transparency and replication standards as well. It is ideal that you provide potential replicators not just the analysis-ready data from the end of the pipeline, but data in its intermediate forms back as close as possible to the raw data ingested at the beginning of the pipeline, along with as much as possible of the pipeline instantiated in code.

From here, the data science community and literature are not entirely settled on what approach best meets the ideals of transparency and reproducibility. At one extreme, the ideal is one-button replication. In this view, everything should be provided sufficient for a user to very simply execute the full pipeline on the original data and receive an identical result. Taken to its logical limit, this can best be guaranteed by providing production-level software encased in a virtual copy of the original computing environment via something like a *Docker container*.

At the other extreme, the idea is to expose the bones of the pipeline and the decisions that went into it, with the objective that a user can develop intuition and adapt the code to work with their data or to check the robustness of pipeline choices. Here the demands are for heavy documentation, perhaps even of bits of code and data ultimately not used in the final pipeline, and highly flexible, even interactive, code. Taken to the logical extreme, this can best be achieved by instantiating your code and documentation in literate programming tools like Jupyter or R notebooks.

Some emerging paradigms and accompanying tools strike a balance between these two motivations under the umbrella of *workflow management* systems. Our current favorite is *Snakemake*, which provides a

very readable Python-like language and tool for managing and executing data pipelines. It can incorporate both R and Python scripts, can recreate virtual computing environments via conda for Python or packrat for R and can work with data and other resources on a variety of cloud platforms and through a variety of channels. So a user can execute a more or less exact replication, but also has ready access to the underlying scripts and how they fit together in the pipeline, and can change them as desired. Another emerging workflow management system, which holds considerable promise for tracking *data provenance* directly within data itself, is *Pachyderm*, which has been conceived as ‘git for data’.

### **Data Privacy**

When using large socially generated data sources, projects will eventually brush up against privacy concerns that push in the opposite direction of transparency and open data impulses. We may sincerely wish to protect the privacy of individuals in our data, but naive ‘anonymization’ – just removing names and other direct personal identifiers – isn’t enough. We can remove names from a survey but a combination of demographic and other features may be sufficient to tie a person uniquely to their answers. We can remove names from a GPS tracking dataset, but easily deanonymize most people by the location where their tracks tend to end at night and start in the morning.

The dominant contemporary framework for thinking about statistical data privacy is *differential privacy*. It is a highly technical literature, closely related to cryptography, but the high-level intuition is straightforward: an individual should face (almost) no risk from participating in a statistical database. A differentially private algorithm applied to a dataset seeks to provide a statistical guarantee to any individual appearing in the dataset that the answer from the algorithm will allow an adversary to learn essentially no more

about that individual than they could learn if the individual were not in the dataset. The simplest differentially private mechanisms add noise of sufficient magnitude and type to meet the needed guarantee. Among the more interesting approaches is using the actual data to generate *synthetic data* that has maximal utility in terms of capturing the statistical properties of the original, subject to the differential privacy constraint.

And, of course, data release can have unintended consequences for privacy over and above even the strict requirements of differential privacy. A striking recent example was the release by Strava of their ‘global heat map’. Strava is a fitness social networking site, where users upload tracks from their phones or other GPS devices of runs, bike rides, etc. The heatmap showed all of Strava’s users’ GPS tracks in aggregated form. Given that tracks merge into one another and had no times attached, it would be very difficult to learn much about the paths of any individual. But observers were quick to locate regular ovals and similar tracks where there shouldn’t be any, such as in a remote part of Mali. These were the traces of US soldiers going on regular jogs around undisclosed military bases. That is, by using a fitness tracking app, soldiers unwittingly released sensitive military information and, arguably, compromised their own safety.

### **Algorithmic Bias**

Many people have the unfortunate impression that algorithms produce an ‘objective’ understanding of the world around us, distinct from our own human biases. This is, of course, untrue. Models are designed to find patterns in data, and, in a biased world, those patterns will reflect that bias and often worse. Say we want to train an algorithm to classify resumés into ‘would hire’ and ‘wouldn’t hire’ categories. If we train it on past ‘did hire’ and ‘didn’t hire’ data, and hiring practices in the past displayed racial bias, the algorithm will

seek out features such as names or zip codes that not only encode that bias, but use it to make recommendations that repeat or even amplify that bias.

There is much work being conducted on debiasing algorithms, but it's an elusive concept (Caliskan et al., 2017). For example, Bolukbasi et al. (2016) find that word embedding models encode gendered usage of words, placing the vector for the word 'woman' closer to that of 'homemaker' and placing the vector for 'man' closer to 'programmer'. This is useful as a measurement of the underlying societal bias. This is obnoxious if it underlies a black box algorithm recommending career advice websites to our children. It is similarly obnoxious that such models place 'man' nearer to 'doctor' and 'woman' nearer to 'nurse', particularly given that we just framed words as job titles. But framed as verbs perhaps we should see a difference, given that either a man or a woman can doctor a test result, but only a woman can nurse a baby.

This is another reason why interpretability of models is so important. These subtleties are difficult enough to unparse when they're isolated like this. They are more or less impossible to identify when the biases in the data are unexamined or the impact of biased data on our algorithmic task is black-boxed.

## CONCLUSION

The sheer breadth of subjects discussed here hopefully makes clear that the prospective data scientist needs to be comfortable with *team science*. The scope of data science projects, and the number and variety of specialized tasks a typical project requires, very often necessitates a collaborative interdisciplinary research team. Interdisciplinary collaboration is a learned skill that requires patience. Other disciplines have different assumed knowledge, different conference and publishing cultures, different scientific

questions, different approaches to learning from data and jargon just different enough to create abundant opportunities for confusion. Our best advice is that when you inevitably reach a point of mutual confusion with your potential new interdisciplinary colleague, stay in the room. All the good stuff is after that.

We also want to re-emphasize that calling the process 'data science' does not exempt us from social scientific and ethical standards (Monroe et al., 2015). While the practice of data science is often associated with early stage Facebook's infamous internal ethos 'move fast and break things', we less snap-pily encourage the social scientific data scientist to move purposefully, learn things and play nice.

## Notes

- 1 The senior author insists that 'data' is, like information, an abstract noun that *is*, and like sugar or sand, a collective noun that *is*. Our agenda are too full here to elaborate at length.
- 2 These may be literally instantiated in code with a *pipe operator*, like `|` in a Unix shell or `%>%` in R (through `magrittr`).
- 3 This, and all of our specific advice regarding 'tools', will no doubt eventually read as dated. This reflects a snapshot as of this writing in 2019.
- 4 Arguably, we should perhaps also include Java and (Java-based) Scala. Many 'big data' tools – e.g., Hadoop, Hive, Flink, Elasticsearch, Spark ... more than half of the projects under the Apache umbrella – are written in Java and/or Scala, as are many established machine learning, NLP and similar libraries – e.g., Weka, Mahout, CoreNLP, Deeplearning4j. The learning curve is steeper, however, and the advantages of Java reveal themselves mainly in the context of modular software engineering for large multi-person/multi-team industry settings. Viewed as tools for social scientific data science, most of these can be interfaced from Python and increasingly R. (There are other possibilities, of course – Julia, MATLAB/Octave, Haskell, etc. – but none of these yet has a footprint in data science, much less social science, to rival Python or R.)
- 5 Scholars working on tasks that require intensive numerical computations may benefit from learning a *compiled language* like C++, Cython or

- Rust. Many common R and Python libraries, as well as R and Python themselves, call such code ‘under the hood’ for speed purposes. This is useful in that context, but the learning curve is considerably steeper.
- 6 For example, the one-liner `curl http://www.gutenberg.org/files/28885/28885-h/28885-h.htm | tr '[:punct:]' ' ' | tr 'A-Z' 'a-z' | tr -s ' ' | tr ' \n' | sort | uniq -c | sort -rn` retrieves the text of *Alice in Wonderland* (in a few seconds) and outputs a sorted table of word frequencies from it (instantly).
  - 7 There is an additional practical benefit, as increasingly one’s github account serves as part of a job portfolio.
  - 8 Although this is a common characterization in textbooks, it is widely understood in measurement theory that this typology is insufficient. For example, it does not distinguish between ordinal and count data, and has no category for percentage (or ‘counted fractions’ or ‘gradation of membership’) data (Mosteller and Tukey, 1977).
  - 9 A similar-looking problem occurs with scrapers ignoring *html entities* leaving text littered with things like ‘&nbsp;’ or ‘&quot;’ (the telltale signs are the opening ampersand and concluding semicolon). But this is unrelated to the encoding, and best dealt with at the scraping stage with an HTML specific parser like the Python library BeautifulSoup.
  - 10 Loosely speaking, this is a ‘data.frame’ in base R, a ‘tibble’ in the R tidyverse, a ‘data.table’ in R’s data.table package and a ‘DataFrame’ in Python’s pandas, although some of these can hold more general structures. In different contexts, these types of structures are also known as ‘attribute-value representations’, ‘flat data’, ‘object-predicate tables’, ‘Aristotelian data’ and more.
  - 11 There are several ways to do this. For example, Python’s scipy offers seven distinct sparse matrix formats, each with particular strengths and weaknesses.
  - 12 [https://en.wikipedia.org/wiki/List\\_of\\_file\\_formats](https://en.wikipedia.org/wiki/List_of_file_formats).
  - 13 API stands for ‘Application Programming Interface’. It is a general concept in computer programming, indicating a set of methods for communication between two distinct software components. But in the data science context ‘API’ almost always refers to a web-based service for accessing underlying data. Twitter, for example, provides several APIs that can be called by apps or scripts to retrieve (limited) data about tweets using certain search terms or recent history of particular users.
  - 14 A third human-readable text-based format, YAML (too cutely by half, ‘YAML Ain’t Markup Language’) is arguably even more readable and compact than JSON, as well as being more flexible, but is not yet very widely used as a general data exchange format.
  - 15 A folk quote attributed to dozens of different sources.
  - 16 Technically, ‘third normal form’, which is a bit much for us here.
  - 17 It does help tremendously if filenames serve as unique identifiers, as well as sort in a way that is meaningful. This means if you number files, use enough leading zeroes to avoid ‘file1.img’ → ‘file10.img’ → ‘file2.img’; if you date files use ‘YYYY-MM-DD’ or similar format.
  - 18 Students often guess this is related to Ramadan or the Hajj, but those are on the 354-day cycle of the Islamic calendar, and out of phase with the dynamics observed here.
  - 19 Terms highly correlated in weekly search volume with ‘islam’ include: ‘judaism’ ( $\rho = +.80$ ), ‘christianity’ (+.80), ‘greek art’ (+.79), ‘buddhism’ (+.79), ‘hinduism’ (+.78), ‘essays’ (+.78), ‘roman art’ (+.78), ‘voltaire’ (+.78), ‘chaucer’ (+.78), ‘articles about’ (+.77), ‘uses of the’ (+.77), ‘aristotle’ (+.77), ‘summary of the’ (+.77), ‘interpretation of’ (+.77), ‘chemical elements’ (+.76), ‘international relations’ (+.76).
  - 20 <https://books.google.com/ngrams>.
  - 21 This is also closely related to the functional programming notions of *map* and *reduce* as well as the MapReduce logic underlying the distributed processing of Hadoop.
  - 22 This pixel aggregation is a naive way to downsample an image. There are other ways to downsample images that minimize these sorts of visual artifacts.
  - 23 If we were taking this seriously as image analysis, we would be more likely to use a Fourier Transform or similar.

# Designing Qualitative Research Projects: Notes on Theory Building, Case Selection and Field Research

Ezequiel González-Ocantos

## INTRODUCTION

Why did World War I break out in 1914? Why did states create the International Criminal Court, and what explains the choice of certain design characteristics over others? Why did Mexico democratize in 2000 after 70 years of one-party rule? Why did Britain, Germany and Sweden adopt different types of welfare states? Why did Argentina and Peru prosecute and punish former dictators following their most recent episode of democratization whereas Brazil did not? Qualitative researchers in political science and international relations are usually interested in explaining outcomes such as these. Instead of seeking to estimate the average effect of a causal factor or independent variable in a population, our projects focus on puzzling within-case transformations, or variation in events and institutions across a limited number of cases. Qualitative empirical research thus proceeds to unpack the historical, social and political processes that cause

these effects. To be sure, the puzzle-driven nature of qualitative scholarship means that our projects tend to be highly contextual and, more often than not, research questions feature proper names. The goal, however, always remains to contribute to the general understanding of the conditions favoring classes of events or outcomes, such as inter-state conflict, sovereignty-constraining forms of international cooperation, democratization, redistributive public policies or progressive judicial activism.<sup>1</sup>

Outcome-oriented qualitative research leverages within-case evidence to probe the theoretical models proposed to answer these questions. While cross-case comparisons are often important features of qualitative designs, the main source of inferential power comes from the in-depth tracing of processes in each case (Goertz and Mahoney, 2012). Instead of devising methods to systematically obtain comparable measures of a host of variables across a large number of cases, and using statistics to estimate correlations or the

average effect of a variable, we rely on multiple, context-specific data sources to uncover pathways linking independent and dependent variables (Brady et al., 2004). For qualitative researchers, to explain is to show ‘how’. And this usually requires diving into a case to carefully document the existence of an uninterrupted chain of events or actions and reactions that together bring about the outcome of interest. We thus trade the appeal of generalizations based on finding regular conjunctions of causes and effects in a population, to gain relative certainty that a plausible connection exists between cause and effect in a limited number of instances (George and Bennett, 2005; Beach and Pedersen, 2013; Bennett and Checkel, 2015). As we shall see below, models guide the choice of evidence and the selection of relevant rival explanations for consideration in each case, with the goal of reconstructing these causal chains in full.

How do we go about designing projects to understand outcomes in specific cases, trace processes and thus meet the aforementioned explanatory standards? In this chapter I draw from my experience to answer this question. I argue that it is essential to begin the research by proposing a theoretical model of the sequence or pathway linking cause and effect in positive cases. This sequential account should identify the *steps in the causal chain* and *mechanisms* that explain the flow of causal energy that brings about the outcome of interest. I also suggest that doing so involves providing a stylized description of a ‘field’ of action on the basis of three parameters: the *actors* involved, with their preferences, logics of action and resources; the *spaces of action* where these actors act; and the consequences of the *interactions* between them.<sup>2</sup> After conceptualizing these three parameters, and illustrating them with examples, I contend that this type of theorization can help researchers discipline three additional components of the research process. First, I discuss how sequential models serve as roadmaps during fieldwork. Second, I suggest that sequential models facilitate the

identification of relevant rival explanations. Third, I show how they can assist the case selection strategy. Toward the end, the chapter makes it clear that while well-specified theoretical priors are crucial for the success of qualitative research projects, induction and the dialogue between theory and data also play a critical role.

## CAUSAL PATHWAYS

The method of within-case analysis used by outcome-oriented qualitative researchers is often referred to as ‘process tracing’. According to George and Bennett (2005: 206) process tracing ‘attempts to identify the intervening causal process – the causal chain and causal mechanism – between an independent variable (or variables) and the outcome of the dependent variable’. In Mahoney’s (2012) formulation, process tracing is about documenting sequences: ‘process tracing can help a researcher establish that: (1) a specific event or process took place, (2) a different event or process occurred *after* the initial event or process, and (3) the former was a cause of the latter’ (571; emphasis in original). As Collier (2011: 823) suggests, this involves the ‘systematic examination of diagnostic evidence selected and analyzed in light of research questions and hypotheses’. In this sense, Bennett (2015) and Beach and Pedersen (2013) have shown that process tracing is governed by a form of Bayesian probabilistic reasoning which uses the tools of logic and deep knowledge of context to evaluate the inferential power of individual ‘causal process observations’ (Brady et al., 2004: 252). The method ‘emphasizes that the probative value of evidence relative to competing explanations is more important than the number of pieces of evidence’ (Bennett and Checkel, 2015: 16).

These definitions highlight three essential features of process tracing *qua* method.

First, the goal of process tracing is to evaluate hypotheses. These are not hypotheses about average independent effects or about the constant conjunction of cause and effect in a population. Instead, process tracing involves the evaluation of hypotheses about the presence or absence, in a specific case, of the constituent steps of a stylized causal pathway. Process tracing therefore results in a narrative structured by theory, variables, competing explanations and concomitant observable implications. Second, process tracing primarily involves the quest for causal processes or connections. It is grounded in the assumption that although these processes may be part of the unobservable ontological 'deep', they are still traceable because they leave fingerprints in reality. In fact, explanations that do not account for processes, and therefore do not transcend correlational statements, are incomplete and unsatisfactory (Bunge, 1997; Waldner, 2007). Finally, good description is essential for effective process tracing (Mahoney, 2012). Researchers must strive to describe the component parts of the hypothesized causal pathway in their cases. On their own, these descriptive inferences are not 'causal', but when looked at as a system and ordered in a temporal sequence, and when logical links that comport with theory can be established between them, they allow researchers to put together convincing stories about how causal energy flows from independent variables to outcomes.

The causal pathways that are the object of process tracing have two components: steps in the causal chain and mechanisms (Waldner, 2014). Steps refer to the theoretically relevant events that need to be obtained in order to move from the causal condition to the outcome of interest, or to observe a change in the dependent variable. The different events included in the model must be able to provide a logical or internally sufficient account of the states of affairs, decisions or actions required to produce the transformation under study. For example, if we want to explain a democratic transition,

these could include deteriorating economic conditions, followed by a split in the ruling coalition, followed by mass protests, and so on. Mechanisms, by contrast, refer to what 'makes the system in question tick' (Bunge, 2004: 182). In social science this usually points to the reasons why actors behave in certain ways, the 'ultimately unobservable physical, social, or psychological processes through which agents with causal capacities operate' (George and Bennett, 2005: 137). Mechanisms account for the progression of a case along the chain of steps, and specify why actors or other entities transmit 'either a physical force or information that influences the behavior of other agents or entities' further down the line (Waldner, 2012: 76). As Hedström (2008: 320) puts it, in mechanistic explanations 'the focus is not on relationships between variables, but on actors, their relationships, and the intended and unintended outcomes of their actions'. In the above example, a mechanism could be the calculus that, in light of changing economic conditions, induces soft-liners to cause a split in the ruling coalition, or that leads trade union leaders to stage protests once they observe a divided government.

Researchers are advised to 'draw' causal pathways using flowcharts, with boxes representing the events, and arrows representing the mechanisms that connect them and indicate the direction of causality.<sup>3</sup> In my view, this is a necessary first step in any outcome-oriented qualitative project. While methodologists have identified different types of process tracing, including theory *building* and theory *testing* process tracing (Beach and Pedersen, 2013), a project cannot start without a clearly defined set of theoretical priors. Even when building theory, the researcher should arrive in the field with a preliminary map of the events, actions and reactions that she thinks could account for the connection between the independent variable and the outcome. Without the guidance of a proto-theory of the causal pathway at play that contains relatively well-specified steps and

mechanisms, it will be impossible to know what evidence to look for, distinguishing the accessory from the essential, and to weight the explanatory value of that evidence *vis-à-vis* alternative accounts.

Having to come up with a theory or model that specifies the causal pathway linking the independent variable and the outcome of interest sounds intimidating. To make matters worse, very little has been written in terms of practical advice on ‘how to theorize’ (e.g. Kohli et al., 1995; Lake and Powell, 1999; Gerring, 2001; Coppedge, 2012). In what follows I will try to demystify this crucial component of the research process by providing a series of guidelines that have helped me in the past.

## MODELS AS FIELDS

A ‘theory is a mental model designed to make sense of reality: to describe and explain or predict what we observe’ (Coppedge, 2012: 49). In order to be useful and portable heuristic devices, theories and models need to simplify reality and be pitched at a high level of abstraction. But we never theorize or model out of thin air. This is especially true in outcome-oriented qualitative research, where theories or models are usually mid-range, highly bounded and narrow in scope. We always have some level of familiarity with the countries or institutions we want to explain, and this knowledge inevitably informs theoretical assumptions about the nature of the causal pathways at play. In fact, one can think of theories or models as a transparent exposition of these priors, or what we think is going on in our universe of cases. We then probe these priors with new evidence from the cases. This does not mean, however, that our theories or models will be necessarily idiosyncratic, or cases ‘minus the proper names’. Any mid-range theory is also informed by, and anchored in, more general assumptions about how the world works,

derived from other theories, documented regularities in human action or cognition and common sense. This kind of integration makes theorizing less daunting, facilitates knowledge accumulation and adds intelligibility to our arguments within a broader scientific community (Coppedge, 2012: chapter 3). Crucially, it also renders our models testable in cases that do not constitute the direct object of the research, but are part of the relevant universe.

I like to think of the models that inform qualitative research projects as stylized descriptions of the *field* of action in which our outcomes of interest are generated. I borrow the term ‘field’ loosely from Pierre Bourdieu (e.g. Bourdieu and Wacquant, 1992: 94–110). Bourdieu uses the term to refer to distinctive social domains that emerge throughout history, such as the artistic field, the academic field or the political field. It is useful to think of a field as a space of action. These spaces have certain morphological and institutional features. For example, in the artistic field you have museums, auction houses, foundations, academies, art studios and so on. Spaces also house a variety of actors, such as artists, critics, art collectors and museum curators, which take different positions in the field and play different roles in the game that determines artistic success. The agents that inhabit a field have varying resource endowments, ‘whose possession commands access to specific profits that are at stake in the field’ (ibid: 97). Artists can paint, foundations have money and critics have authority. Importantly, not all agents have enough resources to secure goals, and most importantly, not all of them have the right kind of resources to succeed. In fact, fields favor the possession of some forms of capital over others. In the case of artists, the types of skills that can be converted into success very much depend on the taste of rich collectors and influential critics. Depending on the state of the field at any given point in time, the master of still life may or may not become a name. There are also formal and informal rules that govern behavior inside

the space. The field thus ‘guides the strategies whereby occupants of those positions seek, individually or collectively, to safeguard or improve their position in this field’ (ibid: 101). In this sense, the field structures behavior, but is also a site of ‘struggles aimed at preserving or transforming’ the rules (ibid: 101). For instance, marginalized artists may try to court critics to transform the dominant sense of taste. Finally, the boundaries that delimit the field exclude other spaces and actors, such as the millions of tourists that pack museums day in and day out but have little impact on the dynamics of artistic success.

Theorizing is therefore the process whereby we specify the boundaries and characteristics of the field in which the outcome we seek to explain is generated. Models indicate what is relevant to understand a particular phenomenon and what is not. The political world is not obviously compartmentalized into fields, so we need to bring order to it by thinking through, and justifying, our assumptions about what our domain of interest looks like and how it works. To do so, it is important to specify three key parameters of the field of action. These parameters suggest who and what matters to explain the outcome. First, the model needs to identify the *actors*, as well as their preferences, logics of actions and resources. Some actors will be considered relevant, whereas others will be considered irrelevant in the process that engineers the outcome. Similarly, some resources are crucial for them to become competent and effective players, while others are completely superfluous and therefore orthogonal to the explanatory effort. Second, the model needs a clear conceptualization of the *spaces* in which these actors act. This involves making a choice about which are the venues where the relevant developments unfold. It also entails describing the main characteristics of those venues, including the scripts, rules, vocabularies and resources relevant to navigate through such spaces, and the institutional features that constrain or enable behavior. And finally,

the model should include an account of the *interactions* between the actors, the effect of these exchanges on other actors and the space of action, and how interactions permit the flow of causal energy. Interactions could be of a strategic nature, meaning that actors with stable preferences make choices in light of what they anticipate others will do (Lake and Powell, 1999). They could also be constitutive, for example, when some actors behave in ways that fundamentally transform the preferences, beliefs and capabilities of others. Collectively, these three parameters – actors, spaces and interactions – form the basis of any explanation for why and how we get from an antecedent causal factor to the outcome of interest.

Table 6.1 summarizes the key components of the ‘field’ approach, and lists a series of questions to guide the specification exercise. In what follows I illustrate how I used this guide in my own research (González-Ocantos, 2016). I will then discuss the implications of my modeling choices for other components of the research design, including data collection, identification of alternative explanations and case selection.

## SPECIFYING THE FIELD

In *Shifting Legal Visions: Judicial Change and Human Rights Trials in Latin America* (González-Ocantos, 2016), I investigate the determinants of judicial behavior during the wave of human rights trials that swept Latin America beginning in the 1990s. Why did Argentina and Peru experience waves of human rights prosecutions after democratization, whereas Mexico did not? To answer this question I trace the processes whereby litigants and other civil society actors diffused knowledge of international human rights law as well as new professional role conceptions among local judges, thus enabling the successful prosecution of human rights criminals – including former dictators.

**Table 6.1 Specifying the field**

<i>Components of the field</i>	<i>Guiding questions</i>
<i>ACTORS</i>	Who are the main actors? Which actors play a supporting role, and which ones are irrelevant? What do these actors want? For example, status, money, power, prestige, social approval? How do these actors think? For example, are they interest-maximizers? Or are they rule followers, thinking in terms of professional norms or some other type of shared standard? Where do these norms/worldviews come from? How are they produced and reproduced? What kind of cognitive constraints do these ways of thinking impose on the actors? What resources do these actors have, and which ones do they lack?
<i>SPACE OF ACTION</i>	Where does the relevant action unfold? For example, is the space of action found in formal organizational or institutional structures, or in more informal venues? Is it limited to the nation state or does the space include international venues? Is the space temporally bounded or does it extend into the distant past? What features of the space of action matter for the process in question? For example, are there any formal institutional constraints that block or discourage certain courses of action? Are there any important power imbalances? How do actors become effective players in this space of action? Are any resources or forms of capital needed to act in certain ways or to visualize productive modes of behavior?
<i>INTERACTIONS</i>	How do the actors come to encounter each other in the space of action? Do these interactions happen naturally or do they have to be actively pursued by some of the actors? What does each actor do to the others in the space of action? For example, do actors issue threats, mount pressure, transfer money, communicate new ideas? What are the mechanisms via which these actions produce reactions? What are the reactive properties of the things transmitted through action, and what are the conditions under which they trigger the desired reactions? Which types of interactions fail to produce reactions that are consequential for engineering the outcome of interest? How is the chain of actions and reactions connected to the outcome of interest?

Theoretically, the book adopts a sociological institutionalist perspective on judicial behavior that is centered on the concept of ‘legal preferences’. I argue that legal preferences constitute a relatively stable and deeply engrained bureaucratic lens through which judges perceive the cases they are asked to adjudicate and determines which solutions they deem appropriate or possible. In the case of human rights prosecutions in Latin America, victims and their lawyers had to undermine the hegemony of formalistic legal preferences, which predisposed judicial actors to dismiss lawsuits against the perpetrators and left judges and prosecutors ill-equipped to investigate these complex crimes. Their formalistic instincts had to be replaced with a new bundle of legal preferences anchored in the values of international human rights law. This is because international human rights law makes possible innovative readings of

constitutions and criminal codes and opens up the necessary legal space for successful prosecutions. The theory specifies the conditions under which external shocks produced by organized litigation campaigns lead to such ‘shifts in legal visions’, triggering structural transformations in the jurisprudential criteria applied by the courts. The book thus explores how the reproduction and transformation of ideas about the law and received standards of legal praxis shape the role judges are willing and able to play in politically salient debates, conditioning the exercise of judicial power.

Political outcomes are always the product of people doing things. Even if the story is deeply structural, there must be a discussion of the *actors* involved, and why they are driven to act in certain ways. In my case, the actors who determine whether or not there is justice for the victims of state repression are the judges and prosecutors. For example,

they are the ones who must decide whether to uphold amnesty laws or declare them unconstitutional and proceed with the investigations. Judges and prosecutors are also in charge of devising creative strategies to collect evidence. This is an extremely difficult task because the crimes in question were usually committed decades before and covered up using the state apparatus (e.g. forced disappearances). And once the evidence is collected, judges and prosecutors have to evaluate whether or not it is enough to convict the defendants. All of this may sound obvious, but many accounts of transitional justice in Latin America ignore judicial actors, or relegate them to a secondary or passive role.

In addition to specifying what the protagonists need to do in order to produce the outcome, it is also important to explain our assumptions about how these actors think and what they want. In the case of judges and prosecutors, I contend that they inhabit an environment that is highly regulated by norms of professional conduct, which are the result of socialization processes inherent to the legal field.<sup>4</sup> Socialization promotes dispositions, ways of reasoning and patterns of behavior that are scripted by the language of the law, and results in the institutionalization of what I call 'legal preferences'. Legal preferences encompass views about the reach and pliability of formal judicial prerogatives, and what constitute legitimate sources of law (domestic, international, doctrinal), acceptable forms of legal argumentation or reasonable standards of proof. These preferences thus engender a logic of behavioral appropriateness that leads judges to believe that certain legal solutions ought to be favored and defended, regardless, for example, of what politicians may prefer or instruct them to do. In addition, because legal preferences promote adherence to routine decision-making templates, they structure the judicial imagination and constrain the types of decisions judges are likely to reach. Unlike other scholars of judicial politics, I therefore do not think of judicial actors as

interest-maximizers who behave strategically to advance policy or career goals, but rather as followers of professional behavioral standards. This characterization is relevant because it means that judges need to be persuaded that there are plausible legal arguments in favor of a specific case outcome before they can become champions of particular causes or interests. Political pressures in one direction or another do not necessarily determine how they rule. Moreover, radical changes in decision-making routines and the adoption of novel legal criteria that enable jurisprudential innovations are unlikely to happen in the absence of re-socialization processes that uproot existing legal preferences and diffuse alternative ones.

Latin American judiciaries were historically dominated by formalistic legal preferences, which, in cases of state repression, biased judicial actors in favor of upholding amnesties and statutes of limitations, and left them ill-equipped to gather the necessary evidence and evaluate its probative value in ways that benefited the victims of repression. Importantly, these legal preferences made most judges ignorant or deeply skeptical of international human rights law, which is the body of law that makes prosecutions possible. This characteristic of the main actors in the story and their milieu has critical implications for identifying other key actors, as well as the forms of capital they need to amass to induce judges to produce waves of human rights trials.

Unlike other accounts, mine does not emphasize social pressure in the form of protests or activists' presence in the media, the relative power of the military post-transition, the levels of support for transitional justice among politicians or the international processes whereby human rights legal norms are created and diffused. I put judges at the center of the story; they are the ones who hold the keys to the outcome. Importantly, because I assume that judges behave as rule followers and not interest-maximizers, the argument is that politicians or passionate protests cannot

easily whip them into handing down prison sentences or acquittals out of fear of losing their jobs or seeing a decline in popularity. Moreover, since the standards which judges follow are deeply engrained, international human rights norms do not easily trickle down into domestic jurisprudence. Learning doesn't happen by osmosis; actors outside the judiciary must actively promote it.

If the above assumptions about how judges think are correct, the success of criminal prosecutions depends on the extent to which formalistic legal preferences are replaced by new ones, specifically, legal preferences based on the values of international human rights law. This allows me to identify the other key actor in the story, namely victims of state repression and the organizations they create to fight for justice. Victim organizations prevail when they are able to bring cases to court, and, crucially, engage in re-socialization efforts, diffusing new legal knowledge and innovative standards of adjudication that enable the success of those lawsuits. And to do so, they must amass very specific kinds of resources that allow them to infiltrate the judiciary, speak the language of judicial actors and craft skillful and ambitious interventions to change how judges and prosecutors see their obligations in cases of state repression. Staging mass protests and obtaining other forms of political capital doesn't do the trick; instead, victims need to recruit professionalized legal teams and allies in the academic world capable of transforming formalistic legal preferences.

The model therefore highlights the relevance of formal and informal processes at the level of the nation state associated with litigation efforts by victims and their lawyers. The *space of action* is not the street, presidential palaces, military barracks or the international forums where human rights norms develop, but national courts and their surroundings. It is here that the battle for justice is ultimately won. Furthermore, my characterization of the institutions and logic of action of the legal field leads me to identify the forms of capital

that are needed to act effectively in pursuit of certain objectives. Victims must be able to intervene in very specific ways in order to achieve their aims. In this sense, I emphasize the importance of contacts between victims and judicial actors that enable the spread of new ways of thinking about the law.

After specifying a space for action embedded in the judiciary and inhabited primarily by judges, prosecutors-and litigants, the next step is to describe the relevant *interactions* conducive to the outcome of interest. I argue that when victim organizations are equipped with professionalized legal teams, they are able to understand the obstacle posed by the incompatibility of arguments based on international human rights law and dominant formalistic legal preferences. By taking seriously how judges and prosecutors think about these cases as professionals of the law, litigants are able to design effective tactics of legal contention that produce necessary changes in legal preferences. The main tactic consists of orchestrating pedagogical interventions.<sup>5</sup> These include the organization of seminars on human rights law for judicial personnel and the circulation of academic material in court. Litigants thus teach members of the judicial community complex and often ignored juridical doctrines, and in the process disrupt bureaucratic inertia, manufacturing a legal framework that favors indictments and convictions. The ideas circulated in these venues have a technical component that creates a roadmap for new patterns of judicial behavior, and also a normative component that legitimizes unusual courses of action.

Pedagogical interventions activate a re-socialization mechanism that transforms legal preferences and jurisprudence. I rely on existing theories of education and socialization to specify the characteristics that make these interventions effective. I suggest that if pedagogical interventions are designed in certain ways they will trigger psychological reactions that facilitate persuasion. I also describe contextual factors that make success more likely. For example, I contend that the timing

of pedagogical interventions vis-à-vis similar efforts by those who seek to promote impunity, or vis-à-vis court-packing initiatives by anti-transitional justice coalitions, matters a great deal. If victim organizations strike first, they usually encounter a wider pool of persuadable judges and can engineer more robust ideational transformations. Robust ideational transformations guarantee that trials are more far-reaching and ambitious.

The model specified to answer my research question suggests that waves of human rights trials are not so much the result of the political will or capacity of democratic politicians to hold dictators accountable, but occur when judges are equipped with the legal preferences needed to deal with these unusual and complicated cases. Judicial actors must learn about international human rights law to be able to deliver justice, and victim organizations are the ones who supply this information. The causal chain thus begins with victim organizations forming professionalized legal teams, which in turn enable them to understand the problem posed by formalistic legal preferences and the need to change them. It continues with these organizations deploying specific tactics of contention, that is, pedagogical interventions that activate a re-socialization mechanism. The third step is the ensuing transformation in legal preferences, which equips and commits judges to adopt innovative patterns of behavior compatible with transitional justice. Importantly, the new sense of professional mission that is instilled by the new legal preferences encourages judges to resist military or political pressures contrary to prosecutions, and continue working for the victims. All of these modeling choices are based on prior knowledge of the cases (e.g. Latin American legal cultures and their incompatibility with the international legal case for prosecutions), as well as on well-established theories and empirical findings (e.g. assumptions about the psychological underpinnings of socialization processes).

In the following sections, I discuss how spending time on theory development along

the lines of the field approach can be of great use further down the line.

## IMPLICATIONS FOR DATA COLLECTION

Thinking in terms of fields, and the processes that unfold within them, disciplines key components of the research project. In particular, these models serve as roadmaps during fieldwork and structure the data collection process by making it easier to derive observable implications.

Ideally, our fieldwork should follow a sequence that mirrors the sequence of steps specified in the causal chain. There are two reasons for this. First, our models are only validated when all steps in the causal chain are adequately documented (George and Bennett, 2005: 207; Beach and Pedersen, 2013: 39; Waldner, 2014: 132; González-Ocantos and LaPorte, forthcoming). Insofar as our goal is to provide a logical or internally sufficient account of the outcome of interest, the inability to document some of the steps in the model will force us to go back to the drawing board to rethink the causal chain. And because models assume that each step describes a reaction or state of affairs that is brought about by a preceding step, it makes sense to try to document them in the order we specified in the model.

For example, when I conducted my research on transitional justice, I first documented how victim organizations assessed the obstacles they faced at the start of the process, followed by an analysis of the tactics they deployed as a result of their diagnosis of the nature of the challenge ahead. Once I had gathered enough evidence suggesting that they indeed understood the problem posed by formalistic legal preferences, and reconstructed the informal spaces subsequently created for pedagogical interventions, I proceeded to interview the judges to probe legal preference change. Had I not been able to

establish the first two steps in the sequence, I would have had to rethink the model before contacting judicial personnel.

Second, this sequential approach to data gathering makes fieldwork more productive. Each step in the causal chain essentially involves actors doing things to other actors. So if we first obtain information about the actors instigating the process and their behavior, we immediately have a better sense of what information to look for regarding the targets of those actions. In my case, knowing the details of pedagogical interventions allowed me to identify relevant judicial personnel, and improved my ability to question them about those experiences and the effects, if any, that the interventions had on legal preferences.

Another way in which the field approach contributes to more effective data collection is by making it easier to derive observable implications. Before arriving in the field site, researchers must produce a comprehensive list of the kind of empirical evidence that would be compatible with the model. These are the fingerprints that the process leaves in the available record if our story is correct. The assumptions and choices we make at the model specification stage are an obvious point of departure: 'if this assumption is correct, I should observe X, Y and Z'. Moreover, listing observable implications for each step of the chain makes the task more manageable.

For instance, my assumptions about the relevant space of action led me to think in advance about the characteristics of the informal venues where pedagogical interventions take place. As a result, I had a sense of what to look for when rummaging through the archives of victim organizations: funding bids to support the interventions, reports to funding agencies describing how the funds had been used, lists of participants, syllabi and course packages distributed among participants, and so on. Another challenge was to document legal preference change and its consequences, in line with my assumptions about the non-strategic nature of judicial

behavior. I posited that judges and prosecutors must recognize shifts in their knowledge and standards of adjudication as a result of the pedagogical interventions, and assign greater importance to these changes than to their prior legal knowledge or other forms of influence. Specifically, changes in legal ideas should be reflected upon and admitted, and prior formalist preferences should be evaluated negatively. I deemed this a hard test for the argument because I expected judicial actors to be quite reticent to admit prior ignorance of international law or the informal influence of the victims. The exact nature of the evidence was of course determined by access and country-level characteristics. Whereas in Argentina I relied mainly on in-depth interviews, in Peru I supplemented interviews with a survey of prosecutors that I was able to conduct with the help of the authorities. Similarly, the sheer volume of court cases in Argentina allowed me to build a dataset of rulings, and use simple statistics to test the impact of instances of overt political pressure on the judges on their decision-making patterns. This produced evidence incompatible with strategic models of judicial behavior.

## **IMPLICATIONS FOR IDENTIFYING ALTERNATIVE EXPLANATIONS**

A robust modeling exercise at the start of the research project also facilitates the identification of relevant rival explanations. Process tracing methodologists advise us to 'cast the net widely for alternative explanations' (Bennett and Checkel, 2015: 23). This is crucial for the success of the qualitative enterprise because the quality of the data is not determined by the sheer amount of evidence, but by the extent to which different observations are compatible with our story and incompatible with its rivals. But casting a wide net can be quite challenging, and is usually a source of anxiety. An obvious resource

is the existing literature on the topic. After all, when we design the project we always do it with reference to this literature in an effort to carve out a space for our work, showcasing its originality and import vis-à-vis existing accounts. While the literature will probably not reveal an exhaustive list of rival explanations, it will certainly give us a sense of the most influential ones.

Modeling in terms of fields is equally helpful. As Lake and Powell (1999: 14) put it, '[a]ll theories attempt to simplify a complex reality, and, as a result, they all reflect judgements made by theorists as to what to put into their analysis and what to leave out'. When we specify the contours of the field and its inhabitants we make choices about who and what matters, and who and what does not. We contend that some venues may be hidden from view but actually exist and are crucial for understanding the outcome, that some logics of action take primacy over others, that some forms of capital are more productive than others or that some tactics work better than others. It follows that what we consciously leave out or downgrade in importance is a good candidate for a rival explanation. This does not mean that all of the assumptions that produce exclusions of this sort can or need to be tested, but our work will be more convincing if we minimize the number of assumptions that goes untested.

In my case, the model produced two important rivals. First, I assumed that judges hold the keys to unleash waves of human rights trials. Moreover, I argued that they behave as rule followers rather than interest-maximizers that think strategically to determine how to behave. This led me to position myself against influential models of transitional justice, which emphasize, for example, the centrality of the balance of power between military and civilian authorities post-transition, or the preferences of elected politicians vis-à-vis human rights prosecutions, in determining the outcome of the trials. In these accounts, judges are epiphenomenal actors, and respond to signals from politicians and military officers, handing

down convictions or stalling the investigations accordingly. By contrast, my depiction of the space of action and the cast of relevant actors suggested something very different, and forced me to document the crucial role of factors and processes downplayed by other work.

Second, I circumscribed the space of action to the nation state – specifically, to judicial institutions and the informal venues litigants create for pedagogical interventions. Whereas the human rights doctrines that litigants need to teach are the product of international processes of norm development, my claim was that the relevant action in cases of transitional justice takes place at the domestic level. International norm development is insufficient because it does not explain why or how national judges come to learn and accept standards of adjudication so foreign to their legal culture. Accounts that emphasize the direct influence on judicial behavior of events that take place abroad (e.g. international litigation efforts, international campaigns against impunity, etc.), affirming global human rights standards and shaming local authorities who remain reluctant to assist the victims, were therefore competing explanations to which I had to attend.

## IMPLICATIONS FOR CASE SELECTION

Qualitative researchers often choose cases for non-methodological reasons, including our personal obsessions and linguistic skills. We are also drawn to cases because of their historical significance, or because they have been sparsely researched. For instance, I am originally from Argentina and could not conceive of a research design that did not include this case. Transitional justice has been a defining issue of the country's politics during my lifetime, and always preoccupied me. In my view, there is nothing wrong with applying such criteria. As Guillermo O'Donnell put it, 'my questions still come from broad political and moral concerns [...] I've tried to

deal with the kinds of real-world problems that deeply bother me when I'm shaving' (Munck and Snyder, 2007: 297).

Having said this, justifying the case selection with methodological criteria is of critical importance. For example, a good case selection strategy may allow for a rigorous probe of the scope of the argument by examining it under a variety of theoretically relevant conditions. This in turn enables a defense of the portability of the model beyond the main empirical referents. Similarly, if one is lucky enough to be able to craft tightly controlled comparisons, it may be possible to rule out alternative explanations by design. The literature already offers excellent advice on case selection, so my goal here is admittedly quite modest.<sup>6</sup> I simply want to point out ways in which thinking of our models as stylized descriptions of a field may also help us select positive and negative cases.<sup>7</sup>

With regards to positive cases, that is, those in which the outcome occurs, specifying the main contours of the field and its internal logic helps identify the contextual factors that the design should try to vary within and across cases. This variation is often needed to show that the argument applies in a variety of contexts – that is, it is not idiosyncratic – and, most importantly, to show that those contextual features do not necessarily explain the outcome. The latter is a good way to undermine alternative explanations. To accomplish this, we should seek variation in contextual factors that are associated with an alternative explanation and that are therefore not expected to fundamentally affect the dynamics of the field or the production of the outcome. This could be because changes in context introduce irrelevant actors, or trigger interactions outside the relevant space of action, that can be shown not to affect the outcome. Changes in context may also fail to condition the supply of productive capital to the relevant actors or the successful deployment of the tactics that, according to our theory, activate key mechanisms of change. In other words, by specifying the field along the

lines suggested here, it is possible to anticipate whether different background conditions or environmental shocks will be inert, or collide with the field and produce consequential reactions.

For example, the two positive cases in my study, Argentina and Peru, offer within and cross-case variation in the preferences of elected officials vis-à-vis transitional justice and levels of hostility of the political environment toward victim organizations. By analyzing how the process unfolds in contexts with more or less hostility, I am able to show that the implementation and success of pedagogical interventions does not depend on the tolerance for prosecutions among the political class or the strength of the military, and that the judiciary does not necessarily rule with an eye on these strategic incentives. I can also show that in favorable environments where the political class strongly supports the trials, the absence of pedagogical interventions, or the presence of interventions that are not designed carefully, leads to a weaker impetus for justice among judicial actors. This is because the logic that governs the judicial field requires legal preference change in order to observe dramatic shifts in the jurisprudential criteria applied by the courts. And the ability to induce such changes, that is, the type of capital that 'confers power' or is reactive in this field (Bourdieu and Wacquant, 1992: 101), is not dependent on political power but on skillful pedagogy.

A robust modeling exercise at the start of the research project can also help select negative cases, that is, cases in which the outcome does not occur. While the main source of inferential leverage in outcome-oriented qualitative research comes from the reconstruction of uninterrupted causal chains in positive cases, a comparison with a negative case provides empirical evidence in support of counterfactual reasoning. But negative cases present unique challenges when it comes to case selection. There are usually a huge number of cases, both historical and contemporary, where the outcome

of interest is absent. So which ones should we pick? Mahoney and Goertz (2004) argue convincingly that one should apply the ‘possibility principle’ to select relevant negative cases, that is, cases where the outcome could have occurred but didn’t. They propose two selection rules. According to the ‘rule of inclusion’, the value of at least one independent variable must be associated with a positive value in the dependent variable. According to the ‘rule of exclusion’, the value of none of the independent variables must predict a negative outcome with certainty. Cases that do not meet these criteria should be avoided.

The field approach is useful to think about how to apply these rules. If our point of departure is a clearly specified causal chain, with actors, spaces of action and interactions, it is possible to identify negative cases where at least some of the elements of the field and the causal chain are present. In particular, we should strive to select cases where the main actors are present, have some of the forms of capital needed to activate key mechanisms of change and interact with each other in various ways. This means that the outcome could have happened had the right kinds of interactions taken place, or had the actors amassed additional forms of capital. A negative case with these characteristics allows us to trace the point in the sequence at which the flow of causal energy is interrupted or stops, bolstering claims regarding the importance of all component parts of the model in producing the outcome. Moreover, the interactions between the key actors leave footprints, which enable the application of the tools of process tracing. Without these fingerprints, it is hard to apply the method.

The main negative case in my study is Mexico. I chose it because I knew that, as in the positive cases, the judiciary harbored formalistic legal preferences incompatible with human rights prosecutions, a key feature of the field of action. Moreover, Mexico has a vocal and well-organized human rights movement that fought hard to punish those responsible for the crimes

of the ‘dirty war’. In other words, the cast of central actors was complete. Finally, in the aftermath of the 2000 democratic transition, a special prosecutor was appointed to investigate these cases and subsequently filed numerous lawsuits against former politicians and military officers. This created the space for sustained interactions between victim organizations and judicial personnel, which left behind traces. During fieldwork, I found out that victim organizations focused on amassing unproductive forms of capital, such as links with political parties or mobilization capacity, instead of investing in professionalized legal teams. They therefore failed to understand the logic that makes the legal field ‘tick’, and were incapable of designing and deploying the tactics of contention to activate the re-socialization mechanism. In their encounters with judicial actors, activists did not diffuse new legal knowledge or jurisprudential standards to transform legal preferences, and this interrupted the flow of causal energy.

## CONCLUSION

In this chapter I reflected upon my experience as a qualitative analyst and provided some advice on how to design a project. The discussion is mainly relevant for research that explains political outcomes by tracing processes within cases, and that compares a small number of cases. The key message is that attention to theoretical priors from the very beginning is crucial, and has implications for data collection, the identification of alternative explanations and case selection. Importantly, the emphasis on modeling choices suggests that qualitative research is not merely about ‘soaking and poking’, but is disciplined by variables, hypotheses and concomitant observable implications. Modeling may at first seem like a daunting task, but thinking in terms of fields and their three components – actors, spaces of action and interactions – can make the job easier.

Qualitative research is not for the faint of heart. It requires the collection of copious amounts of data, often of radically different kinds within and across cases. This in turn forces researchers to become attentive to infinite sources of bias. We are also highly vulnerable to disconfirmation in the event that we end up with gaps in the evidentiary record. This is because, unlike an empty cell in a quantitative dataset, missing information about key steps or mechanisms fundamentally undermines the central promise of process tracing methods, which is to reconstruct the proposed causal pathway in its entirety (González-Ocantos and LaPorte, forthcoming). But qualitative research is also exciting and tremendously rewarding, especially during those eureka moments when we stumble upon precious smoking guns. Having well-specified models from the start structures the research process and gives it a clear direction of travel, boosting the chances of finding such evidence and generally making fieldwork more productive. It also adds rigor to the project because it provides readers with a yardstick to evaluate the logical consistency and persuasiveness of the narrative.

By way of conclusion, I would like to point out the wide range of applications of the field approach. First, the emphasis on strong theory does not mean that inductive research is off the table. While the model is designed to offer a roadmap for the research process, it still allows for detours as we enter into a dialogue with the cases and the evidence. Amending parts of the model as we go along is not 'unscientific' insofar as the goal of outcome-oriented qualitative research is precisely to provide a comprehensive explanation of political outcomes. In my case, for example, my model only specified re-socialization as a key mechanism of change. When I started collecting data about judges, however, I realized that some of them were deeply recalcitrant and not amenable to persuasion. Furthermore, I saw how victim organizations reverted to other tactics (e.g. impeachments) to get rid of them and make

way for new voices in the judicial branch. My amended model thus offered a more adequate characterization of the cast of actors in the field and the mechanisms of change, and as a result, it was better equipped to explain outcomes within and across cases.

Second, the centrality of actors and interactions may leave the impression that the field approach is not useful for probing structural accounts. This is not the case. By employing the term 'actors' I do not necessarily endorse a strong version of methodological individualism. With the right theoretical justification, the entities that act in our models could be specified at various levels of aggregation (e.g. president, cabinet, ruling party or even dominant class). Moreover, nothing stops us from assuming that individual actors are more or less determined and constrained by deeper social forces at play in any particular field. For instance, behavior by members of a social class need not be conscious or planned, but the result of atomized choices resulting from shared circumstances. The point is simply that structural factors impact reality through the beliefs, perceptions and actions of individuals and groups, so these remain a crucial component of any model. Without some reference to actors, their behavior and interactions, the story is likely to remain logically incomplete. As George and Bennett (2005: 142) explain,

[m]acrosocial mechanisms can be posited and tested at the macrolevel [...] All that commitment to microlevel consistency entails is that individuals must have been capable of behaving, and motivated to behave as the macrolevel theory states, and that they did in fact behave the way they did because of the explicit or implicit microlevel assumptions embedded in the macrolevel theory.

Or in Kitschelt's (2003: 59) words: 'weak methodological individualism is not inimical to the consideration of structural and collective phenomena. It only requires that we treat individuals' actions as critical ingredients in any account of structural transformation.'

A related concern is that an emphasis on actors and interactions favors explanations

that are too proximate to the outcome to be considered 'causal'.<sup>8</sup> This is also not the case. Thinking in terms of fields and their constituent parts does not mean that one should only look at decisions immediately prior to the outcome. In fact, causal chains usually extend back in time because we must account for the antecedent process, including the creation and transmission of necessary forms of capital to the final decision-makers, mechanisms of preference change or the entrance of the relevant actors into the space of action. How far back to go is a theoretical decision that is not necessarily constrained by the need to specify actors and their interactions.<sup>9</sup> In this sense, there are a variety of ways to locate theoretically the starting point of the causal chain. For example, in the case of outcomes characterized by some form of path dependence, we may look for relevant critical junctures (Capoccia, 2015). We may also choose to begin where rival accounts take off in order to challenge the presence of a causal pathway along the lines specified in those models. Or we may decide to start when the relevant cast of actors is complete or at a point when the main contours of the space of action are already constituted.

Finally, economicist terms such as 'capital' could also suggest that the 'field' approach is only suitable for rational choice scholars or game theorists. This is also a misperception. The primary logic of action of any particular field or actor could be consequentialist, strategic or utility maximizing, but it can also be rule oriented, role satisficing and deeply constituted by social norms. Similarly, the deployment of (or quest for) certain forms of capital could result from conscious calculations or unconscious dispositions. However we define these preferences and logics of action, the 'field' approach allows us to identify the types of behavior that are capable of making the system tick in the direction of the outcome of interest, removing blockages and shifting the balance of power against champions of the status quo. These are the moving parts of the model (which some researchers,

but not all, may see as a 'game' of strategic interactions) that explain within-case variation or stasis in the dependent variable.

## Notes

- 1 This is not to say that qualitative researchers never start with a comparative research question that doesn't feature proper names, and proceed to choose cases deductively. This is common, for example, in the case of cross-regional comparative studies (e.g. Lieberman, 2009).
- 2 For a similar approach, see Lake and Powell's (1999) strategic-choice template for theory building. I thank Branislav Slantchev for pointing this out. The 'field' approach, however, does not necessarily rely on rational-choice assumptions. For a more detailed discussion, see the concluding section.
- 3 Waldner (2014) refers to these as 'causal graphs'.
- 4 For Bourdieu's own application of the field approach to the legal field, see Bourdieu (1986).
- 5 The model also includes a second tactic, namely personnel replacement strategies. For ease of exposition, I will not refer to this part of the argument.
- 6 Important contributions include Lijphart (1971), Mahoney and Goertz (2004), George and Bennett (2005), Lieberman (2005), Gerring (2007), Gerring and Seawright (2008), Slater and Ziblatt (2013), Beach and Pedersen (2016), Seawright (2016) and Goertz (2017).
- 7 Dependent variables need not be binary (positive/negative, present/absent) or ordinal (various degrees of presence/absence). For example, many qualitative researchers work with categorical dependent variables.
- 8 For example, Coppedge (2012, chapter 3) makes the case that distant factors are analytically superior. For a defense of proximate factors, see Kiser and Hechter (1991), Capoccia and Ziblatt (2010) and Mainwaring and Pérez-Liñán (2013: 30–3).
- 9 But there might be a trade-off between causal distance or 'depth' and our ability to trace mechanisms that inhere in the minds of actors. See Kitschelt (2003).

# Theory Building for Causal Inference: EITM Research Projects

Thomas Bräuninger and Tilko Swalve

The golden rule that any empirics without theory is, at best, descriptive is likely to be taught to any undergraduate student in her very first year. And there is nothing wrong with this. At the most basic level, the rule reminds us that whatever the co-occurrence of two events, or however strong the correlation of two variables might be, we should not stumble into a fallacy, for example, believing that babies are delivered by storks when observing an association between the number of storks and the number of human births. At a more specific level, the rule includes a warning, namely that any sort of evidence for the specific causal mechanism which a theoretical argument postulates does not rule out alternative explanations. Data may provide strong empirical evidence for a causal mechanism; at other times, the argument fits into a broader, more general, or established theory. Neither case rules out the appropriateness of any other conceivable mechanism in some hypothetical theoretical account. Practically, the question then becomes how to find a

method for inference that lets the data speak to the specific mechanism we have in mind, not to any conceivable mechanism. This is the aim of the Empirical Implications of Theoretical Models (EITM) approach. The EITM approach is a device to ‘think about causal inference in service of causal reasoning’ (Aldrich et al., 2008).

We should stress that, while the EITM approach seeks to bridge the gap between theoretical and empirical work, it is not just a missing piece to fill a gap in a research design. We think of the EITM approach more as a way to think about related questions. First: how do you improve your methodological reasoning so that empirical work is most effective and informative about theories? Second: how do you improve your theoretical reasoning to provide a larger number of useful theoretical hypotheses that can be evaluated against the evidence of empirical models? In doing so, the EITM approach provides a ‘coherent approach to evaluating information and converting it into

useful and effective knowledge' (Aldrich et al., 2008: 828).

This chapter introduces the EITM approach; discusses its methodological foundations, virtues, and challenges; and exemplifies good practices using recent academic work on topical research issues. We discuss three different research designs for how to assess the usefulness of a theoretical model to explore a causal mechanism using data: (1) equilibrium point predictions; (2) comparative statics (the evaluation of relationship predictions); and (3) structural estimation approaches. We introduce each approach with a simple example and pieces of recent research that are exemplars of how to exploit the strength of each design. Finally, we give some advice on how to strengthen research designs using the EITM methodology.

## WHAT IS EITM?

The EITM approach promotes the idea that, in the best case, there is a tight connection between a theoretical argument represented by a formal model and an empirical data analysis used to learn when and how the model finds empirical support (or not). There are ontological and methodological presumptions underlying this idea. One is that the ultimate goal of social science inquiry is the explanation of empirical events in the sense of deducing the specific event or statement from a general, theoretical statement about causal relationships. The creation and evaluation of such theoretical statements, then, is an integral part of scientific inquiry. Another assumption is that theoretical statements about states, events and causal relationships can reasonably be captured by formal models.

In making such a claim, we also assume that empirical data can be useful to identify or evaluate the model (the two are not the same; nor is empirical analysis the only way to evaluate a model: see more on this below),

and that evaluation and model identification can tell us something about the usefulness of the theoretical model, and therefore give us a better understanding of the world. Note that we shy away from using the term 'model testing' here. As Clarke and Primo (2007: 749) remark, models are representational objects; they cannot be true or false. Also, as models serve more than just predictive purposes (they may also be foundational, structural, generative, explicative), they 'should be assessed for their usefulness for a particular purpose, and not solely for the accuracy of their deductive predictions'.<sup>1</sup>

Starting from these assumptions, the diagnosis and motivation for the EITM approach is the observation that much research squanders a great deal of the enormous potential of close links between theoretical and empirical work. This criticism concerns at least one of two points.

First, much theoretical work remains at the level of theory, forgoing the chance to learn more about the *theoretical* argument by exploring empirical data. When the EITM project began in 2001, with an NSF workshop to discuss avenues for improving technical-analytical proficiency in political science, a widely shared concern was the perceived uncoupling of theory building and empirical research as a result of the fast advancement of the discipline's research methods. Since the 1960s, theory building in political science has largely benefited from and partly moved to represent and quantify abstract concepts mathematically, using tools and concepts of social choice, game theory and microeconomics. This fostered precision in theory building, and hence improved research transparency, lent credibility to this type of work and resulted in knowledge accumulation. At the same time, the evolution of novel statistical and computational methods fostered the specialization of researchers employing applied statistics and empirical modeling. It was felt that a split had developed between the two camps, or, at least, that graduate training was too often one-sided and created

sophistication in either formal or empirical modeling, but not both (National Science Foundation, 2002: 1). The critical question then became how to link rigorous theoretical reasoning and appropriate identification strategies to learn about a causal mechanism.

Second, data analysis is often not tied to the theoretical model and, therefore, it is not informative about the causal relationships postulated by the model. Moreover, the focus of analysis often is on one specific causal effect. Much more could be done with a theoretical model, however, in order to derive empirical implications that can then be combined with data to support modeling assumptions, provide a better understanding of the causal mechanism or gain insight into an entire chain of postulated causal relationships. All these types of analyses in the EITM approach offer valuable payoffs.

## FROM THEORETICAL MODEL TO IMPLICATIONS

We use the terms ‘theory’ and ‘theoretical model’ in a quite pragmatic way. A theoretical model is a representation of a causal mechanism. A theory is a set of models that is linked by hypotheses to a set of related features of the real world (Giere, 2010: 85). In this definition and in accordance with common usage in the social sciences, the term ‘theory’ means a larger structure that collects models that may address different aspects of the real world, such as the ‘theory of coalition formation’ or ‘bargaining theory’. The really important term here is ‘representation’. A theoretical model does not mirror the world on a smaller scale; nor does it simply represent a part of the world. A model simplifies and, in doing so, it focuses more on some aspects and less on others.

To be sure, there are decidedly different ideas on how the term model should be defined and, consequently, what a model really captures. One view is that there is a

*data generating process* that is behind what we observe (Morton, 1999: 33). This mechanism can be detected, at least in principle. The goal of science is, then, to reveal the mechanism, or get as close as possible to it. From this point of view, it makes sense to say that a model is valid (or invalid). Thus, model testing is an instructive scientific strategy. If the model repeatedly fails to pass some benchmark, it is considered falsified by the data, and thus rejected (Popper, 1959). In this classical falsification framework, the test against data is the relevant benchmark, and any such test probes both the model’s postulated mechanism and all (often implicitly stated) auxiliary assumptions.

Another, no less extreme, view is that real world processes are so complex that we can hardly hope to come even close to the true data generating mechanism. From this perspective, models are gross simplifications of the world that, given enough data, would always be rejected (Keane and Wolpin, 2007: 1351). The very idea of model testing thus becomes meaningless. What we can say and do, however, is gauge whether one model fits the data better than a second one – a procedure one may dub model selection. There might even be alternative models, so that each performs best in some contexts, but not in others. The real danger here is to mistake the selection of a proposed and stated mechanism with atheoretical, ad hoc curve fitting that might fit the data well, but consistently performs worse out-of-sample and hardly reveals a deep theoretical structure. A model that relates election results to pre-election polls of the days and weeks before is likely to predict the data with stunning accuracy, but is not very enlightening.

Though interesting, the epistemological debate about what is best conceived as a model is less important for our discussion. The EITM approach is useful in a wide range of contexts and with different epistemic interests (though we lean toward the second perspective in what follows). In some cases, we are interested in the effect of one specific

feature of the world, say  $X$ , on some outcome  $Y$ . Suppose there are other features,  $Z$ , that arguably have an effect on  $Y$ , but we have good reasons to assume that some separability condition holds and the relation of  $X$  and  $Y$  is unrelated to  $Z$ . Then, if our (novel) theoretical argument is captured by a model that includes  $X$  and  $Y$ , possibly in some complex way, a comparative static tells us *how*  $X$  is related to  $Y$ . A ‘test’ of the model would focus on the expected covariation of  $X$  and  $Y$ . The focus here is on the correctness of the model prediction: can we see in the data that  $X$  is related to  $Y$ ? Whether, or to what extent, the model is successful in predicting observed outcome  $Y$  is not important here.

In other cases, we are interested in the substantial effect of some rule change, institutional reform or novel policy program. Does a 10% decrease in the required majority for a cloture cut the average duration of legislation in half? Does a 5% increase in child benefits have a larger effect on education equality than a 10% reduction in daycare fees? The focus with these types of research questions is on the size of the change in  $Y$  given some intervention  $X$ . A model useful to answer the latter question would take into consideration, for instance, how child benefits and daycare fees affect consumption and schooling decisions, while also taking into account expectations about the implications of these decisions in the future, and so on. While some mechanisms are better understood, other critical features of the model, like risk aversion and foresightedness of parents, have to be estimated as model parameters from the data. As the evaluation of a policy change is based on the comparison of effect sizes, a model must not only capture the key mechanism but also fit the data reasonably well. The approach here is closer to the idea of model selection (via estimation of parameters). What we are interested in is also completeness; that is, how much of the systematic variation in the data that the model aims to explain is captured by the model (Mullainathan and Spiess, 2017).<sup>2</sup>

The key value of a formal model is the clarity of its assumptions. Any theoretical argument that proposes a non-trivial link between a cause and an effect builds on a long list of assumptions about who acts and interacts when, how and with whom. It will also make auxiliary assumptions on the set of cases the model applies to, the nature of the (collective) actors, the cognitive capacities of agents, etc. Often these assumptions are seemingly innocent, as they appear to be common sense or trivial. A formal model makes these assumptions explicit.

Suppose we are studying popular protest in authoritarian regimes. While there are plausible arguments on socio-economic conditions favorable for uprisings, a formal model to capture the theoretical argument will not just explicate what motivates and constrains individuals. Instead, it will also make explicit whether the argument operates on the level of the public at large or on the level of individuals; whether, and, if so, how these differ and how individuals solve their collective action problem; or whether these problems are assumed away by auxiliary assumptions.

Auxiliary assumptions are a key part of a model, as no model can possibly capture every aspect of reality (Low and Meghir, 2017: 34). A model captures something essential of the data generating process, but not everything. A model of legislative oversight might consider variance in institutions, legislative majorities, and legislators’ preferences for one or another form of oversight while deliberately ignoring the role of a supreme court (McCubbins and Schwartz, 1984). This is not to suggest that supreme courts do not play any role in a legislator’s decision-making. It does assume, however, that decisions over police patrols or fire alarms are not substantially affected by long-term considerations. The question is: what can and cannot be left out to ensure the substantive conclusions of the model remain valid?<sup>3</sup>

A helpful term in answering the question is the term ‘separability’. Separability can

**Figure 7.1 Models, theoretical implications, and features of the real world**

Source: Adapted from Clarke & Primo (2012)

be understood as the invariance of an ordering on a subspace with respect to changes of variables outside the subspace (Blackorby et al., 1998). In fiscal policy literature, for instance, budgetary politics is often considered as either a top-down or a bottom-up process. In countries with a bottom-up process, so the story goes, individual portfolio ministers draft sectoral budgets, which are then aggregated and finally settled in bargaining. Where fiscal institutions allow for a strong finance minister, the budget process is more top-down: the finance minister decides on the total budget, and the allocation to portfolios is determined by intra-cabinet bargaining. In the first case, the total amount to be spent and the allocation are interrelated, and there is strategic interaction between agents. Whatever the ministerial draft looks like, it will affect both the total budget and the allocation. This is different in the second scenario, where bargaining over the allocation happens when the total budget is already fixed.

When modeling intra-ministerial bargaining, we therefore may consider the total budget as a fixed parameter, rather than reflecting on a full model that would model both the finance minister's decision and the allocation decision. The total budget can be thought of as *sufficient statistics*: something that summarizes decisions made outside the model (Low and Meghir, 2017: 34).<sup>4</sup> From the discussion, it should be clear that practically any political science model makes separability assumptions.

Whether or not a model has bite (we deliberately avoid terms such as right or wrong: see above) largely depends on the appropriateness of the separability assumptions made.

Figure 7.1 shows how we think about the relationship between model, theoretical implications, and features of the real world.

$M$  is the model with auxiliary assumptions: features that we assume about agents and the nature of the interaction – agents' preferences, the information they possess, individual information processing, rationality, decision-taking modes, choice sets, strategies available and equilibrium concept used. We think of these features as being fixed.

$\theta$  is a set of parameters: features that we think of as fixed in one specific case under study, but that will vary across different cases of interest. Parameters usually serve one of two purposes. Sometimes, we know or suspect that the cases under study vary greatly with respect to some marginal condition such as an individual trait, a sufficient statistic or an institutional feature that we know is critical to the mechanics of the model. Assuming one specific preference relation or utility function, a specific discount factor or voting threshold may amount to having a model that applies only to a single real-world case. If there is reason to believe that we can capture the variation in marginal conditions by some parameter, a parametrized model increases the scope of the model. Comparative statics is, then, a tool to study the effect in the

variation of these marginal conditions. At other times, it is unclear whether some marginal condition has any effect on the feature we study. In a parametrized setting, we might want to show that outcomes we are interested in do not vary in the parameter.

$f_1, f_2, \dots$  are outcomes in a very broad sense: features that are associated with the real world and that we argue or predict to occur or vary conditional on  $M$  and  $\theta$ . One common aspect of politics in which we are interested is the actions of agents: does a foreign state wage war? Does the incumbent invest in a costly campaign? Does the president delegate authority over trade policies to the legislature? This is all observable behavior, even though collecting data on actions taken by agents might be difficult. For instance, while it is pretty straightforward to verify whether a state has declared war on another, collecting data on whether the government has prepared for war might be intricate.

Observable actions must be distinguished from strategies, which are only partially known. Strategies are, using game-theoretical terminology, an agent's complete plan of what action to take at any contingency that might occur. By their very definition, strategies cannot simply be inferred from behavior. As they provide a rule for action in response to any contingency, they refer to cases that – in equilibrium – are counterfactuals. Consider the threat to fight. If the threat is credible, it will be successful and deter the opponent from making a certain move, for instance, an attack. To be credible, however, the strategy must include the plan to fight in the counterfactual contingency of an attack. Such a self-commitment is not readily observable.

Another aspect of politics in which we might be interested is outcomes, defined as consequences of the equilibrium behavior of agents. These can include policy output and outcomes, the evolution of an institution, some form of coordinated behavior and an international treaty or war. What we consider an outcome depends both on the puzzle that

we wish to understand and on the solution concept we use in our theoretical model.

$TI_1, TI_2, \dots$  are theoretical implications that link all assumptions to features of the real world. Generally speaking, we think of the usefulness of a theoretical model as weakly increasing with the number of its theoretical implications.

## SIMPLE THEORY, NON-OBVIOUS IMPLICATIONS

Let us consider a simple example of a theoretical model that we seek to combine with empirical data. Working through the example in some detail helps to clarify the steps we have to undertake, the assumptions that need to be made and the pitfalls we might end up with. Suppose we study the conditions when leaders wage a war. We have an argument that we seek to confront with empirical data. In our simple decision-theoretical model of going to war, a leader has two options. She can accept a previous offer to settle the dispute over a piece of territory yielding utility  $u_r$ .<sup>5</sup> Or she can wage war at costs  $c$ , which results in one of two events: a victory generating utility  $u_w$ , or a defeat with utility normalized to 0. The odds that the country will win the war is given by some exogenous, fixed and known probability. So, the model is indeed quite simple, as it ignores any strategic interaction with an opponent who himself might prepare for war, etc. Finally, we assume the leader values the two choice options with other criteria that are unrelated to the ones above, ones that we do not know and observe. We assume that disturbances are both unrelated to any other model parameter and known to the leader but unobserved by us (the researcher). For reasons that we will see in a second, we denote these by  $e_r$  and  $e_w$ .

To evaluate the argument empirically, provided that there is a sufficient number of cases, we would collect data on these cases and how they differ with respect to the above

conditions: the gains of winning the war and the gains of settling the dispute without waging war, but also the costs of a war, and the losses associated with losing, and so on. As the observed outcome is binary – the leader chooses war or acquiesces – we might run a standard probit or logit model with measures of gains and losses as covariates. Having estimated the statistical model, we can check whether the parameter estimates of the regressors have the expected sign, for instance, whether the costs of war have a negative effect on the occurrence of war, and so on.

However, given our description of model specification, the statistical model is not exactly capturing the mechanism that the theoretical model postulates. The theoretical model suggests that the effect of the gains of winning on waging war is not unconditional, but instead related to the probability of a victory. Obviously, if the odds of winning are nil, the size of the trophy becomes irrelevant. Thus, any estimation of the model with data that ignores the mechanism will thus not be instructive for the theoretical model. Though this may be obvious here, it may be unapparent with more complex mechanisms and interactions.

In fact, even in this trivial example, walking from the theoretical to an appropriate statistical model involves a number of steps and decisions: decisions that need to be taken and enter the analysis as auxiliary assumptions. To begin with, solving the theoretical model is straightforward here. Let  $p$  denote the probability that the leader's state wins. The leader will wage war if  $pu_w - c + e_w > u_r + e_r$ , and accept the offer otherwise.<sup>6</sup> With the assumption that the difference in the disturbance has some cumulative density function,  $F$ , the probability of waging war is

$$\begin{aligned} q &= \Pr(\text{War} \mid u_w, u_r, p, c) \\ &= \Pr(pu_w - u_r - c > e_r - e_w) \\ &= F(pu_w - u_r - c) \end{aligned}$$

In words, the *theoretical model* implies that the probability that a leader wages a war is

given by the value of the cumulative density function at the net utility of war.

The nice thing here is that the theoretical model easily translates into a statistical model, as the above equation looks like a standard binary discrete choice model. If we denote the observation of a leader going to war by  $y = 1$  and backing down by  $y = 0$ , we can think of the term  $y^* = pu_w - u_r - c$  as the latent preference for war. When the  $e_r - e_w$  are independently drawn from a normal distribution with mean zero, variance  $\sigma^2$  and CDF  $\Phi$ , the probability that the leader goes to war becomes

$$\Pr(y = 1) = \Phi\left(\frac{pu_w - u_r - c}{\sigma}\right).$$

To complete the statistical model, we need to do two more things.<sup>7</sup> First, we need to operationalize the features of the theoretical model,  $p$ ,  $u_w$ ,  $u_r$ , and  $c$ , and then get measures for them. Measurement involves issues of validity and reliability that we do not deal with here. But there is one point we want to stress: suppose that we have a reasonable measure for the leader's *ex ante* probability of winning the war, say  $\pi$ , and also that all relevant costs are material costs that can be estimated *ex ante* in monetary terms, denoted by the measure  $C$ . What is less clear is the utility that the leader associates with the two states of winning a war or accepting the deal. Some observable features of the territory – such as size, geography, natural resources, and physical capital stock – will be important, but as these goods are not easily convertible, there is no a priori rule as to how exactly different goods jointly determine a utility representing preferences.

As a consequence, we have to make auxiliary assumptions to fully specify the statistical model. To keep things simple, let us assume the following:

- $u_r$  and  $u_w$  are fully determined by two observable features of the territory: its size and its natural resources
- $X$  and  $Z$  are valid and reliable measures for size and resources

- all leaders value  $X$  and  $Z$  in the same way
- the functional form of the relationship between observable features and theoretical concepts is linear, such that  $u_r = \alpha_0 + \alpha_1 X + \alpha_2 Z$  and  $u_w = \beta_0 + \beta_1 X + \beta_2 Z$  for some unknown parameters  $\alpha$  and  $\beta$ .<sup>8</sup>

This is quite a list of assumptions. It is, however, what we do, often implicitly, when estimating models. With the above assumption, we can write the latent preferences as

$$y^* = \pi \times (\beta_0 + \beta_1 X + \beta_2 Z) - (\alpha_0 + \alpha_1 X + \alpha_2 Z) - \gamma C.$$

This is not a linear relationship:

$$y^* = -\alpha_0 - \alpha_1 X - \alpha_2 Z - \gamma C + \beta_0 \pi + \beta_1 \pi \times X + \beta_2 \pi \times Z$$

but involves two interaction terms of  $\pi$  and  $X$  or  $Z$ , respectively. The important point here is that a simple linear relationship between the regressors and the odds-ratios of going to war does not capture the mechanism behind the choice problem of the leader.

This will even be less so if there is not a single decision-maker, but two or more actors whose actions and strategies are strategically interdependent. To illustrate, consider a slightly more complex game that considers the strategic interaction of the leader and the opponent state. The opponent state can either prepare for war or not, and either action is observed by the leader. Preparing for war comes at a cost of  $d$  for the opponent, but lowers the probability that the leader wins to some  $p_0 < p$ . While the choice problem of the leader is basically the same – she would account for the opponent's war preparations with  $p_0$  or  $p$  – the opponent has a more intricate decision problem. Whether preparing (or not) is preferable largely depends on the probability that the leader wages war (or not), which again is conditional on the war preparations of the opponent. Using analogous specifications for utility functions  $v$  of the

opponent, the opponent's choice to prepare is the best strategy if

$$q((1 - p_0)v_w - d) + (1 - q)(v_r - d) + e_p > q(1 - p)v_w + (1 - q)v_r + e_n$$

In this case, the statistical model will involve simultaneous estimation of the parameters of the covariates and the choice probabilities. A specification of the statistical model that fails to capture this interaction will not be informative about the causal relationships postulated by the model.

There is a considerable literature on how to derive a statistical model from a theoretical model involving strategic interaction. In the econometric literature, the approach is referred to as structural estimation (Low and Meghir, 2017), though the political science literature is sparse (see, however, Smith, 1999; Signorino, 1999, 2003). The bad news here is that there is no vanilla or one-size-fits-all method that could readily be applied to very different types of (game-)theoretical models. Decision-theoretical discrete choice problems (as the one above) will often lead to some sort of the statistical random utility model (McFadden, 1974). These may differ in assumptions about the distribution of the unobserved, random utilities (resulting in probit or logit models), and also in the source of the uncertainty they capture (Signorino, 2003): agents may simply err when making choices; they may have private information about their own payoffs; or random utilities represent what is actually omitted variables or measurement error of the covariates that are used to capture features of the utilities.

## EITM RESEARCH DESIGNS

There is a great variety of approaches to combine theory building, model construction, and empirical work in political science research. In what follows, we distinguish between three common approaches: (1) equilibrium point predictions; (2) comparative statics; and (3) structural estimation approaches. Throughout, as a running example, we will use a simple

②			
		E	¬E
①	E	$\Pi^{Duo} - c_1$	$\Pi^{Mono} - c_1$
		$\Pi^{Duo} - c_2$	0
¬E		0	0
	¬E	$\Pi^{Mono} - c_2$	0

**Figure 7.2 Entry Game**

entry game (see Figure 7.2, and see Berry and Reiss, 2007), a strategic situation that is ubiquitous in economics and political science, to introduce each research design.

In its original version, two firms decide whether to enter a market ( $E$ ) or not ( $\neg E$ ). Likewise, we can think of politicians deciding whether to enter an electoral race or not. Entering the market comes at an entry cost  $c_1$  for firm 1 and  $c_2$  for firm 2. If only one firm enters the market, the variable profit is  $\Pi^{Mono}$ . If both firms enter the market, their profits are reduced to  $\Pi^{Duo}$ . If a firm decides not to enter the market, its payoff is 0. We will assume that  $\Pi^{Mono} = 2\Pi^{Duo} = \Pi$  and  $\Pi > c_1, c_2 > \Pi/2$ , which means that each firm will prefer to enter the market if the other firm does not, but will prefer to stay out if the other firm enters. Players know profits and costs and make their choices simultaneously. The game has three Nash equilibria: two pure strategy equilibria ( $E, \neg E$ ) and ( $\neg E, E$ ) and one equilibrium in mixed strategies

$$\left( \left( \left( 2 - \frac{2c_2}{\Pi} \right) E, \left( \frac{2c_2}{\Pi} - 1 \right) \neg E \right); \right. \\ \left. \left( \left( 2 - \frac{2c_1}{\Pi} \right) E, \left( \frac{2c_1}{\Pi} - 1 \right) \neg E \right) \right).$$

Having solved the game, a researcher can confront the theoretical model with data in at least three different ways. First, a researcher can focus on the evaluation of the point predictions of the model. Does the empirical outcome or the employed strategies of real

actors match the equilibrium outcome and the equilibrium strategies? The evaluation of point predictions is often useful in laboratory experiments, but has only limited application in large- $N$  studies relying on observational data. Another important research approach that makes use of equilibrium predictions of formal models are analytic narratives.

Second, a researcher can focus on the relationships between variables that the equilibrium of the game implies. Such comparative statics designs usually do not claim that the formal model they use captures the entire data generating process. Instead, they will seek to evaluate relationships between key parameters of the model empirically. Comparative statics is the dominant research design when combining a formal model with observational data.

Finally, instead of seeking to verify or falsify predictions of the model, a researcher might be interested in structurally estimating parameters of the model, either because they are interesting on their own or because they are useful in making predictions for counterfactual scenarios. We will next consider these approaches in more detail.

## EQUILIBRIUM POINT PREDICTIONS

Formal and game-theoretic models are solved by the application of some sort of solution

concept, a rule that defines a priori how to single out events that can be expected and, hence, are 'predicted' from the universe of events. For example, models using non-cooperative game theory usually apply the concept of the Nash equilibrium, or some refinements thereof, to make predictions about strategies players use and the resulting outcome of a strategic situation. Models in the cooperative game-theoretical tradition make use of solution concepts such as the core, the Shapley value, or the Walrasian equilibrium that focus on payoff allocations rather than strategies. An appealing characteristic of many solution concepts from a theoretical point of view is that they often make sharp, deterministic predictions.

For example, in the entry game, a sharp equilibrium point prediction can be derived using mixed strategy equilibrium. Let's assume that the total profit is  $\Pi = 7$  and firms have differing costs for entering the market  $c_1 = 5$  and  $c_2 = 4$ . Then the mixed strategy equilibrium prediction is that the first firm enters the market with probability  $\frac{6}{7}$  and stays out with probability  $\frac{1}{7}$ , whereas the odds that firm 2 enters or stays out are  $\frac{4}{7}$  and  $\frac{3}{7}$ . These are fairly sharp predictions, but how can we use them to evaluate the model?

There are at least four issues. First, as we have shown above, the model has multiple equilibria: firm 1 entering and firm 2 staying out is as much a Nash equilibrium in pure strategies as the reverse case. There is nothing that makes one superior to the other. Second, even if there were only the mixed strategy equilibrium, none of the four observable outcomes could be taken as evidence either for or against the proposed model mechanism. The issue here is that we can only observe behavior, not the actual strategies that individuals use. If both firms indeed use mixed equilibrium strategies, we should observe, for instance, a duopoly with probability  $\frac{6}{7} \times \frac{4}{7} = \frac{24}{49}$  and no firm entering the market

with probability  $\frac{1}{7} \times \frac{3}{7} = \frac{3}{49}$ . A straightforward way to evaluate mixed strategy equilibria is thus to focus on these aggregate outcome probabilities, and compare them to relative frequencies calculated from a larger number of observed cases, preferably in a controlled laboratory environment.<sup>9</sup> Third, how to measure  $\Pi$ ,  $c_1$ , and  $c_2$  in a real market? As we can see above, point predictions of strategies are vastly different when the costs of the two firms are 5 and 4 units, or 4 and 5 units. Fourth, how can we make sense of these point predictions if we are not willing to assume that the model reflects the complete data generating process? Even if the model does not miss any systemic feature of the interaction, observed behavior and outcomes will involve some randomness, leaving uncertainty as to their effect and the manner in which to account for it in the model. From an empirical point of view, sharp predictions can be less appealing since the world is generally stochastic, and sharp predictions are easily falsified. We are rarely able to study the real world 'in equilibrium'.

How should we assess point predictions? There are three basic routes that one can take (see Morton, 1999). One is to make explicit assumptions about the nature of the random effects on the point predictions that may have prevented those predictions from being observed empirically. This will transform point predictions into distributional predictions. If there is a sufficiently large number of observations, distributional predictions are then assessed against the empirical record. In the market entry game, one could assume that firms perfectly know market profits and costs, but err when making their choice. This results in the random utility framework that we discussed in the section above. In the entry game, taking into account that firms err, the probability  $p_1$  that firm 1 enters the market may be written as

$$p_1 = Pr \left( p_2 \left( \frac{\Pi}{2} - c_1 \right) + (1 - p_2)(\Pi - c_1) + \varepsilon_{11} > \varepsilon_{12} \right)$$

where  $p_2$  is the probability that firm 2 enters the market, and the  $\varepsilon$ s are individual and choice specific error terms. Let  $F$  again denote the CDF of  $\varepsilon_{12} - \varepsilon_{11}$  and  $\varepsilon_{22} - \varepsilon_{21}$ . The equilibrium predictions are the implicitly defined distributions

$$p_1 = F\left(-\frac{\Pi}{2}p_2 + \Pi - c_1\right)$$

$$p_2 = F\left(-\frac{\Pi}{2}p_1 + \Pi - c_2\right).$$

Thus, a solution to the problem – that point predictions are likely to fail to receive support because of a partially modeled data generating process – is to turn the model into something more ‘realistic’ and/or use an appropriate equilibrium concept, here a quantal response equilibrium (McKelvey and Palfrey, 1995).

A second way is to use controlled laboratory experiments. Laboratory experiments have a number of advantages for evaluating theories, in general, and equilibrium point predictions, in particular. A major advantage of experiments is that they can isolate the theoretical mechanism. The idea is to eliminate as many random effects that occur in the natural environment as possible. The third route is different from the previous ones in that it builds and evaluates a model in the context of a limited number of cases, often a unique case. Historical events such as the French revolution or the rise and fall of Venice may be instructive for our understanding of political mobilization and institutional design, but their study is plagued with the typical problem of case studies: there are different ways to interpret the historical record. Analytic narratives (Bates et al., 1998) is the attempt to provide a causal explanation for such events by building a formal model to capture the logic of the explanation and evaluating it through testable implications. In that sense, analytic narratives is less a method to simply evaluate a model, and more an approach of both model building and evaluation. We present

showcases of the latter two approaches in the remainder of this subsection.

### ***Evaluating Equilibrium Point Predictions in the Lab: Battaglini et al. (2010)***

An example of the evaluation of the point predictions of a model in a laboratory is Battaglini et al. (2010). Their starting point is the theoretical model that introduced the *Swing voter’s curse* (Feddersen and Pesendorfer, 1996). Feddersen and Pesendorfer show that it can be rational for poorly informed voters to abstain in an election, even when the cost of voting is zero. By abstaining in equilibrium, poorly informed voters avoid deciding the election in the wrong direction and, therefore, leave the decision to better informed voters. A central assumption of the model is that voters form beliefs about the probability that their vote will be pivotal. The model matches some empirical observations, such as selective abstention, but the pivotal voter assumption, along with the theory of strategic abstention, remains controversial.

Battaglini et al. use a simplified version of the model. A set of voters decides by majority rule between two alternatives, A and B. Corresponding to the two alternatives, there are two unobserved possible states of the world, A and B. In state of the world A, alternative A is optimal; in state of the world B, alternative B is optimal. There is a number of independent voters (or swing voters) who want to match the alternative and the state of the world, as well as some partisan voters who prefer alternative A or B, irrespective of the state of the world. Each voter may receive a private informative signal about the state of the world, but may also stay uninformed with some probability. After voters have received the signal, votes are cast, and an alternative is chosen by majority rule. In equilibrium, all partisan voters vote in favor of their preferred policy,

and all independent voters who received an informative signal vote in line with their signal. Uninformed independent voters, however, have incentives to abstain with at least some probability. The reason is that an uninformed independent voter knows that, with some probability, there exists an informed independent voter. By casting a vote, the uninformed independent voter would risk voting against an informed independent voter. The key equilibrium point prediction of the model is, therefore, that independent uninformed voters will abstain with some probability depending on the specific parameterization of the game.

The authors set up a laboratory experiment to evaluate the point predictions of the theoretical model. Values for three different parameters need to be chosen: the number of voters, the number of partisan voters and the prior probability for each state of the world. There are two possible jars (states of the world). The first jar contains six white balls and two red ones, while the second jar contains six white and two yellow balls. A computer randomly chooses a jar with the prior probability. On the computer screen, participants choose one of the eight balls, the color of which is then revealed. This creates a share of informed participants, namely those who see a yellow or red ball, and some uninformed participants, who see a white ball. Finally, each participant decides to either vote for jar A or jar B or to abstain. If the correct jar is chosen by a majority, a higher payoff is paid out compared to the incorrect jar. If there were partisan voters, the participants are told that the computer will cast their votes for jar A and B, respectively. Participants' choices are recorded and compared with the point predictions of the theoretical model.

Battaglini et al. find strong evidence that participants' voting behavior varies as theoretically predicted: depending on the treatment configuration, uninformed subjects abstain, seemingly delegating the choice to informed participants.

### ***Analytical Narratives: Gailmard (2017)***

In US federal and state constitutions, the separation of power is very pronounced, with governors and assemblies having independent power bases. How did this hallmark of US constitutions evolve? Gailmard (2017) argues that, to understand the origins of the separation of powers in the United States, we must look at the era of English colonies in North America. What nowadays looks like a natural institution is actually the result of an institutional choice by a strategic English Crown confronted with agency problems in its colonial governors.

Crown-appointed governors in the New World were hard to control from a distance, and as a result, they would over-tax settlers, thereby reducing the incentive for settlers to invest and reducing the revenue to the Crown. To help settlers restrain the governor, the Crown created liberal institutions, such as an empowered assembly with budget power. While this might have negative effects on the Crown's revenue in the short run, it should pay off in the long run. By turning over some political control to the colonial settlers – introducing the separation of powers – the Crown could solve the agency problem.

The theory embeds a model of the colonial economy into two alternative political environments, one with hierarchical control and one with a separation of powers within the colony. There are three players: the Crown, a colonial governor, and colonial settlers. Settlers can make either a high or a low investment in the colony, and then the governor and the Crown extract resources from the colony's economy. In the first, hierarchical model, the economy is embedded into a moral hazard model of political agency (Ferejohn, 1986). While necessary for military security and economic administration, the colonial governor has incentives to extract rents from settlers that, in turn, decrease the economic investment of settlers and the Crown's revenues. In the separation

of powers model, the Crown chooses to let the settlers determine a budget for the government. This constrains the governor and ensures high investments from the settlers, which in turn increase the Crown's revenue. Gailmard then shows that separation of powers is optimal for the Crown when returns to investment are moderate. Specifically, he establishes the conditions for the environment (parameters of the model) under which the Crown's choice of separation-of-power institutions (strategy) is the equilibrium (point prediction).

Gailmard's analytic narrative approach offers a new way of looking at the evolution of an important, widespread institution. Interestingly, the model suggests that separation of powers was neither invoked to control the Crown (by an assembly) nor invented by the Crown to tie its own hands. Rather, it was designed to empower settlers to restrain the governor. The formal modeling approach also helps address the reasons why this distinct form of separation of powers was unique to North America. An investigation of the model parameters suggests that unlike colonies that provided opportunities for natural resource extraction, economic growth in the North American colonies required settler investment in agriculture. In an even broader perspective, the approach offers insights on American institutionalism but may also be taken up by research in a range of other, colonial or authoritarian, contexts of institutional choice.

It should also be clear that, with analytic narratives, theoretical and empirical work are not delegated to distinct steps in the research process, but rather developed more in a dialogue.

## COMPARATIVE STATICS

Comparative statics asks how an equilibrium quantity of interest changes as some exogenous features change (Silberberg and Suen,

2000). As we have argued above (Figure 7.1), these quantities of interest are outcomes,  $f$ , in a broad sense: features that are associated with the real world and that we argue or predict to occur or vary conditional on parameters  $\theta$  such as actions, strategies or some policy (or outcome). For example, in the entry game above, we could be interested in how the probability that both firms enter the market will change as profits increase. The answer is straightforward. In the mixed strategy equilibrium, the probability that both firms enter is  $p_1 p_2 = 4\left(1 - \frac{c_1 + c_2}{\Pi} + \frac{c_1 c_2}{\Pi^2}\right)$ . Then the positive partial derivative of  $p_1 p_2$  with respect to  $\Pi$ ,

$$\begin{aligned} \frac{\partial(p_1 p_2)}{\partial \Pi} &= 4\left(\frac{c_1 + c_2}{\Pi^2} - 2\frac{c_1 c_2}{\Pi^3}\right) \\ &= 4\left(\frac{c_1(\Pi - c_2) + c_2(\Pi - c_1)}{\Pi^3}\right), \end{aligned}$$

tells us that, when profits increase, it is more likely that both firms enter the market. Less straightforwardly, though, it also holds that sensitivity to profits varies with entry costs. To be precise

$$\frac{\partial^2(p_1 p_2)}{\partial \Pi \partial c_1} = \frac{4(\Pi - 2c_2)}{\Pi^3} < 0,$$

as 1's costs of entry increase, the incentive provided by higher profits weakens. The simple example demonstrates the reason that comparative statics is attractive. First, it is the tool for the 'comparative analysis' of formal models, whether used in case study, comparative, experimental or statistical method design. Second, it is often difficult to exactly measure model parameters as they are unobserved or latent (see example in the third section of this chapter). As long as we know that two cases differ with respect to some parameter, comparative statics can tell us whether and how equilibria or outcomes differ.

Comparative statics is often tricky because when one parameter, such as profit or cost, changes, the resulting change in the strategy of one actor also leads to changes in the strategies of other actors. Solving these models often involves using systems of differentiated equations.

A standard technique to derive comparative statics is to assume specific functional forms about the model primitives, such as that utility is linear in profits and costs (as above), or concave in profits but convex in costs. The reason is that standard techniques to find equilibria and to study their comparative statics usually require continuity of best responses, compactness of strategy spaces, differentiability of utility functions and interior solutions, among others.

Monotone comparative statics (Milgrom and Shannon, 1994) explores properties of games that make such strong assumptions or explicit functional forms superfluous. As Ashworth and Bueno de Mesquita (2006: 214–15) note, monotone comparative statics greatly facilitates the empirical evaluation of theoretical models. On the theory side, not having to assume specific functional forms makes the model robust against many sorts of misspecification, and brings the deep structure of the model to light. On the empirical side, replacing compact strategy spaces (the standard assumption) with partially ordered spaces allows for the generation and evaluation of predictions that are based on just ordinal information. More recently, monotone comparative statics techniques have been extended to aggregate games (Acemoglu and Jensen, 2013) and distributional comparative statics (Jensen, 2017).

### ***A Full Set of Empirical Implications: Snyder and Strömberg (2010)***

Snyder and Strömberg (2010) provide an excellent example of how comparative statics can be used. They investigate the effect of political newspaper coverage on policies at the constituency level. Their argument takes

the form of a chain of relationship predictions between variables that ultimately link newspaper coverage and policies: increased newspaper coverage increases citizens' level of political information, which strengthens the monitoring of politicians who, in turn, work harder for their constituents, finally resulting in better policies. The authors could have chosen to collect data on coverage and policies to test their key hypothesis and stop there. They didn't. Instead, the authors decided to provide empirical evidence for each step in the causal chain, achieving a close connection between theoretical argument and empirics.

To identify the effect of newspaper coverage on policies, they exploit exogenous variation in the congruence between congressional districts and newspapers. The authors expect that the larger the overlap between these districts, the higher the political coverage of local politicians because there exists a higher readership share in the district. As a first empirical step, it is shown that newspaper coverage is indeed increasing in the readership share of a district. The next step in the mechanism postulates that the more extensively newspapers cover local politicians, the better informed the citizens. Using data from the American National Election Study over 20 years, the authors demonstrate that respondents in more congruent districts are more likely to receive their news from newspapers or magazines. Respondents living in more congruent districts are also informed about their local representatives: they are more likely to recall the name of at least one representative and are more willing to place them on ideological scales. Following the causal chain argument, the authors continue to show that congressmen from more congruent districts vote against the party line more often and are more likely to stand witness before congressional hearings and to serve on constituency-oriented committees. Finally, as a last step, the authors provide evidence that more congruent districts receive higher federal expenditures.

While Snyder and Strömberg do not present a formal model for their argument, their

work stands out as a demonstration of how a series of comparative statics can illuminate a theoretical mechanism.

## STRUCTURAL ESTIMATION

Structural estimation turns the logic of the previous two research designs – point predictions and comparative statics – on its head. Instead of using data to scrutinize a theoretical model by evaluating point or relationship predictions, structural approaches assume that the theoretical model is a good approximation of the real world and use data to obtain estimates of model parameters. We see at least two main reasons to derive and estimate structural econometric models.

First, so-called deep model parameters are frequently interesting and useful. For example, political scientists are often interested in the policy preferences of political actors, such as legislators or Supreme Court justices. However, these policy ideal points are generally not directly observable and have to be estimated. Ideal point models, such as Nominat (cp. Poole, 2005), posit a behavioral model (including assumptions about the dimensionality of the policy space) that links deep parameters (here: ideal points) to observables (here: roll call votes). Then, the model can be estimated using roll call data, and the actors' ideal points can be recovered and find use in many contexts (for example, the study of polarization in US politics). Other examples of interesting deep parameters are risk aversion, discount factors, marginal cost, and the value of information (see first example given below, Iaryczower and Shum, 2012).

Second, structural models can be used to assess the effect of hypothetical policy interventions by conducting simulations. Having described and estimated a structural model, a researcher can treat the estimated parameters as fixed and make predictions about equilibrium outcomes as the environment changes. For example, a researcher may be interested

in the effect of a reform that decreases the minimum required sentence on pre-trial bargaining in criminal cases (see second example below, Silveira, 2017). In many cases, it is desirable to obtain estimates of effects of policy interventions *ex ante* because small-scale field experiments are infeasible or unethical. In other cases, structural models can help to extrapolate results from a specific (field) experimental setting to other contexts (Wolpin, 2013).

To demonstrate a structural estimation approach, consider again the entry game example (also discussed in Ellickson and Misra, 2011). Imagine we have collected data of local markets, including information on entry decisions of each player as well as firm- and market-specific characteristics (e.g. population, distance to nearest distribution center) that may affect each firm's payoffs. Let  $X_k$  denote characteristics of market  $k$ ;  $Z_{ik}$  denote characteristics of firm  $i$  in market  $k$ ; and  $y_{ik}$  denote the entry decision of player  $i$  in market  $k$ . Then we can express the payoff of firm  $i$  in market  $k$  as

$$\pi_{ik} = \alpha'_i X_k + \beta' Z_{ik} + \delta_i y_{-ik} + \varepsilon_{ik}$$

where  $\varepsilon_{ik}$  is a component of a firm's payoff that is unobservable to the researcher. In equilibrium, each firm  $i$  will choose to enter the market  $k$  if  $\pi_{ik} > 0$  and stay out otherwise. Note that the payoff depends not only on firm and market-specific characteristics, but also on the entry choice of the other player,  $y_{-ik}$ .

If we further assume that firms (but not the researcher) observe the  $\varepsilon$ s and that firms make choices simultaneously, the Nash equilibrium can be characterized by the following system of inequalities:

$$y_{1k} = \mathbb{I}[\alpha'_1 X_k + \beta'_1 Z_{1k} + \delta_1 y_{2k} + \varepsilon_{1k} \geq 0]$$

$$y_{2k} = \mathbb{I}[\alpha'_2 X_k + \beta'_2 Z_{2k} + \delta_2 y_{1k} + \varepsilon_{2k} \geq 0].$$

where  $\mathbb{I}[\cdot]$  is an indicator function. Note that these outcome equations constitute a binary simultaneous equation system, an

interdependent structure that creates challenges for estimation and identification.

Estimation can usually not be achieved with econometric techniques that are implemented in standard econometric software. The reason is that, in contrast to single-agent decision-making problems, the payoff of each player depends on the action of the other player (note the  $\delta_{i|y_{-ik}}$  term in the inequalities above). Any estimation approach must therefore, simultaneously estimate both equations. In general, structural approaches often require that researchers tailor estimators precisely to the empirical case.

An identification problem arising in many structural estimation approaches – in general, and in this setting in particular – is that the estimation procedure needs to deal with equilibrium multiplicity. As shown earlier, the entry game has two pure strategy Nash equilibria if the market is only large enough to make one firm entry profitable but not two. Since, given a set of parameter values, two different outcomes are possible (either firm 1 enters the market and firm 2 does not, or vice versa), parameter estimation is not identified. To deal with this problem, the researcher could either specify an equilibrium selection rule (Tamer, 2003); aggregate to model predictions that are not affected by multiplicity (e.g. number of entrants: see Bresnahan and Reiss, 1990); make different model assumptions that yield unique predictions (e.g. sequential moves: see Berry, 1992); or adopt a bounds approach (Ciliberto and Tamer, 2009). An alternative would be to assume that firms do not perfectly observe each other's payoffs, a situation which would result in a game with incomplete information (Rust, 1994; Seim, 2006).

### ***Estimating Deep Parameters: Iaryczower and Shum (2012)***

Iaryczower and Shum (2012) are interested in the question how much information to the contrary is necessary to overcome ideological predispositions of justices in the US

Supreme Court. This 'value of information' is not directly observable in the real world, but a quantity that can only be interpreted in the context of the theoretical model. Iaryczower and Shum set up the interaction between justices as a Bayesian game in which biased justices receive a private, noisy signal about the case, update their beliefs, and vote in favor of or against the defendant. Voting can be either sincere or strategic (as in Feddersen and Pesendorfer, 1996).

The key issue to recover the value of information is to estimate two deep parameters: judge-specific preferences (bias) and information (signal precision). Iaryczower and Shum propose the following two-step estimation: first, the authors estimate, for each judge, choice probabilities for each state of the world (guilty or innocent defendant) as a function of judge and case-specific observables via maximum likelihood. In a second step, bias and precision parameters can be recovered given estimated choice probabilities. Finally, given bias and precision parameters, one can calculate the probability that a justice votes differently than he or she would have voted without case-specific information, which the authors interpret as a measure of the value of information in the court. Tracing this measure over time, the authors find that the value of information has decreased over the past 25 years, suggesting an increasing politicization of the Supreme Court.

Iaryczower and Shum's approach offers an alternative to purely ideological characterizations of Supreme Court justices' behavior by specifically modeling and estimating how ideology interacts with the information available to the justices. Doing so allows new insights into the relative weights that justices put on their preexisting ideological leanings versus the information of the case.

### ***Simulating Counterfactual Scenarios: Silveira (2017)***

Silveira (2017) investigates the effects of several hypothetical policy interventions,

namely potential sentencing reforms, on the outcomes of criminal cases. Litigation is modeled as a two-stage game. The first stage consists of pre-trial bargaining with asymmetric information between a prosecutor and the defendant, reflecting the fact that the vast majority of criminal cases in the United States are resolved by plea bargaining. Defendants, because they know the full extent of their culpability, have more precise information about potential trial outcomes than the prosecutor. The prosecutor offers the defendant a sentence to settle the case as a take-it-or-leave-it offer. If the defendant accepts the offer, the game ends. Otherwise, the case is decided at trial, at which the defendant's private information is revealed with some probability. In equilibrium, the prosecutor's offer is a function of the anticipated trial sentence, the trial costs and the perceived odds of winning. The defendant accepts the offer if he or she is comparably pessimistic about his or her chances in court.

To estimate the model, the author proceeds in two steps. First, he non-parametrically estimates the prosecutor's equilibrium settlement offer function using information on the prosecutor's settlement offers when plea bargaining was successful, on sentences assigned at trial when plea bargaining failed and on the probability that plea bargaining was successful. Having identified the prosecutor's optimal offer function, the model primitives (i.e. the distribution of potential sentences at trial, the probability of conviction and the trial costs for defendant and prosecution) can be recovered. The author uses these estimates to conduct counterfactual simulations to explore the effects of lower mandatory minimum sentences and a general ban on plea bargaining. In the first case, a decrease in the minimum mandatory sentence leads to a general decrease in incarceration time due to the fact that prosecutors offer lower settlements during plea bargaining. However, it also leads to an increase in conviction rates because shorter potential trial sentences increase the

probability of a successful plea bargain. In the case of a complete elimination of plea bargaining, all cases would go to trial. The model suggests that conviction rates would decrease substantially; however, defendants would face longer sentences. Thus, the average defendant would be worse off if plea bargaining were to be banned.

Silveira's analysis yields insights into potential sentencing and litigation reforms that would be challenging to assess otherwise *ex ante*. Furthermore, experimental research that could provide *ex post* evidence about the effects could be difficult to implement and is potentially unethical.

## PRACTICAL ADVICE

The development of internal specialization in political science is not a new phenomenon. More than 60 years ago, the APSA Committee on Standards of Instructions noted that 'the political scientist increasingly finds the body of political knowledge so great, and the tools of study so exacting, that he must specialize if he is to master and to communicate his subject matter' (APSA Committee on Standards of Instruction, 1962: 417). Nor has there been a shortage of ideas about methodological unification, with the accomplishments of the Cowles Commission in economics dating all the way back to the 1930s. The EITM approach is a genuine political science approach to break down the isolation of formal and empirical modeling, tailored to the specific questions and methodological problems in political science research.

It would be the best of all possible worlds if researchers were highly skilled in both theoretical and empirical analysis, and this was paired with in-depth knowledge of the substantive field of their interest. However, becoming a skillful formal modeler or data analyst requires an enormous amount of training and the time constraints of PhD education

usually prevent students from becoming experts in both fields. Most PhD students become one of two types: the formal modeler who would like to explore the data or the empiricist who would like to add more depth to her empirical analysis.

Also, career-wise, it can be more productive to persuade one audience than to try to appeal to two at the same time. This applies to both faculty members and reviewers. As editor and reviewers, we saw many excellent papers struggle in the review process because either the theory section did not persuade the theorists or the empirics did not convince the empiricists. Given space constraints in journals, authors often end up cutting the theoretical or the empirical part of their paper or relegating large parts to the appendix in the revisions.

For both types of students, we want to offer some brief (hopefully helpful) advice from our experience as researchers, teachers, editor, and student.

**Not every model is for empirical ‘testing’.** (Nor does the EITM approach suggest so.) Models serve different purposes. They can be foundational, organizational, explanatory or predictive (Clarke and Primo, 2012). Being apt for the derivation of testable implications is one purpose, but testability in the hypothetico-deductive methodology is not the only one. Ultimately, models are just tools to help us understand the world.

**Not every empirical analysis needs a formal model.** For some research questions, the mechanisms behind the data are not of primary interest – at least, not in the first step of research. Whether tobacco or gun control programs have causal effects is a relevant question to answer, even if we do not know how policies change individual perceptions, attitudes, and behavior. At the same time, without a proper theory of what is going on, simply relying on identification techniques such as instrumental variables or regression discontinuity designs can lead to the misinterpretation of the causal effect. As Eggers (2017) shows, there is no such thing as *the*

incumbency effect estimated from regression discontinuity.

**Collaboration.** Where true versatility is rare, collaboration seems to be a logical consequence. However, co-authoring does not mean everyone does her own thing. At a minimum, students must learn each other’s mindsets and languages, which is different than just taking a game theory and an advanced statistics class. For example, when theorists write formal models, they will often emphasize existence of equilibria, generalizability of functional forms, and mathematical elegance over whether their model generates sharp, relevant, and empirically falsifiable predictions. It will help formal modelers to understand the interests of empirical researchers and to write models that are accessible to empirical researchers, providing intuition and the reasons that we should care.

**Start simple.** Armed with lots of detailed case knowledge, the empiricist begins writing a model that resembles the case she observes in the real world as closely as possible. As a result, the model becomes quickly extensive, hard or impossible to solve and adds little to the understanding of the theoretical argument. To make it solvable, the empiricist will be forced to make some heroic assumptions that draw criticism from theorists and empiricists alike. The empiricist, we argue, should have started with the core of the theoretical argument. In many cases, the core of the argument can be phrased as a trade-off. Should I protest or stay at home? Should I turn out to vote or not? The starting point, then, is to build the simplest reasonable model that formalizes this trade-off – and make it more complicated, if necessary, from there.

## Notes

- 1 Others, like Johnson (2014), are even more skeptical, rejecting entirely the idea that models can be subjected to empirical evaluation. For him, models are fables to derive a principle from. By rendering some abstract concept like ‘power’

- or 'deterrence' more concrete, models help to understand what the concept means in the particular circumstance captured by the model (Johnson, 2019: e7).
- 2 It is important to emphasize that the (unknown) benchmark is systematic, explainable variation: a model to predict school choice that uses features such as parental education, socio-economic status and personal traits, and that has an R-square of 5%, arguably is mediocre. A stock market model with an R-square of 1% can earn you a fortune.
  - 3 Or, if parsimony is a goal, what should be left out.
  - 4 The term separability goes back to Sono (1945) and Leontief (1947) in the study of production decisions, where separability is the unaffectedness of the ease of substitution between two factors by a third factor.
  - 5 If unambiguous, we suppress indices for the unit of analysis.
  - 6 We deliberately assume that in case of equality, the offer is accepted. Such knife-edge cases are practically irrelevant, as long as (some of) the model parameters have continuous support. This is not the case in, for instance, a standard 2-by-2 pure coordination game where players are indifferent between coordinating on standing on the left or the right of an escalator.
  - 7 One other assumption we must make is a value for  $\sigma$ . As we do not directly observe  $y^*$ , the  $\alpha$ s and  $\beta$ s, together with  $\sigma$ , are not uniquely identifiable. A standard and inconsequential assumption is that  $\sigma = 1$ .
  - 8 A weaker assumption that captures the case of linear relationships would be to assume that all partial derivatives of the  $us$  with respect to  $X$  and  $Z$  are positive, and all higher-order cross-partials to be zero. The statistical model would then be  $Pr(y = 1 | \pi, X, Z) = \Phi(\pi f(X, Z) - g(X, Z) - C)$  for some appropriate  $f$  and  $g$  that is amenable to non-parametric estimation.
  - 9 Here, we think of mixed strategies as literal randomizations over pure strategies, but note that there are alternative interpretations (Harsanyi, 1973; Rosenthal, 1979).

# EITM: Applications in Political Science and International Relations<sup>1</sup>

John Aldrich and Jim Granato

Empirical observation, in the absence of a theoretical base, is at best descriptive. It tells one what happened, but not why it has the pattern one perceives. Theoretical analysis, in the absence of empirical testing, has a framework more noteworthy for its logical or mathematical elegance than for its utility in generating insights into the real world. The first exercise has been described as 'data dredging', the second as building 'elegant models of irrelevant universes'. My purpose is to try to understand what I believe to be a problem of major importance. This understanding cannot be achieved merely by observation, nor can it be attained by the manipulation of abstract symbols. Real insight can be gained only by their combination. (Aldrich, 1980: 4)

## INTRODUCTION

EITM, Empirical Implications of Theoretical Models, is a way to design a research project; that is, it *is* a research design. EITM is also a way to develop and integrate a stream of research. And it is a way to place a particular

research project in the context of its relevant scientific community (as per Kuhn, 1970 [1962]). It is all of those because it is a way of organizing and communicating scientific knowledge.

A completed piece of science, that is to say, an addition of new knowledge, done consistently with EITM, does two things. First, it provides an integrated set of hypotheses derived from a set of general premises in a logically consistent and coherent way. Second, it provides a set of empirical observations that reflect on the empirical plausibility of those logically coherent hypotheses. Put alternatively, for EITM, the TM part answers the central question of science: why? Why might this part of the world that is being studied be arranged in the way it is? The EI part answers the question of how likely it is that that logically coherent explanation is 'true' (empirically plausible) in the real world. EITM in total, therefore, answers the questions: 'why did this event/choice/outcome occur?' and 'is that reason for why it

happened likely to be found in the real world again, and if so how often?’

Science may be said to be a combination of art and science. The ‘art’ in its science is where science begins, which is with the asking of an important and interesting question. It is the purpose of the liberal arts in general to train people in how to ask important and interesting questions. In addition, it is also often an art, or at least it is artful, to think up what observations, experiments or other ways of gathering data might best give answers to those questions. As to the science part, it is the purpose of science to answer well thought out questions and to communicate their answers, convincingly, to others. Pre-scientific inquiry<sup>2</sup> may be thought of both as the assessment of the empirical terrain in which that question is to be asked and as the search for suitable premises from which derivation of testable hypotheses may begin.<sup>3</sup>

All of the rigorous standards of science, such as corrigibility, reproducibility and others, only begin at this point. That is, there is no reason to hold a scientist to the standard of being able to reproduce her inspiration that led her to ask the question she wants to study, nor why she believes it to be important, nor even to question whether she saw the correct set of premises she used to develop her derivations by staring at a fire. Which is only to say that the ‘context of discovery’ is not the science. The ‘context of validation’, however, does require fealty to rigorous scientific standards. These are the standards of how a potential new piece of knowledge becomes, indeed, a new addition to our corpus of scientific knowledge, and how that knowledge can be communicated convincingly to others.

If TM is providing a logically coherent answer to the question of why, and EI is the evidence that is used to say that that answer is an empirically plausible one in some significant portion of the world, then EITM is simply an acronym for science itself. Or, more accurately, it is a way to think about what it takes to create new knowledge and

tell others what that knowledge is. That is, it is a way of looking over a research agenda and assessing what has been accomplished so far and what more needs to be done to strengthen the scientific understanding of that important question/problem. EITM is not a way to ‘do’ science so much as it is a way to assess the scientific status of a stream of research.<sup>4</sup>

If you are willing to buy these claims, at least for the moment, then the only real way to proceed is to point to accomplishments – in our case, to do so in the political, social and behavioral sciences, including in the study of international relations. We provide two examples to demonstrate the case. But first, we briefly discuss these general points we made about EITM in the context of its history, made possible by the impetus and continuing support of the National Science Foundation’s (NSF) Political Science Program in the Social, Behavioral, and Economic Sciences. There would be no EITM program without the NSF (and the Political Science Program at NSF in particular).

### ***The Role of NSF***

On July 9 and 10, 2001 the Political Science Program at the National Science Foundation (NSF) convened a workshop seeking ways to improve technical–analytical proficiency in political science.<sup>5</sup> This workshop, termed the Empirical Implications of Theoretical Models (hereafter EITM) Workshop, suggested constructive approaches so the NSF Political Science Program could develop linkages and a dialogue – both methodological and interpersonal – between formal and empirical modeling and modelers.<sup>6</sup>

To put it in more technical terms, the 2001 Workshop highlighted an important contribution the EITM approach brought to both political science and the social sciences:

If one were to summarize in one word what bridging the divide between formal and empirical modeling means for the political, social and behavioral

sciences, that word would be *identification*. The ability of a researcher to *identify* or parse out specific causal linkages among the many factors is fundamental to the scientific enterprise. Specifying a model that links both formal and empirical approaches alerts researchers to outcomes *when specific conditions are in place* – and is also one of the best ways to determine an *identified* relationship (EITM Report, 2002: 1–2).<sup>7</sup>

Moreover, by integrating the two approaches, students would be exposed to the strengths of both approaches:

At the most basic level, formal modeling assists in the ‘construction of valid arguments such that the fact or facts to be explained can be derived from the premises that constitute the explanation.’<sup>8</sup> An important virtue of formal modeling is that it often yields surprising implications that would not have been considered had they not emerged from formal analysis. Conversely, if practiced correctly, applied statistical and case study analysis shows researchers where a model went wrong and leaves open the possibility that a more accurate model can be constructed. (Granato and Scioli, 2004: 314)<sup>9</sup>

With this brief background in mind, EITM Workshop participants recommended, in both written and spoken commentaries, that the NSF Political Science Program address the technical–analytical divide between formal and empirical approaches in three priority areas:

- Education: Training and Retraining<sup>10</sup>
- Dissemination of Knowledge: Conferences and Workshops
- Research: Establishment of Research Work Groups.

In addition to the NSF sponsored initiatives above, an EITM certification program has also been created at the University of Michigan’s ICPSR Summer Program in Quantitative Methods of Social Research (see <http://www.icpsr.umich.edu/icpsrweb/sumprog/> and <http://www.eitminstitute.org/index.html>). The certification program requires that students focus on a set of ‘approved’ courses that provide background for using the EITM approach and attending

the EITM Summer Institutes. Between 2011 and 2013 more than 270 students received certification (see <http://www.eitminstitute.org/recipients.html>).

## EXAMPLES

### ***QRE: Proposed as a Solution to a TM Question and as Applied to an EI Question***

**QRE as a TM question:** Richard McKelvey and Thomas Palfrey developed Quantal Response Equilibrium (QRE) as a proposed solution to something they found puzzling in practice (McKelvey and Palfrey, 1995, 1998). That is, they sought a solution to a question that was theoretical. However, it was empirical observations that led them to ask the theoretical question.

The problem that led to QRE was that empirical observations did not align with the theoretical derivations. In particular, in some repeated games – the centipede game being focal for QRE<sup>11</sup> – there is a well-defined result.<sup>12</sup> In the centipede game, there is a unique Nash equilibrium (even more, it is particularly easy to implement: play the ‘take’ strategy at the first opportunity, ending the game).<sup>13</sup> The theoretical problem with this solution is easy to state: very few people play the centipede game that way. Instead they choose almost every imaginable outcome in the centipede game. And they do so even when they know and understand the ‘correct’ outcome. This was a well-known and serious challenge to game theory, per se, because these were among the few potentially interesting and ‘playable’ games with such clear and certain answers, and yet people clearly choose not to make their ‘best’ choices.

In EITM terms, the context of the problem was game theory, so the theoretical answer to the question was likely to be (and was) a mathematically presented theory.<sup>14</sup> And the TM answer was the derivation from

well-stated premises of what they called the QRE. The empirical observations that led to the TM question were essentially ‘case study’ observations that even knowledgeable players very often rejected the Nash equilibrium solution. Testing whether QRE is a potentially ‘correct’ answer was done via more quantitative approaches using game-experimental data.<sup>15</sup> But just as theory need not be mathematical or formally logical, empirical implications need not be tested with statistical methods.

The formal derivation of QRE itself is open to many interpretations and applications. Their interpretation is but one, and it was theoretical. By changing the specification of one of the parameters in the decision-making part of the game model, they changed the game form from one that had a unique Nash equilibrium to one that not only had, but also was better understood as ‘solved’ by the use of, quantal response equilibriums. There were several ways in which that new specification of the premise could be interpreted. The specific one that McKelvey and Palfrey employed from the outset (see 1995) is that the specified term is a parameter able to be estimated as a statistic, and thus enables QRE to be considered as a statistical problem.

They defined QRE as the ‘statistical version of the Nash equilibrium’ (p. 9), one that results from assuming that, instead of utility being a fixed quantity – where, say,  $u_i(p)$  denotes  $i$ ’s utility for outcome  $p$  – it is instead subject to random variability, where, say  $u_i(p) = u_i(p) + e_i$ . McKelvey and Palfrey (1995) prove the existence of a QRE under general conditions for this random utility function that they call the ‘statistical reaction function’ (p. 10). They then specify a more precise (logit) distribution assumption to prove more specific results which they then can apply to answer their theoretical question: might players be playing according to a QRE, with a random utility function, rather than a fixed utility and playing some Nash or refinement?

**QRE as an EI Question:** Given the setup of the original McKelvey–Palfrey QRE as a ‘statistical equilibrium’, its extension to developing empirical applications was foreseeable. Signorino (1999) not only saw how to exploit that opportunity but also had the insight to see that the uncertainty assumed about the players’ utility functions, when plugged into the sequence of play and solved as a condition of uncertainty, yielded a statistical result, such that the unknown parameters in the functions were distributed according to ‘QRE’ uncertainty as a probit. Signorino thus developed a method of estimation that one might call ‘strategic probit’ and wrote a program, ‘STRAT’, for its estimation (2001). This was a brilliant insight that both allowed for a fealty to the principles of game theory and yet also implied a statistical estimation strategy for estimating the parameters in such a game.

Consider Leblang’s paper on the ‘political economy of exchange rate policy’, estimating a game theoretic model that includes strategies of speculative currency attacks (2003; see also Granato et al. (n.d.)).<sup>16</sup> The players are speculators in the currency market and policy makers in what are (in this paper at least) governments in developing nations. The strategies are fairly simple sets of strategies. Market actors can either do nothing and preserve the status quo, or undertake speculative attacks. The policy makers in the government have nothing to do unless attacked, but if they are attacked, they can either defend against the attack or devalue their currency. While these choices are simple, the set of factors that go into their utility functions are lengthier and more complex, and it is this that provides the uncertainty (e.g., for potential speculators in determining whether the government will defend or devalue). And it is these forces that are estimated in the strategic probit estimation (done with data from 95 developing nations). The government’s decision is shown to depend on many factors, including institutional features, electoral characteristics and partisan forces.<sup>17</sup>

### ***RBC Modeling and its Potential Applications in IR***

**Background:** This EITM application – based on a Real Business Cycle (RBC) approach – relies on modeling and testing techniques tracing back to the 1930s and the Cowles Commission. The Cowles Commission approach gave rise to what we now call econometrics.<sup>18</sup> Among their contributions was the *probability approach*. This approach highlighted the issues of *identification and invariance*.<sup>19</sup> Identification was central since a goal of econometrics is to determine the true values of the parameters consistent with the data and with the known or assumed model properties. The second issue was the invariance of a relation. If the structure is known to remain in the future as it was in the past, and if the auxiliary variables have constant values through both periods, then the path of each variable will be predictable from the past, apart from random disturbances.

The Cowles Commission approach also linked both theory and empirics within a system of equations. Rules for identification (such as the rank and order conditions) were based on the number of equations and unknowns. While standard hypothesis testing was one basis for evaluating theories, the other attribute of this approach was to use out of sample forecasts and simulation (resting on invariance).<sup>20</sup> The latter feature meant that rich theoretical ‘experimental worlds’ (what we now call ‘simulations’) were feasible and allowed for various interventions – policy and otherwise – for evaluation.

In sum, and speaking more broadly, the Cowles Commission approach – in addressing the issues of identification and invariance (and the linkage of formal and empirical analysis) – provides a connection to falsifiability, predictive precision and the workings of a system.<sup>21</sup> It should be noted that models possessing these properties also facilitate comparison between rival theories about the same phenomena and thus can enhance efforts for scientific cumulation (Kuhn, 1979).

While the contributions of the Cowles approach are well known and endure to this day, it also drew criticism. In the 1970s fundamental criticisms arose regarding invariance and identification. The criticisms were leveled on both TM and EI grounds. Solutions were proposed that literally blended both theory and empirics.

Regarding TM, in 1976, Robert Lucas questioned invariance durability, based on how people form expectations when the Cowles approach is used. The problem, he argued, is that in-sample estimation provides little guidance in predicting the effects of policy changes because the parameters of the applied statistical models are unlikely to remain stable under alternative stimuli.<sup>22</sup> Or, to put it another way, there was a failure to link micro level findings in a rigorous way (and accounting for agent expectations and their response) with macro level modeling.

As for EI, the results of Lucas’s theoretical challenge was borne out in sustained periods of inaccurate forecasts that contributed to policy failure. Lucas (1981) notes:

Keynesian orthodoxy or the neoclassical synthesis is in deep trouble, the deepest kind of trouble in which an applied body of theory can find itself: It appears to be giving seriously wrong answers to the most basic questions of macroeconomic policy. Proponents of a class of models which promised 3 1/2 to 4 1/2 percent unemployment to a society willing to tolerate annual inflation rates of 4 to 5 percent have some explaining to do after a decade such as we have just come through. A forecast error of this magnitude and central importance to policy has consequences, as well it should. (pp. 559–60)

### **RBC as a Solution to the TM and EI Challenge:**

One response to Lucas’s TM and EI criticisms was Kydland and Prescott’s (1982) RBC approach. This method involves computational experiments that are based on fusing micro and macro level analysis. The initial RBC program was focused on the role of economic shocks; politics and policy were excluded.

The RBC method involves a sequence of steps including: (1) deriving the equilibrium laws of motion for the model economy from

‘well-tested theory’ on agent income, households and firms; (2) ‘calibrating’ the model using parameter values derived from historical data; (3) generating simulated realizations of the equilibrium processes; (4) determining the sampling distributions of the statistics computed from the simulated data; and (5) comparing these statistics to those computed for actual data. Kydland and Prescott’s (1982) ‘computational experiments’ are often referred to as ‘calibration’ because of the use of parameter values derived from simple measures (such as averages) of historical time series to ‘calibrate’ the theoretical models.<sup>23</sup>

This research methodology evolved in the ensuing years to include a variety of factors, making them amenable to policy interventions (and political factors) as well. This update to RBC modeling is typically referred to as *dynamic, stochastic general equilibrium* (DSGE)<sup>24</sup> modeling.

RBC (and DGSE) establishes an important EITM linkage between theoretical predictions (using various behavioral equations and the merging of the micro and macro levels) with actual observations. The formal tools for RBCs – the EITM linkage – rest in the linkage of utility maximization (decision making) with model calibration (prediction).

In political science, Freeman and Houser (1998) introduced the first RBC application but its focus was in comparative political economy. On the other hand, we find an IPE ‘policy’ example in Ghironi and Melitz (2005). They build on Melitz’s (2003) model and develop a DSGE model of international trade that includes the effects of (de)regulation on entry.

Instead of specifying a purely economic explanation based on the behavior of traded and nontraded sectors,<sup>25</sup> Ghironi and Melitz’s model provides an endogenous – policy based – explanation for the Harrod-Balassa-Samuels (HBS) effect (Kravis and Lipsey, 1983). Specifically, policy shocks (i.e., deregulation) influence firms’ decisions to enter or exit in both domestic and export markets. This behavior, in the aggregate, affects real exchange rate dynamics – and macroeconomic outcomes.

A statement of the model revealing the role of policy can be found in the Appendix. The complete system (and the calibrations and simulations that follow) can be summarized below (the variable list is given in Table 8.1):

### 1 Household: utility maximization

Euler equation (bonds)

$$(C_t)^{-\gamma} = \beta(1+r_{t+1})E_t \left[ (C_{t+1})^{-\gamma} \right], \quad (1)$$

$$(C_t^*)^{-\gamma} = \beta(1+r_{t+1}^*)E_t \left[ (C_{t+1}^*)^{-\gamma} \right], \quad (2)$$

Euler equation (shares)

$$\tilde{v}_t = \beta(1-\delta)E_t \left[ \left( \frac{C_{t+1}}{C_t} \right)^{-\gamma} (\tilde{v}_{t+1} + \tilde{d}_{t+1}) \right], \quad (3)$$

$$\tilde{v}_t^* = \beta(1-\delta)E_t \left[ \left( \frac{C_{t+1}^*}{C_t^*} \right)^{-\gamma} (\tilde{v}_{t+1}^* + \tilde{d}_{t+1}^*) \right], \quad (4)$$

### 2 Firm: profit maximization

Profits

$$\tilde{d}_t = \tilde{d}_{D,t} + \frac{N_{X,t}}{N_{D,t}} \tilde{d}_{X,t}, \quad (5)$$

$$\tilde{d}_t^* = \tilde{d}_{D,t}^* + \frac{N_{X,t}^*}{N_{D,t}^*} \tilde{d}_{X,t}^*, \quad (6)$$

Free entry (Policy)

$$\tilde{v}_t = w_t \frac{f_{E,t}}{Z_t} \quad (7)$$

$$\tilde{v}_t^* = w_t^* \frac{f_{E,t}^*}{Z_t^*} \quad (8)$$

Zero-profit export cutoffs

$$\tilde{d}_{X,t} = w_t \frac{f_{X,t}}{Z_t} \frac{\theta-1}{k-(\theta-1)}, \quad (9)$$

$$\tilde{d}_{X,t}^* = w_t^* \frac{f_{X,t}^*}{Z_t^*} \frac{\theta-1}{k-(\theta-1)}, \quad (10)$$

**Table 8.1 The list of variables for the model**

<i>Variables</i>	<i>Definitions</i>
$t$	Period
$C$	Consumption
$B$	Bond holdings
$r$	Consumption-based interest rate on bonds
$x$	Mutual fund share holdings
$L$	Labor
$w$	Real wage
$Z$	Aggregate labor productivity
$\bar{z}_x$	The average productivity level for all home exporters
$z_{\min}$	The lower bound of relative productivity $z$
$N_H$	The number of total home firms
$N_D$	The number of home-producing firms
$N_X$	The number of home exporters
$N_E$	The number of new entrants
$Q$	Consumption-based real exchange rate
$\tilde{v}$	Expected post entry value
$\tilde{d}$	The average firm profit levels
$\tilde{d}_D$	The average firm profit earned from domestic sales for all home producers
$\tilde{d}_X$	The average firm profit earned from export sales for all home exporters
$\tilde{p}_D$	The average relative price of producers
$\tilde{p}_X$	The average relative price of exporters
$f_E$	Entry cost
$f_X$	Fixed cost
$k$	Productivity distribution shape parameter
$\beta$	Subjective discount factor
$\gamma$	The inverse of the intertemporal elasticity of substitution
$\theta$	The symmetric elasticity of substitution across goods
$\delta$	Probability of exit-inducing shock

\*Note: These are home variables and corresponding foreign variables are denoted by an asterisk.

Source: Ghironi and Melitz (2005).

Share of exporting firms

$$\frac{N_{X,t}}{N_{D,t}} = (Z_{\min})^k (\bar{z}_{X,t})^{-k} \left[ \frac{k}{k - (\theta - 1)} \right]^{k/(\theta-1)}, \quad (11)$$

$$\frac{N_{X,t}^*}{N_{D,t}^*} = (Z_{\min}^*)^k (\bar{z}_{X,t}^*)^{-k} \left[ \frac{k}{k - (\theta - 1)} \right]^{k/(\theta-1)}, \quad (12)$$

Number of firms

$$N_{D,t} = (1 - \delta)(N_{D,t-1} + N_{E,t-1}), \quad (13)$$

$$N_{D,t}^* = (1 - \delta)(N_{D,t-1}^* + N_{E,t-1}^*), \quad (14)$$

3 Equilibrium conditions:

Price indices

$$N_{D,t} (\tilde{p}_{D,t})^{1-\theta} + N_{X,t}^* (\tilde{p}_{X,t}^*)^{1-\theta} = 1, \quad (15)$$

$$N_{D,t}^* (\tilde{p}_{D,t}^*)^{1-\theta} + N_{X,t} (\tilde{p}_{X,t})^{1-\theta} = 1, \quad (16)$$

Aggregate accounting

$$C_t = w_t L + N_{D,t} \tilde{d}_t - N_{E,t} \tilde{v}_t, \quad (17)$$

$$C_t^* = w_t^* L^* + N_{d,t}^* \tilde{d}_t^* - N_{e,t}^* \tilde{v}_t^*, \quad (18)$$

Balanced trade

$$Q_t N_{x,t} (\tilde{p}_{x,t})^{1-\theta} C_t^* = N_{x,t}^* (\tilde{p}_{x,t}^*)^{1-\theta} C_t, \quad (19)$$

**Comparing Model Predictions with Actual Data (Calibration):** Ghironi and Melitz test the model via calibration and compute the moments from the simulated data and compare them with the actual moments in the United States.<sup>26</sup> They reproduce key economic features of the United States under exogenous shocks to aggregate productivity and contrast it with the actual data for the period 1954 to 1989 (Backus et al., 1992). The parameter values in their calibrations are presented in Table 8.2. Here we focus on how closely the model mimics actual data for various economic variables: Net Exports/Output, Investment, Consumption, and Aggregate Output.

Figure 8.1 illustrates one comparison between the simulated and actual volatility (e.g., standard deviation). Ghironi and Melitz's model comparisons reveal that their model underpredicts the volatilities of aggregate output, consumption and investment, while it generates a more volatile ratio between net exports and output.

**Policy Effects: Simulation:** Next, we examine the policy regulation effects on entry ( $f_E$ ). Specifically, Ghironi and Melitz examine the trade policy parameters (entry or trade costs) in (7). The expectation is that the policy shocks will affect the real exchange rate dynamics, explaining the HBS effect through endogenous channels.

Figure 8.2 illustrates the impact of a permanent shock to deregulation ( $f_E$ ) – reducing entry costs – on the microeconomic response and, then, the macroeconomic outcomes. The vertical axis indicates the percent deviation from the steady state (response to a permanent deregulation shock) and the horizontal axis shows the number of years after the shock.

We present the results for total labor cost and the real exchange rate. The process in this example is as follows: the deregulation shock (a decline in the deregulation parameter ( $f_E$ )) in the home market raises domestic demand. Subsequently, domestic wages increase, decreasing the relative effective labor cost ( $TOL$  in Figure 8.2) in the long run. The result is that the real exchange rate ( $\tilde{Q}$  in Figure 8.2) appreciates (the cost of a foreign basket of goods falls) in the long term, as it would in the HBS model.

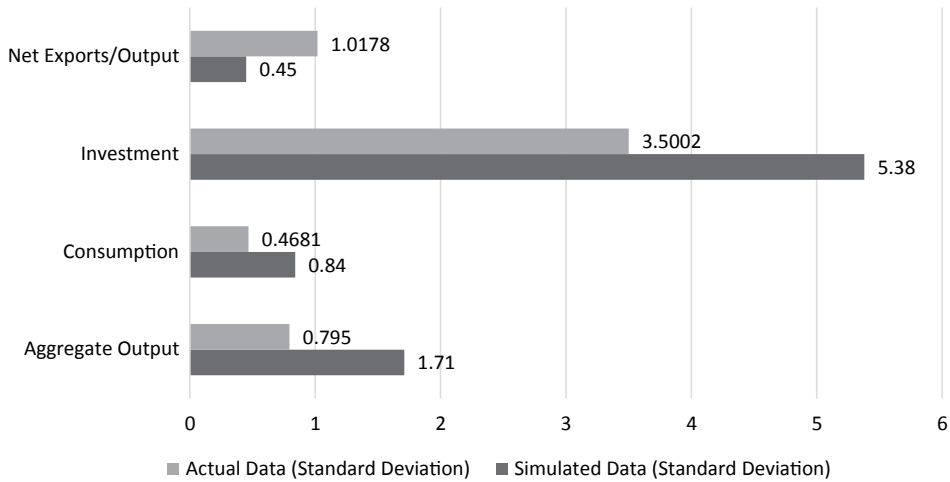

We also find that policy deregulation's influence on the decline in total labor cost and the appreciation of the real exchange

**Table 8.2 Parameter values**

Parameters	Values	Definitions
<b>Policy<sup>1</sup></b>		
$f_E$	1	Entry cost: equation (7), firm profit maximization
<b>Economy</b>		
$\beta$	0.99	Subjective discount factor: equations (1) and (3), household utility maximization
$\gamma$	2	The inverse of the intertemporal elasticity of substitution: equations (1) and (3), household utility maximization
$\delta$	0.025	Probability of exit-inducing shock: equation (3), household utility maximization
$\theta$	3.8	The symmetric elasticity of substitution across goods: equations (9) and (11), firm profit maximization
$k$	3.4	Productivity distribution shape parameter: equations (9) and (11), firm profit maximization

<sup>1</sup> Another policy parameter — fixed cost  $f_x$  — is calculated based on the entry cost  $f_E$ . It equals 23.5 percent of the per-period, amortized flow value of the entry cost, which is roughly 0.008 as the entry cost  $f_E$  equals 1.

Source: Ghironi and Melitz (2005).

**Figure 8.1 Simulated and actual volatility**

Source: Ghironi and Melitz (2005).

**Figure 8.2 Deregulation effects**

Source: Ghironi and Melitz (2005).

rate is not immediate. Within five years of the shock (a 1% decline in the entry cost), less than 20% of the deviation from the steady state emerges regarding the total labor cost. For the real exchange rate, there is about a 15% deviation, but in the correct direction.

**Incorporating Political Factors:** What role for politics in RBC? One avenue has been provided by Freeman and Houser (1998). They built on the work of Chappell

and Keech (1983) and took up the challenge presented by the Cowles tradition. Freeman and Houser set up an RBC model to study the joint equilibrium in the political environment and the macro-economy. As with Chappell and Keech, Freeman and Houser argue that economic decisions and political decisions are often studied separately in the literature. They state that there is ‘a lack of theoretical balance between economic and political theory’ (Freeman and Houser, 1998: 628).

Freeman and Houser's computable general equilibrium model combines the Ramsey-type RBC model with the policy maker's objective function on approval ratings. A summary of their model – without formalizing it here – is as follows: the government is a representative agent who optimally chooses tax rates and gross interest rate on public bonds in order to minimize the present value of expected sum of deviations of approval ratings. Hence, the government chooses optimal policy to minimize the approval target deviations given the optimal decisions made by households and the firms. The more general point of their model is that it opens the way for many rich political models – partisan, institutional and more – and how these models influence fiscal, monetary, trade and regulatory policy within the RBC methodology and EITM framework.

## SUMMARY

EITM was established through the NSF initiative in 2001. As the example in the last section indicates, the motivation of EITM-like research predates the 21st century considerably. Its realization in political science was due in large part to the great successes that both the development of formal modeling and political methodology had achieved in the discipline. It was the concern that they were developing on separate tracks that led to EITM as a way to align scientific development in political science, in the social and behavioral sciences and even in science more generally.

We argued here that EITM is best understood as a way to generate and communicate new scientific knowledge. It is, in that sense, a research design problem rather than a precise set of constraints on research. And, we argued, we see it as a research design applied to a stream of research.

We described two examples of EITM-consistent research. We take two basic

conclusions from these examples. First, EITM can be applied both to theory and to empirics. Indeed, the best of EITM research uses the design to solve both sides of the scientific enterprise. Second, both examples unfolded and became richer and broader in their applications over time. That is, pursuing EITM-consistent lines of inquiry in these cases – and, we believe, more generally – facilitates the accumulation of knowledge. Perhaps this is indeed the greatest promise of EITM.

## APPENDIX

**The Model:** The formal model consists of two countries, home and foreign, where households and a continuum of firms exist in each country. In the home country, the representative household supplies  $L$  units of labor inelastically in each period  $t$  at the nominal wage rate  $W_t$  (in home currency). Households make optimal decisions on consumption ( $C$ ) to maximize their utility. Firms are heterogeneous with different relative productivity,  $z$ , that translates into differences in production cost. The same holds true for foreign representative households and firms.<sup>27</sup>

The dynamics of the model *and for policy* focus on entry. Prior to entry, home (foreign) firms are identical; facing a sunk entry cost of  $f_{E,t}$  ( $f_{E,t}^*$ ) effective labor units, equal to the home (foreign) consumption goods. Upon entry, home firms draw their productivity level  $z$  from a common distribution  $G(z)$ , bounded by  $[z_{\min}, \infty)$ , while foreign homes draw theirs from an identical distribution.

All firms can serve both domestic and export markets. The cost of exporting includes a trade cost  $\tau_t \geq 1$  ( $\tau_t^* \geq 1$ ) and a fixed cost  $f_{X,t}$  ( $f_{X,t}^*$ ). Home (foreign) firms decide whether to export depending on the profits, which is determined by the firm's productivity level. A firm will export if and only if a nonnegative profit is earned from exporting,

which they assume will be the case provided  $z$  is above a cutoff level  $z_{X,t}(z_{X,t}^*)$ . They also assume the lower bound of  $z$ ,  $z_{\min}$ , is small enough relative to the export costs and that  $z_{X,t}(z_{X,t}^*)$  is above  $z_{\min}$ . This assumption determines that a nontraded sector exists. These firms can change their decision over time if profitability changes in the export market.

Firms interact with households in the following way.<sup>28</sup> On the demand side, the model assumes households in each country maximize expected intertemporal utility from consumption:

$$E_t \left[ \sum_{s=t}^{\infty} \beta^{s-t} C_s^{1-\gamma} / (1-\gamma) \right], \quad (1a)$$

where  $\beta \in (0, 1)$  is the subjective discount factor and  $\gamma > 0$  is the inverse of the intertemporal elasticity of substitution. In period  $t$ , the household consumes the baskets of goods:  $C_t = \left( \int_{\omega \in \Omega} c_t(\omega)^{\theta-1} d\omega \right)^{\theta/(\theta-1)}$ , where

$\Omega$  is a continuum of goods and  $\theta > 1$  is the symmetric elasticity of substitution across goods. The model also assumes households possess two types of assets, including risk-free bonds ( $B$ ) and shares ( $x$ ) in a mutual fund of domestic firms. Taking the home country as an example (at time  $t$ ) the representative household buys  $x_{t+1}$  shares in a mutual fund of  $N_{H,t} \equiv N_{D,t} + N_{E,t}$  home firms (where  $N_{D,t}$  is the number of home-producing firms,  $N_{E,t}$  is the number of new entrants).

Among the firms producing in the home country, there are  $N_{X,t}$  exporters. The household receives gross interest income (from bond holdings), dividend income (from mutual fund share holdings), as well as the value of selling its initial share position and labor income. They allocate this income stream to the purchase of bonds and shares to be held into next period and consumption. Thus, the period budget constraint for the household is:

$$\begin{aligned} B_{t+1} + \tilde{v}_t N_{H,t} x_{t+1} + C_t \\ = (1+r_t)B_t + (\tilde{d}_t + \tilde{v}_t) N_{D,t} x_t + w_t L, \end{aligned} \quad (2a)$$

where  $\tilde{v}_t$  is the expected post entry value given by the present discounted value of prospective home entrants' expected stream of profits,  $r_t$  is the consumption-based interest rate on bonds holdings from  $t-1$  to  $t$ ,  $\tilde{d}_t$  represents average firm profit levels, and  $w_t \equiv W_t/P_t$  is the real wage ( $P_t$  is the consumption-based price index).

For the supply side, aggregate labor productivity is indicated as  $Z_t(Z_t^*)$ . Firms are heterogeneous with different technologies measured in relative productivity  $z$ . A home firm, for instance, produces  $Z_t z$  units of output per unit of labor employed – the production function. It is assumed that  $z$  follows a Pareto distribution with lower bound  $z_{\min}$  and shape parameter  $k > \theta - 1$ :  $G(z) = 1 - (z_{\min}/z)^k$ . All firms produce – in any given time  $t$  – until an exit-inducing shock occurs with the probability  $\delta \in (0, 1)$  that is independent of  $z$ . All firms also face a residual demand curve with constant elasticity  $\theta$  in both domestic and export markets. They set flexible prices reflecting the same proportional markup  $\theta/(\theta - 1)$  over marginal cost.

The nominal domestic and export prices are indicated by  $p_{D,t}(z)$  and  $p_{X,t}(z)$  for a home firm; the export prices are denoted in the currency of the export market. Therefore, the relative domestic and export prices are  $\rho_{D,t}(z) \equiv \frac{p_{D,t}(z)}{P_t} = \frac{\theta}{\theta-1} \frac{w_t}{Z_t z}$  and  $\rho_{X,t}(z) \equiv \frac{p_{X,t}(z)}{P_t^*} = Q_t^{-1} \tau_t \rho_{D,t}(z)$ , respectively,

where  $Q_t$  represents the real exchange rate. As a consequence of the fixed cost of exporting, less productive firms may decide not to export at time  $t$ . To make the decision, a firm considers the total profit  $d_t(z)(d_t^*(z))$  in terms of the profit generated from domestic sales  $d_{D,t}(z)(d_{D,t}^*(z))$  and that earned from potential export sales  $d_{X,t}(z)(d_{X,t}^*(z))$ . All these profits are denominated in real terms in units of the consumption basket in the firm's country.

Prices are also assumed to be affected by productivity levels. Following Melitz (2003),

Ghironi and Melitz define two ‘special “average” productivity levels’ (Ghironi and Melitz, 2005: 874),  $z_D$  and  $\tilde{z}_{X,t}(\tilde{z}_{X,t}^*)$ , for all producing firms  $N_{D,t}(N_{D,t}^*)$  and exporters  $N_{X,t}(N_{X,t}^*)$ , respectively. Accordingly, in the home market, the average relative price of producers is indexed by  $\tilde{\rho}_{D,t} \equiv \rho_{D,t}(\tilde{z}_D)$ . The average relative price of foreign exporters is  $\tilde{\rho}_{X,t} \equiv \rho_{X,t}(\tilde{z}_{X,t}^*)$ .  $\tilde{d}_{D,t} \equiv d_{D,t}(\tilde{z}_D)(\tilde{d}_{D,t}^* \equiv d_{D,t}^*(\tilde{z}_D^*))$  denotes the average firm profit earned from domestic sales for all home (foreign) producers.  $\tilde{d}_{X,t} \equiv d_{X,t}(\tilde{z}_{X,t})(\tilde{d}_{X,t}^* \equiv d_{X,t}^*(\tilde{z}_{X,t}^*))$  represents the average firm export profits for all home (foreign) exporters.

Consequently, the average total profits are  $\tilde{d}_t \equiv \tilde{d}_{D,t} + [1 - G(\tilde{z}_{X,t})]\tilde{d}_{X,t}$  for home firms and  $\tilde{d}_t^* \equiv \tilde{d}_{D,t}^* + [1 - G(\tilde{z}_{X,t}^*)]\tilde{d}_{X,t}^*$  for foreign firms. At any given period,  $t$ , there is an unlimited amount of prospective entrants  $N_{E,t}$  in both home and foreign countries. These firms are forward looking and anticipate their future expected profits  $\tilde{d}_t(\tilde{d}_t^*)$  and the probability of the occurrence of the exit-inducing shock  $\delta$ . Firms discount future profits based on the household’s stochastic discount factor  $\beta$ , adjusted for the probability of firm survival  $1 - \delta$ . The entry occurs when the average postentry value (given by the current discounted value of the expected profits) equals the entry cost, resulting in the free entry condition  $\tilde{v}_t = w_t f_{E,t} / Z_t$ . Note, this condition holds so long as  $N_{E,t} > 0$ . Moreover, for this condition to hold in every period, macroeconomic shocks are assumed to be sufficiently small.

## Notes

- 1 We thank Cong Huang and M. C. Sunny Wong for their assistance.
- 2 This phrase can be meant in the way used by Kuhn, 1970 [1962], but here we mean ‘before doing the science’ in a more general sense.
- 3 The last is a paraphrase of a half of a lecture Prof. Arthur Goldberg gave to one of us in the University of Rochester’s PS 401, scope and methods class, in its Political Science PhD pro-

gram, or at least it is paraphrased as well as one of this paper’s co-authors can remember hearing it.

- 4 No one piece of research, say an article in a leading peer-reviewed journal, needs to accomplish all aspects of an EITM contribution (indeed, perhaps it *should* not, or at least should not be expected to do so). However, attention to where it fits in an EITM-consistent stream of research, what it contributes in those terms and what remains to be accomplished in that stream should be a part of any such paper.
- 5 The 2001 NSF EITM Workshop was recorded and transcribed. The written transcript is available on the NSF Political Science Program Web Site: [www.nsf.gov/sbe/ses/polisci/reports/eitm709.pdf](http://www.nsf.gov/sbe/ses/polisci/reports/eitm709.pdf) and [www.nsf.gov/sbe/ses/polisci/reports/eitm710.pdf](http://www.nsf.gov/sbe/ses/polisci/reports/eitm710.pdf). A report of the EITM initiative – based in part on the 2001 EITM Workshop (EITM Report 2002) – is also available at: [www.nsf.gov/sbe/ses/polisci/reports/pdf/eitmreport.pdf](http://www.nsf.gov/sbe/ses/polisci/reports/pdf/eitmreport.pdf).
- 6 The participants in the workshop – with diverse methodological backgrounds – were senior scholars with research experience in various technical-analytical areas and proven track records in activities that have improved technical-analytical expertise in various social sciences. Participants were primarily from political science, but economics and mathematics were represented as well. For background on the motivation for the EITM Workshop see Granato et al. (2015).
- 7 The EITM initiative is part of a multi-method approach. Recall that the motivation for the use of EITM has quantitative roots, but consistent with the arguments of Poteete et al. (2010) it is recognized that qualitative approaches have various strengths, including highlighting the importance of context (Granato and Scioli, 2004: 314–15). But, as with quantitative tools, Granato and Scioli (2004) do highlight shortcomings of qualitative approaches (e.g., Sartori, 1991; Goldthorpe, 1997).
- 8 See Wagner (2001: 3).
- 9 Recall from the introduction, that EITM is a method – even a mindset – where researchers treat formal and empirical analysis as linked entities intended to create a dialogue between theory and test. But how to define EITM? What does it look like when we try to implement the dialogue? Implementation involves defining the elements of EITM – a framework – and showing how one does EITM research and how one trains students to do such research. The development of a framework was deemed important at NSF since ‘without a framework to organize relevant variables identified in theories and empirical research, isolated knowledge acquired from studies ... by ... social

- and behavioral scientists is not likely to cumulate' (Ostrom, 2009: 420). See Granato (2005) and Granato et al. (2010) for a description and examples of the EITM framework.
- 10 A key outcome of the EITM initiative has been the EITM Summer Institutes. The Summer Institutes have taken place at:
    - Harvard University (2002)
    - The University of Michigan (2003, 2006, 2009, 2015, 2018)
    - Washington University, St. Louis (2003–9)
    - Duke University (2004, 2008, 2014, 2016)
    - UC-Berkeley (2005, 2010, 2013, 2017)
    - UCLA (2007)
    - University of Chicago (2011)
    - Princeton University (2012)
    - University of Houston (2012–17, 2019)
    - Emory University (2019).
  - 11 The finitely repeated prisoner's dilemma is the other major example.
  - 12 In the centipede game, the (usually two) players move sequentially. The first player can take an initial sum of money or pass. If the player takes the money, the game ends. If, instead, the player passes, the initial amount increases (say, doubles), and the second player can either take this larger amount of money or pass. If 'take' is played, the game ends. If pass, the money is increased again (say, doubled a second time) and the choice goes back to the first player. The game continues with the play of 'pass' and ends as soon as a player decides to take the money.
  - 13 Of course, the finitely repeated prisoner's dilemma also has a unique (and easily implemented) Nash equilibrium (every player always defects). Like the centipede game, perhaps even more so, actual players rarely follow that strategy under a wide range of conditions, even when they understand that always defect is the unique Nash equilibrium.
  - 14 While there are many good reasons for choosing a (formal) logic or mathematical representation of TM, those are all conveniences made possible through the use of math or logic. There is nothing in EITM that requires formalization of the theory. The requirement is logical consistency.
  - 15 We mean 'game-experimental' in the sense as used in Kinder and Palfrey (1993).
  - 16 Carson published a paper on candidate decisions to run for office, developing a game theoretic model of ambition theory and estimating it via the same method as Leblang in the same year (2003). Thus, the QRE and resulting STRAT-like estimation models have been applied in IPE and American politics shortly after Signorino developed the original.
  - 17 More recently, Palfrey and co-authors have closed the circle, as it were, in developing QRE as what they call a 'statistical theory of games' (Goeree et al., 2016).
  - 18 Econometric research associated with the Cowles Commission includes (but is not limited to): Cooper (1948), Haavelmo (1943, 1944), Hood and Koopmans (1953), Klein (1947), Koopmans (1945, 1949, 1950), Koopmans and Reiersol (1950), Marschak (1947, 1953) and Vining (1949). For further background on the Cowles Commission consult the following URL: <http://cowles.econ.yale.edu/>.
  - 19 The intuition behind the terms *identify* (i.e., identification) and *invariant* (i.e., invariance) is as follows. For applied statistical models *identification* relates to model parameters (e.g.,  $\beta$ s) and whether they indicate the magnitude of the effect for that particular independent variable. Or, in more technical terms, 'A parameter is identifiable if different values for the parameter produce different distributions for some observable aspect of the data' (Brady and Collier, 2004: 290). In applied statistical practice, *invariance* refers to the constancy of the parameters of interest. More generally, 'the distinctive features of causal models is that each variable is determined by a set of other variables through a relationship (called "mechanism") that remains invariant (constant) when those other variables are subjected to external influences. Only by virtue of its invariance do causal models allow us to predict the effect of changes and interventions' (Pearl, 2000: 63).
  - 20 Underlying this approach was the argument that any change in model specification would be traced out through the entire system with new results known *ex-ante* – a fundamental feature of EITM too. Indeed, this is one improvement over single equation models where specification changes would lead to new results but with the *ex-ante* origins of the effects known.
  - 21 Gabaix and Laibson (2008: 295) argue that falsifiability and predictive precision are among the key properties of useful models: 'A model is falsifiable if and only if the model makes nontrivial predictions that can in principle be empirically falsified.' Furthermore:
 

Models have *predictive precision* when they make precise – or 'strong' – predictions. Strong predictions are desirable because they facilitate model evaluation and model testing. When an incorrect model makes strong predictions, it is easy to empirically falsify the model, even when the researcher has access only to a small amount of data. A model with predictive precision also has greater potential

to be practically useful if it survives empirical testing. Models with predictive precision are useful tools for decision makers who are trying to forecast future events or the consequences of new policies. (p. 295)

In the language of econometrics, falsification and predictive precision require the mechanisms relating cause and effect to be identified. There is a large literature devoted to identification problems (see, e.g., Koopmans, 1949; Fisher, 1966; Manski, 1995), but we use identification in the broadest sense for purposes of attaining some order and underlying cause as well. Since we as social scientists do not have controlled environments to conduct our inquiry, our efforts to achieve order and cause in our models can only come about probabilistically – by chance.

- 22 The Lucas *critique* is based on the following intuition: 'given that the structure of an econometric model consists of optimal decision rules ... and that optimal decision rules vary systematically with changes in the structure of series relevant to the decision maker, it follows that any change in policy will systematically alter the structure of econometric models' (Lucas, 1976: 41).
- 23 Here the focus is on isolating parameters and on making greater explicit use of theory at both the individual and aggregate level of analysis. Where RBCs especially differ from the Cowles Commission is in the use of standard statistical significance testing.
- 24 The DSGE evolution is due in part to the inclusion of policy into the RBC modeling process. Indeed, Prescott precisely foresaw this possibility:

The models constructed within this theoretical framework are necessarily highly abstract. Consequently, they are necessarily false, and statistical hypothesis testing will reject them. This does not imply, however, that nothing can be learned from such quantitative theoretical exercises. I think much has already been learned and confidently predict that much more will be learned as other features of the environment are introduced. Prime candidates for study are the effects of public finance elements, a foreign sector, and, of course, monetary factors. The research I review here is best viewed as a very promising beginning of a much larger research program. (Prescott, 1986: 10)

For our purposes we will continue to use the terms RBC and DSGE when one or the other is more appropriate.

- 25 See Melitz (2003).
- 26 To reiterate, these moments are based on the findings in Backus et al. (1992). They introduce

the resource cost of trade in their international RBC model and include the shocks to aggregate productivities to replicate second moments of the United States and international data.

- 27 All foreign variables are denoted by an asterisk in Ghironi and Melitz's work.
- 28 Trade policy outcomes are based on aggregating the budget constraint across home households and imposing the equilibrium conditions under financial autarky. This also holds in a foreign country.

PART II

# Methods of Theoretical Argumentation

*This page intentionally left blank*

# Political Psychology, Social Psychology and Behavioral Economics

Rose McDermott

This chapter will examine the differences, as well as the overlaps, between the procedures, assumptions, criteria for evaluating quality and accepted standards for empirical research across several different disciplines. Particular attention will be paid to how these characteristics vary according to the different questions and aims pursued by each discipline. In addition, underlying differences in disciplinary culture that affect these intellectual pursuits will also be mentioned where relevant.

Although clearly this endeavor could be undertaken around a wide variety of disciplines, here the focus will be on political psychology, social psychology and behavioral economics, primarily because these disciplines share some important overlaps regarding the operative unit of analysis lying with the individual actor. These areas share some overlap with other disciplines that may intersect with political science, such as sociology and anthropology, but those areas tend to focus more on group dynamics and thus are more distinct in their assumptions and approaches. This does not make them better

or worse for analyzing any given political problem. Rather, as with any research question, the particular approach and methods should be driven by what is best suited for properly addressing the central research question at hand, and not by any special fixation on a particular theory or method.

This chapter will proceed by discussing each of the areas mentioned above for each of these disciplines. Although space and scope limitations prevent any substantive analysis of the content of these areas, interested readers will be referred to critical texts in each area that can provide such background. The discussion here is necessarily limited to an analysis of the similarities and differences across fields in each of these areas.

## **ACCEPTED PROCEDURES**

'Accepted procedures' really refers to those particular methodological standards that are considered standard for empirical

examination and analysis within a discipline. Accepted procedures across disciplines typically differ primarily around methodological issues and not theoretical approaches. In particular, dominant methods in each discipline largely inform the criteria by which quality work is evaluated, and which statistical as well as procedural standards are considered acceptable in each area as well.

The gold standard for all of psychology, whether political or social, revolves around the carefully controlled laboratory experiment, where subjects are submitted to conditions that vary between controlled and treatment manipulations. Investigators strive to keep as much of the background environment similar between all conditions and only change the variable of interest. This careful control and manipulation allows observers to determine the extent to which any differences that might emerge in subject responses are attributable to the variable that was manipulated across conditions. These kind of experiments can measure various attitudinal or behavioral responses, but the method of administration remains fairly standard. There are several good reference books on how to conduct experiments appropriately within the accepted standards of social psychology; Aronson et al. (1990) provide a superlative overview with useful examples for how to implement such procedures.

Political psychology encompasses a much broader array of methods drawn in part from other disciplines, including political science, such as qualitative case studies, archival work, surveys, interviews and narratives (McDermott, 2004). This is partly because political psychology is often interested not only in living people but also in historical figures, whose life and influence may only be accessed through archives, oral histories or interviews with people who knew them. In addition, because the focus tends to be more exclusively on political as opposed to broader social phenomena, as is the case with social psychology, political psychology will often examine levels of analysis that go beyond

the individual to examine group behavior, or to explore the influence of larger structural forces on individuals, or vice versa.

Experiments, particularly involving standard games, also populate behavioral economics, which tends to employ these games in interaction with formal models (Camerer et al., 2011). Indeed, the standard formula for a published paper in behavioral economics tends to begin with a formal model that is then tested empirically using experiments with real life subjects. The results of these studies are then used to adjust the formal model to become more consistent with real world behavior. The value of employing standardized games in experimental contexts is that they both simplify and standardize challenges and responses in ways that make it easier to compare across individuals. In this regard it is important to note, however, that not all experimental economics takes place in the area of behavioral economics. There has been, and continues to be, a great deal of work in experimental economics testing such things as equilibrium predictions in games (Goeree et al., 2016) that does not fall under the rubric of behavioral economics, which tends to focus more on how individuals violate assumptions of classical economics in ways that appear as failures of rationality.

The use of standard games derived from behavioral economics is not simply restricted to economics. Political scientists are increasingly employing these procedures particularly in the context of field experiments (Gerber and Green, 2012). Field experiments can mean different things in different fields. In most political science contexts, they involve conducting experiments in public settings – either within American domestic contexts, such as large voting studies (Arceneaux, 2005), or abroad in other countries to explore a wide variety of phenomena, such as using social media to track violence in Gaza (Zeitsoff, 2011) and exploring clientelism in Benin (Wantchekon, 2003). In these field contexts, the use of standard games

derived from economics can be particularly useful in the context of cross-cultural work. For example, work in this vein undertaken by political scientists has explored the ways in which individuals from different ethnic groups might respond to one another by seeing how much money people pass along to others from the same or different groups in a standard dictator or trust game (Bahry et al., 2005; Whitt and Wilson, 2007).

Field experiments are not, however, restricted to behavioral economic games to investigate their phenomena of interest. In economics, field experiments are most often used to examine issues related to economic development and inequality, particularly in places like India (Duflo, 2006). Such work often, but not always, utilizes either survey or so-called list (Harrison and List, 2004) experimental designs. Survey designs (Mutz, 2011) employ a between subjects design by administering slightly different versions of the exact same question to different respondents and then examining the differences in their responses. The value of such designs is that they can be administered in the context of nationally representative populations, allowing for a combination of the internal validity offered by lab experiments with close control over the variables and manipulations of interest, with the external validity provided by large and representative samples of the population as respondents. In political science, survey experiments have also been used in field contexts to examine a wider variety of topics, including such issues as political corruption in Brazil (Weitz-Shapiro and Winters, 2017). I am currently involved in large-scale cross-cultural work using survey experiments to explore differences in attitudes toward gender inequality by sex and religion of respondent across a variety of substantive domains.

List experiments ask subjects to give the number of items on a list to which they might respond in a certain way, for example negatively or positively. Their responses are then compared with a control group where

the sensitive item is not included, allowing investigators to examine the extent to which a socially sensitive issue like race or gender might be causing responses without forcing the individual to feel 'outed' by having to state which item affected their response. Such designs have been used to explore a wide variety of topics in economics, including labor markets and charity, and in political science they tend to be used to examine such topics as support for government forces in Afghanistan (Blair et al., 2014).

## STARTING ASSUMPTIONS

The starting assumptions of each discipline remain largely implicit and are often recognized by practitioners only when they are violated. As mentioned above, some of these assumptions relate to the preferred operative level of analysis. In the three subfields of political psychology, social psychology and behavioral economics, unlike much of the larger field of political science, the default level begins and ends with the individual and very little work concentrates on the level of the group, the domestic state, the regime type or economic system or the international system.

In addition, implicit assumptions regarding what constitutes an interesting or viable question, particularly around issues deeply inculcated with existential identification such as 'rationality', often cause practitioners steeped in different disciplines to talk past each other while ostensibly exploring the same issue. Indeed, many of the differences which unite these areas, but divide them from their respective larger disciplines, revolve around these assumptions of human rationality – assumptions which these areas largely reject, although dominant models in both political science and economics continue to embrace this descriptively inaccurate assumption. As a result, the following discussion will concentrate on these alternative

constructions of rationality because they have been so influential in driving work across fields – similar differences could be shown in other areas as well, but notions of rationality constitute the political ideological divide across disciplines and thus provide the greatest insight into divergences in starting assumptions across fields.

To be clear, the larger disciplines of both political science and classical economics tend to buy into traditional notions of human rationality at both a descriptive and a normative level. Specifically, they tend to start with an assumption of rational choice, arguing that when confronting a choice, the vast majority of healthy individuals will assess, either implicitly or explicitly, the worth and probability of each option and then decide on the one that offers the best combination of odds of getting what they want, along the lines of classic subjective expected utility theory (von Neumann and Morgenstern, 1947, based on earlier 18th-century work on expected utility by Bernoulli). This has proven to be a very useful assumption for many areas of classical economic theory.

However, work in the area of psychology, pioneered by Amos Tversky and Daniel Kahneman (1974; Kahneman and Tversky, 1979, 1984), called these assumptions into question from an empirical standpoint in groundbreaking and hugely influential work on judgmental biases and Prospect Theory, which has been cited over 50,000 times across a wide variety of fields. The work on Prospect Theory won Kahneman the Nobel Prize in Economics in 2002, which he shared with Vernon Smith, another founding father of behavioral economics. In many ways, this work interrogating the nature of human biases in decision making created the subfield of behavioral economics, and has continued to deeply influence the development of the field at large. Indeed, the 2017 recipient of the Nobel in Economics, Richard Thaler, is another behavioral economist famous for his use of methods and theories drawn from psychology to explore and intervene in various

economic phenomena, including the savings rate (Thaler, 2015). The origin of the use of behavioral economics in psychology is part of the reason why behavioral economics relies so heavily on experimental procedures to generate and test its theories and assumptions; it grew out of a field where only experiments are considered credible for clearly demonstrating cause and effect in human attitudes and behavior.

The importance of the biases that Kahneman and Tversky rigorously demonstrated in their elegant experimental work documented the ways in which individuals do not conform to the assumptions of rationality assumed by economists working in the traditional mold. This was very important because it forced many economists to have to confront the empirical accuracy of their starting assumptions around the nature of individual rationality. Kahneman and Tversky were not the first to show limitations in human cognitive processing; indeed, Herbert Simon's (1982) very influential work on satisficing and bounded rationality preceded their work.

While this more empirically grounded model of decision making forced many economists to have to grapple with the discrepancies between their models and reality (Gächter et al., 2009), this was not the only attack mounted against established approaches to rationality. Subsequent challenges have come from the area of evolutionary psychology, which points not only to inadequacies in models of human rationality offered by economists, but also to models which presented deviations from optimal rationality as errors or mistakes. This alternative model (Gigerenzer and Goldstein, 1996) suggested that human rationality remained necessarily contingent on environmental circumstances. As a result, people possessed a kind of 'ecological' rationality that uses very effective and efficient psychological mechanisms developed over the course of evolution by natural selection to render near optimal decision-making strategies from the perspective of survival. This perspective draws on

various strands of research for support, from ethological work showing similar strategies among chimpanzees (Lakshminarayanan et al., 2011) to work showing that what might appear to look like 'irrational' or 'biased' behavior actually makes sense within the context of humans who evolved in small-scale societies. For example, abstract inability to make associations becomes possible in the context of trying to detect cheaters (Cosmides and Tooby, 1992), and the well-known risk insensitivity demonstrated in the classic disease paradigm reverses when applied to very low level population sizes (Rode and Wang, 2000). And certainly it is possible to provide an evolutionary explanation for the modern divergences in risk sensitivity demonstrated in the classic Tversky and Kahneman experiments (McDermott et al., 2008).

These differences in approach do not preclude the possibility that convergences cannot be reached or found. Certainly, theoretical approaches drawn from evolutionary models have reached near consensus across most areas of the life and behavioral sciences, including psychology, anthropology and medicine, although they have so far proved far less influential in the fields of sociology, political science and classical economics. However, other disciplinary integration has occurred and more is possible. For example, Herbert Gintis (2009) has suggested that greater unification across disciplines, including the incorporation of anthropological approaches that study human interaction in small-scale societies, might benefit behavioral economics in particular, and help improve notions of rationality more generally. This kind of approach has already yielded very interesting interdisciplinary work on the nature of leadership (von Rueden and van Vugt, 2015; von Rueden et al., 2014) and status (Cheng et al., 2010), among other topics of great interest to political scientists.

In addition, methodological synthesis is becoming increasingly possible. Camerer et al. (2005) have argued for and shown how neuroscientific advances, particularly in the

use of magnetic resonance imaging (MRI) technology, can be used to enlighten our understanding of how the brain operates, and provide a methodological foundation for a more interdisciplinary approach to the study of decision making. Such work might unite behavioral economics and various strands of psychology, including social, cognitive and evolutionary approaches. By contrast, political science has been remarkably slow to adopt or incorporate such methods into investigations of political behavior (for an exception see Dawes et al., 2012). This likely results primarily from the costs and challenges associated with learning how to use MRIs, but likely also derives from an overall skepticism within the discipline regarding the importance of individual action and behavior for understanding the large-scale organizational and structural phenomena that constitute the primary area of interest and investigation for the vast majority of political scientists.

## **CENTRAL RESEARCH ISSUES AND QUESTIONS**

Perhaps most important of all the divisions noted here, and certainly presaged by the discussion of the notion of rationality just above, all these sources of division and divergence are hugely shaped by the central research issues and questions that preoccupy each discipline. This drives, in part, the methodological differences that divide these fields. Clearly, different substantive areas of inquiry demand different procedures and methods for proper investigation. However, unlike many trends supporting the value of interdisciplinary study, not all questions and methods are considered equally legitimate across disciplines, and often they are not interchangeable. Further divides around the proper level of analysis for investigation can separate scholars who might otherwise share substantive interests, concerns and

questions. Each discipline concentrates on a slightly different yet particular set of aims and questions, and these divergent intellectual intentions infuse the culture and status hierarchies implicit (and sometimes explicit) both within and across fields. Yet different fields such as political science and behavioral economics do continue to share an interest in particular substantive areas, such as voting and deliberation, although they may each take quite different approaches to the same problem.

Political psychology tends to be a quite diffuse field, with practitioners interested in a wide variety of topics that span theory, method and substantive area of investigation. Topics of legitimate inquiry run the gamut from historical psychobiographies (Runyan, 1982) to genetic work on the relationship between political ideology, emotion and attitudes toward important political events (Hatemi and McDermott, 2011). As a result of the diversity in relevant topics, theories and methods, and the lack of clear disciplinary boundaries as identified, contained and restrained within departmental structures, there is less policing around what is and is not relevant or appropriate work in political psychology. The downside of this freedom is that much of this work is often of lower quality because of the relative lack of rigor and discipline.

Social psychology tends to be most interested in issues surrounding individual behavior in the social world, often around topics related to social affiliation (Ross and Nisbett, 2011). This can include a wide range of topics, from impression management to questions surrounding the nature of conformity (Asch, 1955), obedience (Milgram, 1974) and prejudice and discrimination (Dovidio and Gaertner, 1986). Several areas offer tremendous overlap with issues of primary interest to political scientists. These often involve the investigation of attitudinal measure to examine, explore and predict problematic or sensitive aspects of human social behavior, including topics related to

prejudice and discrimination on the basis of categorization (Rosch, 1999; Adolphs, 2003), which may be by age, gender, race, religion, sexual orientation, ethnicity or a host of other factors (Tajfel, 1981). However, these are not the only areas of potential overlap. Others relate to work on in-group preference and outgroup discrimination (Tajfel, 2010) which has implications not only for domestic politics but also for inter-group conflict, including war. Such implications are of interest to international relations and comparative politics scholars.

Behavioral economics, being focused more on economic issues, tends to examine ways in which individuals systematically violate the assumptions inherent in classical economic models. These examinations include further explorations of the iconic Kahneman and Tversky (1979, 1984) work on framing effects and loss aversion in particular. Interesting and important work extending these original insights has explored the nature and function of reference points (Rabin, 2002), including the way that contracts can function as reference points (Hart and Moore, 2008). Some of the big research agendas include questions related to mental accounting (Thaler, 2008) and changing behavior using small or so-called nudge interventions (Thaler and Sunstein, 2008). In the latter area, efforts have included work on health, such as stop smoking campaigns. In addition, there is a great deal of interest in issues surrounding the discounting of time in making decisions (Loewenstein and Prelec, 1992), and increasing attention is being concentrated on the influence of emotion on decision making (Lempert and Phelps, 2014). Topics of interest that provide the greatest area of overlap with area of concern to social psychologists and political scientists involve those areas where welfare decisions remain fundamentally contingent on social variables and choices. These include topics related to trust (Fehr, 2009), fairness and reciprocity (Fehr and Gächter, 2009), equity (Fehr and Schmidt, 1999), third party

or altruistic punishment for enforcing social norms toward cooperation (Fehr and Gächter, 2002) and how preferences and belief formation can effect behavior such as free riding in public goods provision and usage (Fischbacher and Gächter, 2010).

In short, the preoccupation of each discipline, in terms of the topics each finds interesting, engaging and worthy of serious and sustained investigation, closely mirrors the content of the disciplinary focus. Political psychologists, like political scientists, tend to focus on issues related to political organization and ideology, including topics related to leadership and conflict. In particular, political psychologists, like their colleagues in the larger discipline, tend to focus on issues of power and the influence of its imposition on a wide variety of individuals and phenomena. Psychologists, including social psychologists, tend to find issues of social behavior most important, particularly those related to processes of social affiliation. Behavioral economists, by contrast, tend to focus on topics related to money, finances and the social processes that affect exchange.

Clearly, areas of overlap exist between these disciplinary cultures and can be explored within the context of overlapping acceptable methods of inquiry, especially in the area of experimental work. The topics that could easily be explored in interdisciplinary contexts using experimental methods might most easily investigate the effect of particular attitudes or emotions on behaviors related to conflict resulting from power differentials. This includes not only social areas of conflict such as prejudice and discrimination, but also the causes and consequences of economic inequality that both cause and result from such processes. Projects such as this, or work on many other possible topics, could clearly engage individual scholars from across disciplines using mutually acceptable theories and methods to investigate social and political phenomena of great impact and importance for all of society.

## **DIFFERENCES IN DISCIPLINARY CULTURE**

Understanding how to negotiate and translate the various theoretical, methodological and content divides which permeate each sub-field can prove challenging, but being able to do so helps facilitate more efficient and effective interdisciplinary work, allowing for greater progress in illuminating critical areas of social inquiry that cross disciplines.

There are a couple of important cultural differences which are worth further explicit mention since they can often, in and of themselves, prevent scholars coming from different traditions from working together. In some ways, the two most significant ones, related to incentives and deception, reflect different ethical perspectives, but not in the traditional way in which ethics is understood by, say, institutional review boards, who might find all approaches equally acceptable under specific conditions.

The first issue relates to incentives where the norms and rules across disciplines remain contentious. Psychologists often use undergraduate student populations as their subject pool; the students receive course credit for their participation in experiments. These students may be required to participate in a certain number of experiments in order to receive course credit in an introductory class, or may receive extra credit for participating in experiments in upper division courses.

Economists, by contrast, do not believe that honest results can be obtained from subjects without providing monetary incentives to give individuals a stake in the outcome of their behavior and to encourage sufficient attention and honesty in the given tasks (Smith et al., 1993). Indeed, most economics journals will not publish results that come from studies where subjects have not been properly remunerated for their participation. This does not mean, however, that behavioral economists are always ignorant of the costs and consequences associated with only using

monetary incentives to investigate behavior. Indeed, Loewenstein (1999) argues that one of the consequent problems associated with this norm of monetary incentives is that it does not allow for observers to understand the complex ways in which monetary and non-monetary rewards and incentives might interact in the real world: if investigators only ever interrogate the former, they will never be able to provide an empirical foundation for understanding the latter.

These perspectives emerge, if only implicitly, from quite divergent notions of human nature. Psychologists believe that people do all sorts of things for all kinds of reasons, including biological ones. So, for instance, they would agree that people will find sex, food, drink, sleep or other biological inducements to be as compelling, if not more so, than money; indeed, they would argue that individuals simply use money to obtain these other goods and services, and so leaving money out of the equation serves only to simplify the reinforcement. And, indeed, some behavioral economists might agree. For example, Camerer (2007) deprived subjects of food and liquid for a few hours prior to an experiment and then gave them salty treats prior to the experiment. The experiment on time discounting on savings rate in retirement then allowed people to play for money or juice. Not surprisingly, more people chose the juice, but this choice also affected other aspects of their financial behavior, showing the utility of varying incentives in order to understand the variety of human behavior in the real world. However, by and large, economists believe that money serves as a unified proxy of value that can incentivize subjects across different backgrounds and goals. This assumption depends on an extremely narrow view of human nature, and the drives and goals that motivate the diversity of human behavior, but as long as the disciplinary incentives for publication in economics remain narrowly focused on using money as an incentive, all experiments in that area will continue to do so.

It is likely that an increasing number of psychological experiments will use money as an incentive, as the use of web based platforms such as mturk or qualtrics increasingly dominates the experimental space. Because these platforms offer much wider subject pools in terms of age and other characteristics, and because they often provide much faster rates of response among larger groups of people, it is likely that the monetary incentives that drive respondents on such platforms will facilitate an increasing convergence across fields toward using money as the primary incentive in experimental studies. This does not mean that more creative forms of incentives such as those employed by Camerer cannot be used in laboratory contexts.

The issue of deception is, if anything, even more divisive between subfields than that posed by divergent incentive structures. Standard economic textbooks caution that under no circumstances should deception be allowed in or introduced into experiments (Friedman and Sunder, 1994). Usually, the justification revolves around contaminating the subject pool, assuming that subjects who have been deceived will be less likely to be willing to participate in experiments and less honest when they do so (Jamison et al., 2008). Note that, as with psychologists who have not traditionally used monetary incentives having to shift their behavior in the wake of the increasing dominance of platforms such as mturk, economists will have a very difficult time sustaining arguments about crossover effects within population samples that number in the millions where communication – while not impossible over the web – is highly unlikely to affect people whose primary motivation for participation is the money which economists highly prize. In addition, as Gneezy (2005) points out, the financial world is filled with deception, including the huge impact of tax evasion on many other aspects of social welfare: to refuse to study deception renders a great deal, if not the majority, of economic behavior outside the realm of experimental investigation.

Furthermore, while ultimately deciding that lying has consequences, Gneezy notes that the entire model of 'homo economicus' is founded on the notion of the value of a selfish economic actor, and lying is often an intrinsic part of acting selfishly. This observation further highlights the discrepancy between economic models and economic methods of investigation. Moreover, Dreber and Johannesson (2008) describe significant gender differences in deception, showing that men are much more likely than women to lie for purposes of financial gain, demonstrating that the role of deception is not gender neutral in origin or consequence.

Psychology has been grappling with the use of deception for quite a while (Kelman, 1967). Interestingly, most of the work from behavioral economics condemning deception depends on arguments based in moral philosophy, with little research to back up the substantive claims regarding damage to participants. Christensen (1988) provides some experimental data on this very outcome variable, finding that 'subjects who have participated in deception experiments versus nondeception experiments enjoyed the experience more, received more educational benefit from it, and did not mind being deceived or having their privacy invaded'. This is likely due, at least in part, to experiments involving deception being more engaging or involving topics of greater interest to subjects. This is because even experimenters in psychology treat deception in the way that Hillary Clinton once talked about abortion: 'legal, but rare'. Psychologists tend to use deception when investigating those circumstances or situations that remain socially sensitive, such as race and gender discrimination, where it would be easy to expect subjects to lie for reasons of impression management. Yet, most psychologists believe that these topics are so important that they should not be entirely dismissed as potential sources of investigation. In this way, the use of deception in carefully designed experiments provides one way to research socially sensitive topics in a manner

designed to get at individuals' thoughts, feelings and behaviors in accurate ways. There is some work showing that one way in which any negative consequences deriving from the use of deception in experiments can be ameliorated is through employing careful debriefing procedures (Smith and Richardson, 1983). There is also some evidence that forewarning (Allen, 1983) subjects that deception might be used can mitigate some of the ethical issues involved in deception, while not necessarily precluding the possibility that subjects can still be properly deceived as to the real purpose of the experiment or source of the manipulation.

Social psychologists and behavioral economists are likely to converge in unexpected, and possibly undesired, ways in the coming years, as online platforms such as mturk and qualtrics take over more and more of the experimental space. Psychologists who use these populations will have to provide monetary compensation for participation. In addition, economists who use these platforms will have to acknowledge that reputational costs and contamination are extremely unlikely to occur within such wide and diverse populations, where the incentives for communication around these issues are extremely low and costly in terms of time and energy, with very little subjective expected reward resulting from such communication. That said, it will prove much more difficult to deceive people via online platforms, and so the ability to do so will decline as well. In addition, it should be noted that there is a very real cost associated with outsourcing the majority of experimental work to online platforms. They may prove quick and efficient in obtaining large numbers of subjects at low cost, albeit with unknown and likely variant quality of responses, but such studies will necessarily need to focus more on attitudes and less on behavior. While this does not render attitudes unimportant or insignificant, meaningful but difficult to observe aspects of human behavior may increasingly fall outside areas of investigation, leaving us knowing more and

more about fewer and fewer pervasive and powerful aspects of human experience.

## CONCLUSION

This chapter has attempted to highlight some of the significant overlaps, similarities and divergences in method, assumption and content between political psychology, social psychology and behavioral economics. Dominant theories and methods of investigation differ across these sub-disciplines according to the differences in the primary questions and aims which preoccupy each field.

Meaningful and substantive differences exist across these fields. Some of these involve fundamental underlying assumptions. For example, economists and political scientists espouse a fundamentally different understanding of the nature of human rationality, and indeed often possess opposing definitions of what constitutes it. In addition, the primary focus of interest differs across fields, with political scientists primarily interested in power, psychologists in affiliation and economists in money. Furthermore, economists and psychologists have very different values regarding the nature of incentives and the role of deception in experiments.

However, important points of convergence and overlap do exist and are worth cultivating in service of greater opportunities for mutually enriching interdisciplinary work. These involve the obvious convergence around the value and utility of experimental methods of various sorts, including field, survey and list experiments, for investigating important aspects of human social, political and economic behavior. In addition, there is a great deal of overlap in substantive areas of consideration, including issues related to attitudes and emotions involving discrimination, inequality and conflict. These areas offer enormous potential for integration across fields to illuminate critical aspects of human decision making and behavior.

# Institutional Theory and Method

Maxfield J. Peterson and B. Guy Peters

## INTRODUCTION

### *Institutions Matter!*

In the period following the Second World War, political science was characterized by the rapid growth of the behavioral research program, which emphasized the role of individual attributes and decisions in political outcomes. For a time, the ‘behavioral revolution’ seemed to eclipse what had been the dominant paradigm of political science research – institutionalism. Yet despite the relevance of behavioralism, the current wave of populism sweeping the United States and Europe signals the enduring impact of institutions in the political world. When politicians and their supporters rail against the ‘political establishment’, they are articulating a rejection of institutions, but also recognizing the significance of those institutions. If the study of individual political identities merits the amount of scholarly attention it has received, a focus on the institutions that

structure and inform those identities, intentionally or unintentionally, seems equally, if not more, important.

Of course, the contention that institutions play a central role in the construction of political identities is itself an assumption that occupies a central role in the structure–agency debate. The goal of this chapter is to identify and investigate this and other assumptions of the institutional perspective, review the literature that has constructed and advanced institutional theory and discuss how institutionalism, and its perennial focus on structure, remains one of the most relevant approaches to social inquiry.

This chapter proceeds as follows. We begin with a review of the central place of institutions and institutionalism in political science, beginning with their role in ancient political thought, tracing this theoretical tradition through the ‘Old Institutionalism’ of the late nineteenth and early twentieth centuries, and connecting this work to the ‘New Institutionalism’. We then review the major

approaches in institutional research, highlighting the connections between the distinct theoretical foundations of different types of institutionalism and their respective research strategies. Having reviewed institutional theory and approaches, we argue that the theoretical assumptions of institutionalism inform a set of methodological approaches and tools, which we review and discuss. We then face a set of paradoxes in institutional theory, exploring some possible resolutions. Finally, we review some central challenges facing scholars of institutionalism, and offer some concluding remarks.

### ***Central Place of Institutions, and Institutionalism, in Political Science***

The first scholars of politics were students and architects of institutions. One of the oldest political texts, Plato's *Republic* (1992), is a discourse on how to properly structure institutions so as to produce a 'just' society. Plato's student (and perhaps the first empiricist) Aristotle continued this ancient institutionalism in *Politics* (1998), in which he constructed a taxonomy of state systems for purposes of comparison. The wide dissemination of these ancient texts some two millennia later ushered in the Age of Enlightenment and its seminal political philosophers. Thinkers such as Thomas Hobbes, John Locke and J. S. Mill focused on central questions concerning the relationship between state and society, the rights of the individual, and the form of government best suited to serve their respective conclusions on such issues. Enlightenment liberalism as articulated by John Locke, Jean-Jacques Rousseau and Baron de Montesquieu was at its core an institutionalist argument for the establishment of a particular form of limited government that structured a society favorable to property rights, political and religious freedom and constrained, non-radical democracy. Such institutional thought laid the canvas for early American statesmen such

as James Madison, Alexander Hamilton, John Jay and Thomas Jefferson. The detailed arguments for ratification of the constitution found in Madison, Hamilton and Jay's *Federalist Papers* (Hamilton et al., 2009) represents a classic work of institutionalist reasoning.

While the institutionalism of Enlightenment liberalism and early American thought resonates with the Anglo-contractualism of John Locke and Thomas Hobbes, the thinkers of 19th and early 20th-century continental Europe created a distinct strand of institutional thought. Although initially more associated with sociology than political science, the works of Hegel, Max Weber and Émile Durkheim have come to occupy such an important place in the interdisciplinary study of institutions that they merit some brief review here. In contrast to the anti-statism of Anglo-American liberal thought, the state remained central to the political life of continental Europe and its thinkers. For example, Weber saw the state as the organic evolution of authority from traditional forms. Charting the development of the German bureaucracy from its monarchic birth to its role as the meritocratic administrator of modern government, Weber argued institutions were fundamental to the life and character of the state. These arguments would be central to bringing the state back into the work of American scholars.

The German school of sociological institutionalism is key to understanding the growth of political science as a distinct academic discipline in the United States. The earliest American political scientists, such as Woodrow Wilson, formulated a legal-structural understanding of American democracy and its institutional foundations at least in part on the basis of Weberian thought. Wilson's construction of a politics-administration dichotomy, which argued for the insulation of the bureaucratic, executive apparatus from partisanship, is directly influenced by Weber's theory of autonomous, meritocratic bureaucracy. Wilson's contemporaries exuded a similarly state-centric view of political science, as can be seen in T. D. Woolsey's

*Political Science, or, The State Theoretically and Practically Considered*. These early American scholars were architects of the 'Old Institutionalism', a period of institutional thought that balanced an American intellectual heritage of legal-formal analysis and a more theoretical study of the state from the German school. But the emphases on legalism and structuralism (or the elevation of institutions, rather than individuals, as the object of study) supply only a partial understanding of the Old Institutionalism.

Together with legalism and structuralism, Old Institutionalism is characterized by holism, historicism, and a normative rather than positive frame of analysis. With regard to holism, Old Institutionalists tended to compare entire political systems rather than their component parts (i.e. British versus American democracy rather than British versus American courts). Holism assumes that institutions work together to comprise a coherent political system; thus a thorough understanding of the operation and reason of any component must be set in its political and cultural context. Old Institutionalism's historicism meant that institutions must be understood as embedded within historical processes that could account for their existence and functionality. As a mode of analysis, historicism fit well with holism in that it maintained the primacy of context and eschewed the idea that political institutions could be understood in isolation. Finally, Old Institutionalism was set in a normative framework where useful ideas and theories were developed for the purpose of improving society rather than positivist investigation. While this may come as a surprise to today's political scientists given the relegation of normative theory to an isolated subdivision of the discipline, the goal of developing theories for implementation in the real world made sense at a time when a political scientist was US President. Indeed, Woodrow Wilson's studies (1887, 1892) of the bureaucracy informed his brand of early American progressivism, demonstrating the direct link between scholarly

study of political institutions and the exercise of political power.

Further influence of the German sociological school can be seen in the work of early American organizational theorists such as Philip Selznick and Chester Barnard. While 'organizations' may not always be institutions, depending on one's definition (see below), the contributions of organizational theorists are essential to understanding institutions. For example, Selznick's argument (1943) that individuals within organizations function as independent agents with 'dual goal-sets' impacts the extent to which we assign institutions power over their members, and vice versa. Barnard's *The Functions of the Executive* (1968) defined the role of executives relative to the institutional apparatus in which they operate, another way of understanding the relationship between individual leaders and institutions. Further, his theory that organizational survival is predicated on effectiveness and efficiency is clearly an institutional analysis.

Old Institutionalism faded from importance upon the midcentury arrival of the behavioral revolution. In the post-war period, American political science became dedicated to leveraging reams of information to understand individual political behaviour such as vote choice and party identification. This was driven in part by the availability of information, and in part by the interest in individual decision-making. Publication of Campbell, Converse, Miller and Stokes' *The American Voter* in 1960 established the Michigan School at the center of the behavioral movement, under which a generation of American political scientists would be educated. It was not until Theda Skocpol's *States & Social Revolutions: A Comparative Analysis of Social Revolutions in Russia, France, and China* (1979) that institutionalism would return to center stage, albeit co-starring with the ongoing behavioral program. Skocpol's remarkable work demonstrated the value of historical institutional analysis in understanding a question of critical importance to

political scientists. The resounding influence of this work can be seen in the 1970s and 1980s resurgence of institutional analysis, or what James G. March and Johan P. Olsen would deem ‘The New Institutionalism’ (1984, 1989).

While Skocpol’s work can be seen as a bellwether of the coming influence of the new institutionalism more broadly, an extremely productive branch known as rational-choice institutionalism would be instrumental in the reiteration of the classic paradigm. Following Shepsle’s (1989) observation that the study of institutions could benefit from a methodological and perspectival synthesis with the rational-choice approaches, scholars began seeking ‘structure-induced equilibria’, or outcomes that could be seen as the aggregate product of utility-maximizing individuals operating within institutional constraints. By factoring institutional constraints into the mathematical models originally appropriated to predict voting behavior, one could produce outcomes in a much more reliable manner than by focusing on the unconstrained behaviors of individuals.

March and Olsen (1984, 1987) argued that institutional theory blending modern behaviorist influences with an older concern with institutions could produce a distinct and promising agenda for research. This new institutionalism included a rejection of behavioralism’s assumption that politics can aggregate individual preferences efficiently. New Institutionalism revived an understanding of history that appreciated the influence of institutions on political behavior and change. In this view, societal preferences were at a minimum constrained, and at a maximum informed and directed, by the institutional context. The New Institutionalism stood to benefit from the behavioral revolution by channeling gains in understanding individual behavior through an institutional prism. Thus, the New Institutionalism did not imply a return to the normative, holist or even necessarily historicist characteristics of its older form, but rather was a more

modern application of its emphasis on formal structures to the study of politics. One might consider a bowling metaphor, in which behaviorists attempted to understand the movement of the bowling ball with no attention paid to what sort of barriers might be erected on either side of the lane. The New Institutionalism asserted that renewed attention to those barriers would better our understanding of the possibilities for the ball’s movement in the first place.

This rejuvenated emphasis on the roles of institutions in shaping political outcomes is evident in work on legislatures (Tsebelis and Money, 1997; Tsebelis, 2002; Krepel, 2002; Saiegh, 2016), political economy (North, 1990; Fish, 1998; Johnson, 1982; Nölke and Vliegenthart, 2009) and regime change and democratization (Lijphart, 1999; Linz and Stepan, 1996; Evans and Skocpol, 1985; Herbst, 2000), among many others. As can be seen in these works, the new institutionalism is not monolithic in its approach. Some scholars have embraced the rational-choice assumptions common of behavioral work and applied them in institutional contexts, while others have hewed closer to the old institutionalism in their reliance on historicism. A more detailed discussion of the new institutionalism and its subgenres will follow later in this chapter. Here what is important to understand is that institutionalism, and its assumptions about the role of the state institutions – as well as institutions such as political parties – in guiding behavior, rules and incentives, has returned to a central place within the discipline. The new institutionalism represents a maturation of the discipline in its ability to incorporate some of the gains from behavioral research while restoring important theoretical assumptions that remain critical to understanding the political world.

### ***The Major Approaches***

Before entering a discussion of the relationship between institutional theory and

methodology, it is important to understand that institutionalism comprises a set of approaches built upon distinct ontologies which lend themselves to different methods. We now turn to a review of the major approaches within the institutionalist paradigm: normative, rational choice, historical, empirical and discursive. This will be followed by a discussion of how these different approaches (and ontologies) lend themselves to particular methodological choices. And we will also need to inquire whether there is one contemporary version of institutionalism, or many disparate strands of theorizing about institutions.

### *Normative*

When March and Olsen (1984) issued the call for a new institutionalism, they were essentially advocating what has come to be called normative institutionalism. Normative institutionalism attempts to understand the social and political world through analysis of the normative underpinnings of institutions; that is, the values, ideas and norms that form their basis. Normative institutionalism exists in sharp opposition to atomistic individualism, which assumes attitudes and actions to be exogenous to political systems and a product of the ideas, values and norms of individuals. Thus, rather than understanding action by understanding individuals, we should try to understand how institutions shape their behavior, and what the norms and values of that institution are. This does not mean, however, that the values and attitudes of any individual or group of individuals is easily equated to the values of a given institution. Individuals tend to be embedded in multiple overlapping institutions, which compete for influence. Some institutions might be more salient than others depending on the issue at hand. For example, membership in the American Medical Association may have little impact on how a doctor in a state legislature chooses to vote on a gay marriage bill, while that same doctor's membership in the Southern Baptist Convention

may have a profound influence on such a decision. Either way, in the normative institutional view, the doctor's decision to vote one way or the other is seen as a product of the influence of institutional membership rather than a rational, calculated decision.

The roots of normative institutionalism lie in the sociological school pioneered by Émile Durkheim and Max Weber. Durkheim argued that institutions, or 'the beliefs and modes of behaviour instituted by the collectivity', were at the heart of understanding society (1982 [1895]: 45). The study of such institutions could, in Durkheim's view, be leveraged to discover structural social facts – universal truths constructed by the existence and constancy of social and political institutions. A resounding early exercise in this approach is Weber's *The Protestant Ethic and the Spirit of Capitalism* (1958), in which Weber argued that Protestant ethics in Western Europe encouraged Protestants to engage with the secular market economy, forming a normative basis for the form of Western capitalism that continues to dominate the world's economic systems.

Philip Selznick argued for a distinction between two types of institutions: those that could be considered an aggregation of individuals' rational behaviors, and those which influence individual behavior through individuals' commitments to those institutions' goals. The former may be thought of as instrumental institutions: for example, individuals join a labor union to lobby for collective benefits that would be unattainable through purely individual advocacy. The latter may be thought of as consistent with March and Olsen's 'logic of appropriateness': individuals agree to donate a monthly membership fee to the American Civil Liberties Union (ACLU) because, although it may not yield clear individual benefits, they are committed to the preservation of civil rights. In this latter form, individuals may adopt beliefs and behaviors that the institution considers appropriate. They do so out of an understanding that the institutions' rules and recommendations serve values that they themselves hold.

### *Rational-choice*

Rational-choice institutionalism represents an approach that is distinct from the rest of the paradigm in its accommodation of the atomistic individual. Rational choice asserts that individuals maintain independent preferences that may be bounded by institutions. So although an individual may be a member of an institution, we cannot (as normative institutionalism might have it) understand their behavior solely by understanding that institution (or the combination of institutions) that may be influencing action). Instead, we should view institutions as impacting otherwise exogenous individual behavior by limiting the available choices for the individual and modifying the incentives that inform preferences (see Katznelson and Weingast, 2005).

Whereas much of institutionalism owes its intellectual heritage to sociology or contractual political philosophy, rational-choice institutionalism derives its assumptions from economics. The rational-choice model has become a powerful presence in economics and behavioral political science because of its ability to consistently predict outcomes across contexts based on a calculus of human activity. Individuals are seen as 'utility maximizers' who aim to gain the most benefit out of any situation. Thus, political outcomes can be understood as a function of the interactions between utility maximizers, who must bargain among each other to achieve optimal outcomes. Looking at the political world this way has several advantages; for example, it enables complex phenomena to be collapsed into abstract models, and these models can then be used to identify equilibria, or stable outcomes. A rational-choice model of behavior theoretically applies just as much in a back alley poker match in Calcutta as on a Wall Street trading floor.

Unlike pure rational-choice analyses, rational-choice institutionalism invites politics back in to understand how institutional rules, incentives and values may impact otherwise individual utility maximizing

behavior. As with institutionalism more broadly, rational-choice institutionalism is characterized by several different sub-categories that are defined as follows: historical, principal-agent, transaction-cost, veto-players. The historical tradition applies a rational-choice framework to historic periods in order to explain political, social or economic outcomes. A classic example is North and Weingast's analyses (1989; see also Greif, 2006) of the evolution of public institutions in 17th-century England, which details how institutional reforms drove rational actors to construct and invest in an open and regulated system of capital markets. More recently, the work of Elinor Ostrom, Larry Kiser and others involved in the Institutional Analysis and Development (IAD) framework has contributed to modern historical rational-choice institutionalism. This framework emphasizes the need for an interdisciplinary approach to institutional analysis that embeds the rational-choice assumptions as applied in the 'new institutional economics' into the accumulated knowledge of historians and anthropologists. This perspective has led to a series of works in political economy that emphasize the role of institutional development in the promotion of contract enforceability and communication in otherwise thinly institutionalized contexts where violence and cheating were commonplace (La Porta et al., 2008).

The principal-agent (PA) literature applies rational-choice assumptions to institutions' interactions with one another and with individuals (Miller, 2005; Carpenter and Krause, 2015). A principal (some individual, entity or group) with a desired outcome assigns an agent (another individual, entity or group) to be responsible for achieving that outcome. Classic principal-agent relationships include the public (principal) and their executive (agent), the legislature and the bureaucracy or the organizational leader and their subordinates. The principal agent formulation may provide a useful way of understanding

seemingly unorthodox behavior; agents may be allowed to act in ways inconsistent with the proximate goals or values of the principal if the principal believes their long term goal will be accomplished by allowing such latitude. For example, intelligence agencies (particularly in the United States) have been known to have a cavalier attitude toward legal authority, a stance which is often tacitly allowed by their principal (the president) because of the principal's belief in their ability and expertise in neutralizing security threats. Agents may also act in inappropriate ways because the institutional design of the PA relationship enables them to keep the principal in the dark.

The principal-agent model has been applied to understand a diverse array of institutional environments. In the study of public administration and bureaucracy, PA models have been applied to understand the relationship between leaders of organizations attempting to maximize resources for their organizations (wherein the leader serves as the agent and the organization as the principal) (Wildavsky, 1992; Savoie, 1990). PA approaches have become fairly standard in the analysis of regulatory policy in the United States, wherein Congress is cast as the principal and independent regulatory agencies are cast as the agents (McCubbins et al., 1989). In these applications, the object of curiosity is how institutions impact Congress' ability to keep the activities of independent regulatory authorities (the EPA, BLM, SEC) in line with legislative goals. Institutional variation can occur via incentive structures that motivate agents to actuate policy goals, or 'fire alarms' which empower the public or interest groups to alert Congress when agencies are in dereliction of their duties.

Another strand of the rational-choice institutionalism literature views institutions as mechanisms for reducing 'transaction costs'. Transaction costs can be understood as the inherent risks and inefficiencies involved in any transactions between two actors or

entities, the certitude that one receives payments for services rendered, the difficulty of communicating goals and plans across cultural or linguistic barriers or simply the time it takes for two actors to arrive at a mutually beneficial bargaining arrangement (Durant, 2006). Some of the previously discussed historical rational-choice institutionalist literature emphasizes this role, but it is perhaps most common in the comparative literatures on legislatures and the international relations literature on international cooperation. The comparative legislatures literature emphasizes how the committee system reduces transactions costs by (1) allowing legislators to specialize in policy arenas, enhancing their informational resources and thus reducing uncertainty about consequences; and (2) enabling legislators to 'credibly commit' to returning a policy favor, as their committee seat ensures continuing influence over a given policy arena.

In the international relations literature, the ability of institutions to make credible commitments has been important for the neoliberal institutionalist paradigm. Most notably advanced by Robert Keohane (2005), these scholars argue that institutions such as the World Trade Organization provide a forum for communication and mutual enforcement of deals. While nations could presumably renege on a multilateral trade agreement, reaping short-run benefits while evading long-run costs, such behavior is likely to be mutually punished by other institutional members, imposing a cost for such actions. Because nations recognize the costly 'shadow of the future' posed by renegeing on deals, they generally comply, or refuse to enter agreements that they would otherwise violate. Thus, institutions are seen as a way of reducing uncertainty and enabling otherwise risky forms of international cooperation. Again, this rather functionalist understanding sees institutions as emerging to serve the exogenous preferences of atomistic utility-maximizing actors rather than informing their initial preferences.

A final and important category in the rational-choice institutionalism literature is the veto players framework. Developed by Tsebelis (2002; but see Ganghof, 2003), the veto players framework views outcomes as a function of the number of 'veto players', or actors with the ability to block legislation, and their preferences. Veto players may be committee chairs, executives or any member of a decision-making body whose approval is required for a motion to progress. Veto players' preferences are represented spatially with 'indifference curves', or shaded circles surrounding a veto player's ideal point along a multidimensional policy space. The overlap between the necessary veto players indifference curves is deemed the 'winset', or the set of potential actions given what is acceptable to the players.

The veto players framework reveals an important dynamic of group decision-making in institutional contexts. Frequently, especially in legislatures, the winset is defined primarily by a single player known as a 'gatekeeper', who has the power to unilaterally block legislation. Thus, the likelihood of a particular motion moving forward is defined more by what this individual is either supportive or indifferent to than by the preferences of the other members.

Another important value of the veto players framework lies in its parsimony and versatility: it can be applied in essentially any institutional setting where decisions are made, and effectively limits the range of potential outcomes in a methodologically consistent fashion. Further, it can allow us to understand outcomes without a thorough understanding of every member of an organization, because it directs our focus to those members who matter most. The veto players' framework has been applied to understand the development of the rule of law in emerging democracies (Andrews and Montinola, 2004), the impact of globalization on welfare spending (Ha, 2007), the conclusion of civil war (Cunningham, 2006) and many other

problems of comparative and international politics.

### *Historical*

Historical institutionalism differs from other categories in its admission of historical-contingent factors as important aspects of institutional evolution and impact. Historical institutionalism is explicitly structuralist; that is, actors are seen as reacting to, and operating within, macro-structural constraints posed by the interaction of social, economic, political and institutional forces. In this view, history is viewed 'inefficiently', in that political outcomes cannot be seen as an efficient function of the preferences of the masses or elites. Instead, changes in technology, the sociological groupings of individuals, legal conventions and other historic factors are seen as advancing or constraining change (David, 2001).

For example, consider Theda Skocpol's (1979) classic work on revolutions. In this analysis, revolutions are seen as the product of imperial monarchic institutions' inability to rise to the financial and organizational challenges of increased international military competition. The historical evolution of international military competition is seen as having an inefficient relationship with domestic institutional development, priming domestic pressures for institutional change. Again, all of these changes are embedded in historical-contingent shifts rather than the preferences of individuals.

More recently, Steinmo et al. (1992) have made the modern case for historical institutionalism, arguing that a focus on the policy choices made when an institution is formed have a long-term influence on its policy choices into the future. While this pattern is conventionally referred to as 'path-dependency', Mahoney and Thelen (2010) and Streeck and Thelen (2005) have made the case for a historical institutionalism that rejects the 'punctuated equilibria' model of historical institutional change in which 'critical

junctions' (see Capoccia and Keleman, 2007) are seen as the singular temporal mode of reform. Instead, they argue that the distribution of interests within an institution can leverage a variety of techniques for gradual and endogenous institutional change. These contributions suggest an affinity between the rational-choice and historical schools that runs counter to their traditionally distinct ontological commitments (to individual agency and structure, respectively) (but see Katznelson and Weingast, 2005). Even with the addition of these mechanisms for gradual change, the historical institutionalists can be criticized because of a seemingly excessive emphasis on stability within institutions.

### *Empirical*

Empirical institutionalism is closely related to the old institutionalism in its focus on formal governmental structures and rules. Privileging constitutional documents over parties and interest groups, the empirical school attempts to infer the long-term empirical consequences of discrete choices in governmental design. Arend Lijphart's *Patterns of Democracy* (1999) argues that sets of institutional conditions lead to 'consensus' or 'majoritarian' democracies, each with their own consequences for policy, economy and conflict. Horowitz has been a consistent voice of dissent from Lijphart's views, arguing that electoral rules designed to foment universalistic electoral appeals offer more promise for divided societies (Horowitz, 2004). Shugart and Carey (1992) and Linz and Stepan (1996) debate the impacts of presidential versus parliamentary systems in two now foundational texts in the empirical institutional literature.

The empirical institutionalism is not, however, confined merely to studying differences between presidential and parliamentary systems. For example, one question within this approach relates to the effect of the autonomy of institutions – whether central banks or bureaucratic agencies (Laegreid

and Verhoest, 2010) – on the performance of public sector organizations. The analysis of federalism and other patterns of intergovernmental relations also falls into the domain of empirical institutionalism (Hueglin and Fenna, 2015). Even patterns of interest intermediation – corporatism, pluralism and other alternatives – could be analyzed through the lens of empirical institutionalism.

What distinguishes contemporary empirical institutionalism from the old institutionalism is the more explicit attempt to build theory. In addition, empirical institutionalism draws from other strands of institutional theory to develop expectations about the behaviors of institutions and the individuals within them. The questions may not be so different from those of the old institutionalists – after all, Woodrow Wilson advocated parliamentary government for the United States in 1885 – but the means of addressing those questions certainly have changed.

### *Discursive Institutionalism*

Discursive institutionalism argues that the internal discourses among institutional members, and institutions' discourses with their environments, provide a useful way of understanding political outcomes. In this view, the evolution and distribution of ideas is central to institutions' roles in organizing political and social life. The preeminent member of the discursive school has been Vivien Schmidt (2008, 2010), although her arguments emerge in part from the constructivist tradition as articulated by Colin Hay (2008) and Nicolas Jabko (2006). Perhaps most fundamentally, the discursive approach emphasizes the importance of ideas and arguments in defining the institution.

Unlike other institutional theories discussed, discursive institutionalism is not causally oriented in the material world. As such, it places substantially less emphasis on formal institutional structure, which is seen as a result of causally prior ideological discourses. This has important implications for the nature

of institutions: if formal rules do not entrench predictable and stable behavior, but are rather subject to evolutionary effects of changing ideological preferences, institutions may fail to serve the purposes central to other schools of institutionalism (see Panizza and Miorelli, 2013). While normative institutionalism lies closer to this discursive view, it is still distinguished from it by its focus on organizations and their capacity to influence the views of their members in an enduring manner.

Discursive institutionalism appears to allow considerably more room for the role of individuals, as they can be seen to be instrumental in the advocacy of particular ideas within institutional discourse and as important interlocutors between institutions and their environments. This is perhaps most evident in constructivist work in international relations, which appears intimately related to discursive institutionalism. For example, Finnemore and Sikkink (1998) outline a 'norm lifecycle' whereby idea entrepreneurs may utilize institutions to infuse norms on the domestic and international levels. Similarly, Schmidt (2008) views individuals and their organizations as active agents in the local dissemination of global ideas, leveraging awareness of domestic institutions (formal and cultural) to elevate particular norms, rules and practices.

## **THE METHODOLOGICAL IMPLICATIONS OF INSTITUTIONALISM**

Institutionalism is first and foremost a set of theoretical assumptions and understandings about humanity: individuals always operate within organizational contexts, and these contexts modify behavior through rules, incentives and values. But these assumptions have important implications for methods because they preclude certain approaches while privileging others.

Why is this so? A useful starting point is to consider how institutionalist assumptions

impact the appropriate level of analysis in approaching a research question. If we are curious about the growth of right-wing populist parties in recent European elections, rather than beginning by analyzing the individual level voter demographics of their supporters, we might first look at the institutional environments in which they have been successful. One could run a regression at the individual level and conclude that the average right-wing populist party supporter is white, elderly and working class. But this would only help us understand the outcome (right-wing populist victories) if we assume a purely efficient relationship between societal attitudes and political outcomes. If instead we embrace the institutional assumptions that history and political processes are inefficient and subject to modification by institutions, we must ask a different set of questions. Further, we might ask about the decline of other organizations within the party system, which has opened more niches for these parties.

At this point, the appropriate line of inquiry begins to turn on the particular brand of institutional theory one is following. If one opts for a rational-choice or empirical institutionalist account, one can continue to accept preferences for populist parties as exogenously given, and proceed to model their success as a function of popular support and electoral rules. Do right-wing populist parties perform better in electoral systems with proportional representation? Do they perform better under electoral systems with lower thresholds for participation? Do they succeed in environments with high district magnitude? One can include controls for these questions in a familiar regression analysis, and perhaps come closer to understanding this phenomenon.

One of the more exciting innovations of the new institutionalism is the incorporation of micro-level analysis into an institutional context. That is, if the answer to a particular research question is not evident at the macro level, there are now ways to model

micro-level behaviour within known institutional constraints. Pioneers of this method such as Tsebelis, Krehbiel and Weingast allowed institutional factors to influence preferences and options, enabling the modeling of micro-level behavior without ignoring formal influences. For example, Jonathan Rodden's *Hamilton's Paradox: The Promise and Peril of Fiscal Federalism* (2006) applied a rational-choice framework to understand how varying institutional environments impact the fiscal behavior of local and national governments. While these works draw their conclusions from micro-level analyses, they do not violate the assumptions of institutionalism because they incorporate institutional values and rules into individual preferences.

If, however, the analyst adopts the ontological commitment of the embedded, rather than atomistic, individual, a separate set of questions arises that are not so easily answered through quantitative means. Returning to the example of European populism, a sociological institutionalist might consider how trends of liberalization in economic and immigration policy have influenced social cleavages. Are there cultural changes that have manifested in institutional biases that elevate anti-immigrant populism? Institutionalists in this school might begin at the level of state institutions, formal and informal, seeking relationships between these characteristics and the outcome of interest.

Historical institutional analysis permits deep focus on the roles of organization, laws and culture on political outcomes. Acemoglu and Robinson (2006) apply this method to identify four ideal-type pathways to democracy (or its failure). The authors identify changes in the political and economic institutions of Britain, Argentina, Singapore and South Africa that led to democratic consolidation or failure. Qualitative comparative analysis (QCA) allows for the systematic comparison of multiple institutional features across a small or medium number of cases to identify whether particular conditions are associated with an outcome of

interest. Process-tracing (see Collier, 2011 for a review) focuses on precise causal pathways within a single case, and can reveal path-dependent outcomes that might elude other forms of analysis. A shared asset of all of these methods is their embrace of complexity and context; they allow the researcher the opportunity to compare a range of institutional features to derive whether or not they may have a relationship with an outcome that is causally prior to or endogenous with micro-level behavior.

A more generalized process of inquiry would look something like this: (1) what is the institutional context for the phenomenon under study; (2) in what ways does that context constrain or expand the probability of a given outcome? These questions tend to be difficult to answer with strictly quantitative analysis for two reasons: (1) the process of understanding institutional contexts (Peters, 2013) often requires more attention to the detail and history of individual cases than quantitative analyses typically (although not always) allow; (2) more often than not, the higher the level of analysis (that is, legislatures versus individuals), the smaller the sample, reducing the leverage of most quantitative tools.

In addition to the methodological implications of institutionalism mentioned above, Diermeier and Krehbiel (2003) argue that institutionalism is fundamentally a methodology. This argument is based on a rational-choice assumption about the nature of institutions and the manners in which behavioral assumptions shape individual and collective behavior. In this view, perhaps the most significant element of institutional theory is its capacity to guide the design of institutions to produce equilibria in well-defined circumstances.

## **CONTRADICTIONS AND PARADOXES OF INSTITUTIONAL THEORIES**

This final section of our chapter will discuss some apparent contradictions and paradoxes

within institutionalism, and within institutions themselves. These contradictions, or apparent contradictions, can be taken as continuing challenges to scholars who seek to understand institutional theory and apply it to the real world within the public sector. But they also illuminate some of the key points of institutional theory, and can be seen almost as summaries of the fundamental points of this approach to political science.

### ***Institutions Are Stable, but Institutions Change***

One of the fundamental paradoxes of institutions, and institutional theory, results from the presumed permanence of institutions, as compared to their continuing need to change and adapt. The fundamental logic of institutions is to create some order and predictability in situations that might otherwise be uncertain. The increased predictability may be a function of rules or of normative commitments to the values of the institution, but the important point is individuals functioning within an institution behave in more regular patterns than do those outside, and those regularities persist over time.

But few if any institutions can survive without change. Any institution is embedded in an environment that will generate pressures for change. These pressures may be political, functional and social (Oliver, 1992), and will require adaptation on the part of the institution if it wishes to survive. Some institutions may change so much that they lose their identity and become in essence new institutions, while most adapt more gradually and recreate their identity in reference to their changed environment.

Further, all but the most strongly institutionalized institution will have some internal conflicts that will generate change (Peters et al., 2005). These internal conflicts may produce even greater challenges to the institution than will external challenges, given that they can undermine the functioning of

the institution or lead to its disintegration. Similarly, internal dissent can lead to ongoing subversion of the purposes of the institution and reduce its performance (O'Leary, 2006; Olsson, 2016).

### ***Institutions Have Common Goals, but Often Are Internally Diverse***

One common image of an institution, at least in the popular conception of an institution, is that it should be relatively well integrated and have a common set of values that guides its actions. And some theoretical approaches to institutions, such as normative institutionalism, stress very strongly the importance of the institution creating a uniform set of internal values that will guide the behaviors of the members of the institution. Institutions develop myths, symbols, values and routines, all intended to create predictable behaviors among the members of the institution, and to make the values of members endogenous to the institution.

The problem is that few if any institutions are that uniform and predictable. For some institutions, such as the military, there is a clear need for high levels of internal compliance and for the members to march to the same drum (literally and figuratively). For other institutions, however, that need for uniformity is not so great, and may not be obtainable even if it were desired. And in some cases internal differences may be desirable, especially when the institution is engaged heavily in innovation and problem-solving, and may want to have members advancing disparate ideas (see Peters, 2019).

Theoretically, at least two approaches within the institutionalism literature speak to the degree of internal difference and debate. Within political science, discursive institutionalism (Schmidt, 2010) assumes that there will be several internal discourses within an institution. This internal debate may result in a single communicative discourse dealing with the outside world, while internally

there is some discord. Similarly, the institutional logics literature in sociology (Thornton et al., 2012) assumes that institutions contain a variety of different logics that may be more or less dominant in any one situation. Likewise, individuals within the institution may be connected more or less strongly to the various possible logics. The presence of different logics and cultures permits the institution to innovate more readily, and also to coordinate more easily with other institutions (see below).

### ***Institutions Shape Individuals, but Are Shaped by Individuals***

The relationship between individuals and institutions is also complex. On the one hand, institutions are created by individuals, but they are often created in order to constrain the autonomy of others, or even the autonomy of the individuals who created them. The obvious example is creating political institutions – the constitutions that are designed to constrain behaviors and produce certain types of outcomes (Buchanan and Tullock, 1962) in a presidentialist system, for example, are intended to make decision-making more difficult as compared to parliamentary systems.

But institutions, as human creations, can also be changed by human intervention (Grafstein, 1992). Therefore, assuming that institutions are somehow immutable or impervious to the actions of individuals tends to understate the role of agency in defining and changing institutions. And the capacity to exercise agency is more available to individuals occupying leadership positions than to ‘ordinary’ members of the institution. When those leaders disregard the norms of the institution, as President Trump has done with the presidency (and American government more generally), these actions can produce change within the institution. The institution may have some tendency to revert to the *status quo ante*,<sup>1</sup> but in the short term can be altered by leadership.

The example of the president altering an institution by his behavior reflects, to some extent, unintentional change within the institution, but the question of designing change is perhaps more interesting. For rational-choice versions of institutionalism this would appear to be relatively easy: all one needs to do is to change the rules and incentive structures and the behavior should be changed accordingly. For other versions of institutionalism, exercising individual agency in changing the institution will be more problematic, given that change may involve altering underlying beliefs or overcoming established inertia.

### ***Institutions Are About Structures, but Also About Individual Agency***

Explanations based on institutions are almost inherently structural, or depend upon inertial forces that are not necessarily personified. And given that in many versions of institutionalism the preferences of individuals are endogenous to the institution, there may appear to be little opportunity for agency. However, any institution will depend upon the actions of individuals. The danger in some versions of the general approach, such as historical institutionalism, is that individual actions are assumed and not really understood properly (but see Pierson, 2000). Further, institutional change may depend heavily on exogenous forces, notably human agency.

Therefore, any reasonable version of institutionalism must find a way to integrate individuals and the institutions that they populate. The theoretical approaches available tend to be better at explaining how institutional rules and values shape individual behavior than at explaining how individuals shape the nature and functioning of institutions. But the individuals do shape institutions, bringing with them values and behavioral patterns to which the institution may have to adapt – or which it

may attempt to change. And individuals may also bring with them ideas that they wish to use to alter the norms of the institution.

### ***Institutions May Be Organizations, but They May Be More Than That***

One of the continuing questions in institutional theory, as well as in organization theory, is how institutions and organizations differ. Or do they? Some discussions of institutions tend to use organizations virtually interchangeably with institutions. There are indeed many important similarities. Both are more or less formalized structures populated by individuals and designed to reach goals. What makes them different – or is there really any significant difference?

At one level, institutions are discussed as broad social institutions such as law, the market and the polity. At a somewhat lower level of generality, as with most other questions about institutions, the answer may depend on the approach. For example, Selznick (1957) argues that an institution is an organization that has been infused with values. Scholars coming from economics argue that institutions are broad sets of rules while organizations are actors playing by the rules (North, 1990; Khalil, 1995). And in some discussions within historical institutionalism, institutions appear to be synonymous with policy, while organizations are those entities charged with making the policy function.

### ***Institutions Address Collective Action Problems, but May Also Create them***

Especially within rational-choice institutionalism, institutions are designed to address collective action problems. Elinor Ostrom's (1990, 2005) work on the commons and common pool resources demonstrates the importance of developing institutions to address collective action problems. Other

perspectives on institutions can also be understood as addressing collective action issues. For example, in normative institutionalism, the 'logic of appropriateness' can be used as a means to have individuals pursue the collective interest of the institution, or perhaps even the society, rather than individual self interest.

But, somewhat paradoxically, the more successful an institution is in solving collective action problems within its own domain, the more likely it may be to create collective action problems across domains. A thoroughly institutionalized structure may have the same narrow goals and conception of interest, and appropriateness, as an individual pursuing their personal utility. They may therefore be unwilling to engage in cooperative behavior that may be perceived to weaken the institution's own benefits. For example, within the public sector, one institution may pursue its own goal of maximizing its power but in the process weaken the governance capacity of the system as a whole.<sup>2</sup>

### ***Institutions Are Independent, but Share Space with Other Institutions***

Much of the literature on institutions tends to discuss institutions as largely independent, autonomous actors. We have already argued that institutions are influenced by their individual members, but they are also influenced by their environment. The environment of institutions is composed largely of other institutions and organizations. For example, the market, as an institution defined by economic principles, is shaped or even defined by other institutions, such as law and the political system. The market and market actors may be powerful, but they cannot avoid the influence of other institutional actors. These institutional and organizational fields mutually constrain the actions of all the participants, and can also serve as mechanisms for monitoring and accountability.

The constant interactions among institutions lead to isomorphic pressures (DiMaggio and Powell, 1983). The interactions among institutions may be facilitated if there is a common pattern of organization among them, and if they, to some extent, have some of the same institutional logics. As a simple example, market organizations tend to organize themselves on the basis of states and provinces in federal systems; committee systems in legislative organizations tend to mirror the structure of the executive branch. These are simple examples, but the basic process of replication of structural formats and process across institutions can be observed in more complex settings as well.

***An Institution Is an Institution, but May Be More or Less So (Institutionalization)***

Most of the literature on institutions treats institutions as a dichotomous variable: an institution exists or it does not. Thus, no matter how shaky an institution may be – see, for example, the presidency in the last days of Richard Nixon’s time in office – it is still an institution. While this simple dichotomy is to some extent true and it does simplify the analysis of institutions, it also wastes a great deal of information. Institutions are not always stable and are not all equally well organized, and therefore we can gain a great deal of analytic leverage by attempting to understand how well structured the institution is in practice.

The concept of *institutionalization* can be used to address the differential levels of structuring within the institution. The various versions of institutionalism rather naturally have different conceptions of institutionalization. For example, for normative conceptions of institutions, Selznick (1957) discussed institutionalization in terms of infusing structures with values and meaning, rather than depending upon mere mechanical achievement of tasks. Empirical studies of institutions, such

as that by Ragsdale and Theis (1997), have developed a number of measures that can provide some basis for comparing levels of institutionalization.

The causes and processes of institutionalization and deinstitutionalization are also important for understanding how institutions are formed and then wax and wane. Oliver (1992) has discussed the processes of deinstitutionalization, but if these processes are run in the other direction they can also help to explain institutionalization. She argues that deinstitutionalization occurs because of three types of pressures on the institution: functional, social and political. Further, those pressures arise both from within the institution and from the environment. Thus, institutions are constantly facing changing pressures that alter their internal capacity and their capacity to influence their environment.

***Multiple Approaches, but One Institutionalism***

Perhaps the ultimate paradox, or question, in contemporary institutional theory is whether there is one institutionalism or just a set of rather disparate approaches to institutions. To what extent is there any capacity for institutionalism to function as a paradigm for understanding political life – or is it just a set of approaches to institutions that do not mesh together in any meaningful way? In either case the institutionalism literature can be valuable, but each alternative serves different purposes and will make different contributions to the social sciences.

We can make a case that there is one institutionalism. This perspective is based on the existence of a number of points of similarity among the various approaches discussed above. The most obvious point of similarity is that all approaches focus on institutions, or more generally tend to emphasize structure over agency in explaining outcomes of the political process. Although some approaches, such as that of the empirical institutionalists,

use structure in an almost commonsense manner and other approaches use it more analytically, they all depend upon structure (see Easton, 1990).

Second, all the approaches to institutions represent attempts to reduce the amount of variance in the behavior of individuals who are members of an institution. This reduction in variance can be achieved through inculcating values, the creation of rules, the use of internal discourses or simply inertia, but all approaches to institutions attempt to explain reductions in variability of behaviors. The reduction in variance does not necessarily imply that institutions are involved heavily in controlling their members, given that many members join an institution knowing what the expectations are, and are thus prepared to comply.

Third, all versions of institutions (and organizations) have some notion of boundary maintenance. Some actors are inside the institution and others are outside, and although the environment of the institution is important for shaping and constraining its behavior, maintaining some differentiation from that environment is important for institutions. Boundary maintenance for the institution is used in part to identify levels of commitment of members and potential members, as well as a means of controlling resources.

Finally, all forms of institutionalism are faced with problems of change. The logic of institutions is to create stability, but excessively stable institutions are likely to be unsuccessful over time, as their environments and the nature of the personnel being recruited change. Although there are more robust ideas about institution change now than there were in the earlier days of the new institutionalism (see Mahoney and Thelen, 2010), change still presents problems for this body of theory. The *a priori* assumption for institutionalism appears to be that change is the exception, while in the real world of politics and governing, change appears endemic.

These similarities among the approaches are important, but in some people's minds

they may be outweighed by the differences among the approaches. Whether the glass is half full or half empty is to some extent a perceptual question, but the way in which institutionalism is perceived – both by its advocates and its critics – will affect its capacity to have broader influence in the discipline. The tendency to emphasize differences among the approaches<sup>3</sup> may have undermined the ability to identify, and to utilize, the similarities.

## CONCLUSION

Institutionalism is a major approach within contemporary political science. Although there are numerous approaches to the concept of an institution, and therefore multiple mechanisms through which institutions are argued to influence politics and governance, there is a common core that argues that institutions are important. Within the approach there is broad agreement that the structures within the political system, both formal and informal, are crucial in shaping the actions of individuals.

Like all approaches within political science, institutional theory continues to evolve. Part of that evolution is the tendency to blend some of the approaches, and to make the differences among them less stark. Rational-choice theories have taken on some of the ideas of the normative approach, and have increasingly argued that social norms are significant in, for example, overcoming collective action problems. And historical institutionalism has now long abandoned its emphasis on radical change by accepting more gradual forms that resemble other types of political change. It is too soon to tell whether these various approaches will in the long run evolve into a single, more powerful approach, but there are some hopeful signs.

## Notes

- 1 This raises an interesting point about historical institutionalism. If the path on which the

institution, or policy, is traveling is sufficiently strong to reassert itself after some changes, can we say that the assumptions of historical institutionalism are supported?

- 2 Conflicts between presidents and legislatures in presidential systems are an obvious example of this phenomenon.
- 3 One of the authors of this article must plead guilty to this charge.

# Applied Game Theory: An Overview and First Thoughts on the Use of Game Theoretic Tools

Adam Meirowitz and Kristopher W. Ramsay

In this chapter we put forward a framework for using game theory to study politics. In our view, the rigorous analysis of strategic interactions can make a number of contributions to our collective understanding of political phenomena. Game theory can be used to develop theoretical insights into how the structure of an interaction, the preferences of actors, the information available to different actors and some idea of purposeful choice combine to create forces that push politics toward certain outcomes, sometimes desirable and sometimes tragic. Game theory connects these fundamental elements of the political world through equilibrium (or steady state) analysis. This approach to theory building, at its core, starts from the premise that what happens in political interactions is fundamentally a consequence of the interdependence of actors' choices, their objectives and the constraints they face.

Game theory clearly is a useful tool for theory building. Since at least von Neumann and Morgenstern (1944), scholars and analysts

have built game theoretic models to study the general properties of contests, electoral competition, bargaining and nuclear deterrence, to name a few topics. This approach to applying game theory to the study of politics, while substantively motivated, tends to be general in both its mathematics and its predictions about strategic behavior, but not primarily empirical. A typical claim might be that deterrence success requires a credible threat or that bargaining favors the patient. The primary purpose of such modeling is to identify general mechanisms and forces in politics or explore the logical foundations related to a specific class of problems. The output of this work is not intended to be tested, and a test may not even make sense.

But game theory can also be used with more empirical objectives in mind. The scientific development of knowledge relating to a subject does not just depend on general theories or stylized analysis emphasizing important trade-offs and incentives; it also consists

of building a library of empirically informed models. These models are specific representations of concrete political domains, such as crisis bargaining between countries, environmental policy making or coordination in elections, that incorporate elements understood to be relevant from general theoretical analysis. Each of these domain specific models emphasizes different aspects of the political context – such as who they take to be important actors, what choices are available to players, the nature of actors' preferences and the existing information environment – and then compete to explain phenomena, often with different implications for our understanding of causation and the consequences of policy intervention. Often these models are most valuable for their predictions linking changes in fundamental characteristics of an environment, such as military power, preferences or information, to outcomes through the process of strategic interaction. The empirical plausibility of such models is often explored through statistical tests, derived from equilibrium comparative statics, linking observable characteristics of the 'real world' to changes in outcomes or choices. In this exercise, data and model are distinct objects and the value of the model is assessed based not only on the novelty or elegance of the analysis itself, but also on the quality of the tests to which it can be subjected.

Sometimes, and with increasing frequency, similar domain specific models are empirical in a completely different way. In these circumstances researchers look to quantify the theoretical model directly using observed behavior and data to estimate fundamental, and unobservable (or unobserved), theoretical quantities through the actors' revealed preferences. Here the model and equilibrium concept acts as a set of identifying assumptions specifying what observed actions must imply about the preferences, information, actions or values of important theoretical variables unobservable to the analyst *if* the modeled strategic interaction is producing the observed data. This quantifying exercise

can rely on estimation and statistical inference or calibration. The result allows both for forecasting and for the evaluation of theoretically motivated and empirically consistent counter-factual analysis.

With a randomized controlled trial, careful thought about research design prior to implementation and empirical analysis is highly recommended. Similarly, considering what kind of game theoretical analysis is best depends on its purpose, and consideration of these issues prior to analysis can be quite valuable. In what follows we flesh out this framework for thinking about applying game theory in political science and provide examples in the literature. As we are not intending to write a review, our selection of examples is incomplete and influenced by the areas in which we work.<sup>1</sup>

Before jumping into particulars, it is useful to summarize the implications of our view of the role of game theory in political science. Game theory is a valuable tool for synthesizing the effects of structure (such as institutional rules), preferences, beliefs, information, learning, dynamics and strategy into one coherent theoretical framework. It is also very flexible and permits the inclusion of conventional notions of rationality as well as a broad range of models of behavioral decision-making in these environments. Given its flexibility, there are naturally multiple ways in which game theoretic models and analysis can be useful for the scientific development of political science and, because of the breadth of potential uses, the criteria by which one evaluates the contribution of a particular piece of research varies by its targeted contribution. In some cases the choice to develop a stylized and seemingly narrow model is well justified and in other cases generating conclusions from such a model is deeply problematic. So a reasonable assessment of a piece of work requires the reader to think about how the modeling tool is being used in a given case.<sup>2</sup>

Our chapter proceeds first by briefly reviewing some key concepts and elements

of game theory. Here we do not intend to teach the reader the technical details of game theory, but rather to be clear about the terms we will use later in the chapter.<sup>3</sup> Second, we will discuss the use of game theory for building theory *per se*. Here we will develop a simple illustrative bargaining example and review some examples of this kind of theoretical work in the literature highlighting their contributions. Next we will turn to what is really the bread and butter of the modern application of game theory to political science: modeling. Again we will turn to our running bargaining example to think about how a model is used differently, review some examples of this kind of work, and point to their contributions and how the growing library of strategic models is advancing our understanding of politics. Last, we will turn to recent work that aims to quantify game theoretic models for purposes of ‘measuring’ important theoretical quantities, for counterfactual analysis and for theoretically based and empirically consistent prediction.<sup>4</sup> In this area published work is more sparse, but a substantial literature is circulating and in development.

## THE LANGUAGE OF GAME THEORY

Before we begin talking about how game theory has and can be used to study politics, we need to have a common language to discuss these models. We need to describe what elements constitute a particular model, what general assumptions are made about actors and behaviors, and how the analysis of this environment leads to explanations and predictions of political and behavioral outcomes.

A non-cooperative game consists of a set of players, a set of strategies available to each player, a structure or game form that links strategy profiles to outcomes, an information structure, and utility functions that represent the preferences of players over outcomes of the game.

For example, we could think about the strategic problem of bargaining between two states over a territory or prize that may be divided. For convenience call the states *A* and *B* and treat the prize as a unit resource,  $[0, 1]$ . A split  $x$  provides  $x$  to *A* and  $1 - x$  to *B*. The payoff to each state from their share is  $u_A(x)$  and  $u_B(1 - x)$ . Here we could imagine that offers are made back and forth, each state taking turns until someone makes a proposal which the other agrees to accept, where neither state enjoys spending time bargaining. This description of possible actions, their timing and their consequences describes a structure. States may be uncertain about each other’s patience. Here beliefs, influenced by whatever information each side of the negotiation has, will also affect their assessment of the choice they should make. And bargaining actions will potentially reveal information about players’ patience.

Given a non-cooperative game, how do we reason about how the agents play the game? The natural starting point is to assume that agents play Nash equilibrium or one of its many well-studied refinements. For example, in games of multiple periods with complete and perfect information, it is standard to focus on subgame perfect Nash equilibria which require that agent choices are based on expectation that agents would behave rationally at choice nodes that aren’t actually reached. In static games in which players possess private information it is standard to focus on Bayesian Nash equilibria which require mutual best responses for each type of each player when agents take expectation over the attributes of other players. In games with imperfect information and sequential choices perfect Bayesian Nash, sequential or some further refined equilibrium concepts which require that agents reasonably form beliefs about what they don’t know based on conjectures of strategies and the things they do observe are typically employed. In general these concepts prune away Nash equilibria that involve choices which are justified by at least one player anticipating actions that

would turn out to be difficult to justify as rational given plausible assessments of how others are playing the game. Equilibrium then becomes the link between what we observe and what that implies about unobservable elements of the political environment.

**USES OF GAMES**

With the preliminaries out of the way, we next consider the different uses of game theory in political science.

**Theory Development**

One use of game theory is theory development. What do we mean by theory development? This kind of work focuses on understanding an abstract representation of a class of problems where the focus is on mechanisms and logic, but not empirics. This kind of general theoretical development can take a number of forms. One focuses on creating stylized games that capture some intuition about a general strategic problem, and tells a story. The other attempts to find general results that apply to a very broad set of circumstances and generates theorems that can be used in future work.

Let us return to the example of bargaining between states.<sup>5</sup> The world is complicated, and models by design are less complicated; they are simplifications that ignore some, if not most, details. Why should scholars bother developing and analyzing a simplification? The first order answer is to clarify intuition. Much like how an experimentalist designs an experiment to isolate the consequences of a specific intervention or treatment, such a model looks to isolate a set of incentives and equilibrium forces in a simplified setting to better understand how some specific mechanism or set of mechanisms influence behavior and outcomes.

For example, consider any bargaining model that has two potential outcomes, either

a successful division of the pie or bargaining failure, and ask: how does the settlement that is obtained relate to what happens if the states do not reach an agreement on the split? Let  $v_A, v_B$  denote the payoffs that state A and B would receive if either player walks away from the bargaining table. Here we don't assume any specific bargaining protocol but we assume that minimally, if a bargain is reached, it is on the payoff frontier. That is, our bargaining game does not waste resources in the process of dividing them. This represents a bargaining situation where we imagine that prior to accepting a split,  $x$ , and terminating the game, each player has the option to walk away and receive their reservation payoffs, and end the game with  $v_A, v_B$ . It is not difficult to see that in any Nash equilibrium that ends with a split  $x$  we must have  $u_A(x) \geq v_A$  and  $u_B(1-x) \geq v_B$ . Consider the bargaining problem illustrated in Figure 11.1. The arc,  $c(x)$ , represents the frontier of bargaining solutions in utility space for states A and B. Suppose that the bargaining process were to produce an outcome, *without* the outside option, of  $x^*$ . Now suppose that the point  $(v_A, v_B)$  is the walk-away value for states A and B. Clearly A would walk away from  $x^*$ . In fact, we know that in this case states A and B would only both agree to a bargain that is on the arc  $c(v_A)$  between points  $(v_A, c(v_A))$  and  $(c^{-1}(v_B), v_B)$ . All these options are preferred to walking away, and which would materialize

**Figure 11.1** The bargaining problem with unilateral outside options

depends on the bargaining interaction, but we know that an efficient bargaining protocol would have to pick one such point. We thus see a strong dependence and general relationship between utility from an acceptable agreement and the players' values of walking away. Outside options matter. Generally, the better a state does from not reaching an agreement the better she must do in any voluntary settlement.

Importantly, the main contribution of this analysis is not really something to be tested. We have an example of a general finding that makes no specific prediction about how exactly the strategic interactions will end without a more detailed model of the bargaining process. Recognizing the importance of outside options is, however, clearly valuable.

### ***Breadth and Limits of an Intuition***

Not all theoretical contributions seek to develop an intuition. Some seek to say what does and does not happen. For example, in international relations it has become standard to build on our bargaining example to develop models of crisis bargaining. Suppose that we delve deeper into the outside option. Imagine that if A and B do not agree to a split then they will fight a war. Let  $v_A$ ,  $v_B$  represent the payoffs to A and B from fighting a war. One natural idea might be that  $v_A = p - k$  and  $v_B = (1 - p) - c$  where  $p$  is the probability that A wins the war and  $c$  and  $k$  are the costs to A and B from fighting. A researcher might seek to understand how uncertainty, in particular private information, influences the odds of war. In this model, war is equivalent to bargaining failure (Fearon, 1995).

A starting point might be the assumption that one of the players is unsure about the other's cost. For example, suppose that we assume that both players know  $k$  but only B knows  $c$ . The standard approach then is to assume that A treats  $c$  as a random variable with some known distribution. It might be convenient to assume a particular functional

form for this distribution, say the uniform on  $[0, 1]$ . What structure governs the interaction of A and B when they negotiate? In the language of game theory, what is the extensive form game? A scholar may seek to get the ball rolling by assuming something simple like the ultimatum (take it or leave it) protocol. Suppose then that we assume that A can make an offer. Then B either accepts or rejects it and the game ends with consumption of the offer or war. Finding equilibria of such a game is direct. Sequential rationality requires that B accept any offer with  $1 - x \geq 1 - p - c$ . So B accepts if  $c \geq x - p$ . Given this, the payoff to A from an offer,  $x$ , that has a chance of being rejected is given by  $x(1 - x + p) + (p - k)(x - p)$ . Differentiating and solving the first order condition, we find that A's optimal offer is  $x = p + \frac{1 - k}{2}$  (assuming that the equilibrium involves a risk of war – otherwise the offer is  $x = p$ ). Importantly, in an interior equilibrium, war happens with positive probability. It is tempting to conclude then that uncertainty (at least of this form) can cause war.

One could and perhaps should also ask: how general is this or any particular intuition? There were many specific assumptions in the above paragraph's worth of analysis. It is natural to focus on the assumptions that show up in the formulas: linearity of utility in shares; one-sided private information given by a uniform distribution. Relaxing these assumptions is not particularly taxing. For example, relaxing the assumption that  $c$  is uniform to the case of some smooth distribution function,  $F$  yields an implicit characterization of the equilibrium offer that is no more informative than the solution above, and the same basic insights come out of it.

But there was another important assumption: that player A makes an offer and B decides whether to accept or reject. Does this matter? How do we check? While the relevance of any particular functional forms can be tested by considering different functional forms or more generalized specifications,

testing and relaxing assumptions about the game form and informational assumptions can be more challenging. Here, one could select a particular bargaining protocol and re-solve the game. This approach could be repeated ad infinitum. An alternative approach is demonstrated in Banks (1990), and more recently in Fey and Ramsay (2011), drawing on mechanism design, the approach that has become standard in areas of auction theory and contract theory. Instead of solving for equilibria to a particular game, the analyst seeks to characterize properties of all equilibria to a well-defined class of games. In this setting we may ask about equilibria to any games in which each state has the ability to veto a deal in favor of war. Although the equilibria to the take it or leave it game involves a risk of war, there are games that achieve peace for certain.

Consider a game that offers A the share  $p$  and B the share  $1 - p$  and gives each player the choice to accept the split or veto it in favor of war.<sup>6</sup> A gains  $k$  compared to her war payoff and every type of B obtains a higher payoff here than from war (the strongest type,  $c = 0$ , is indifferent). So in this game form war does not occur in equilibrium. But this game still has the same private information that is typically described as the cause of war. What is learned? Among other things, by sticking with a particular game it is possible to misattribute the risk of war to private information. This identification is false. By varying the game, one learns that war occurred above not just because there is private information, but because of a conjunction of private information and the fact that the game form gave the uninformed player an opportunity to extract rents from commitment power.

Moving to two-sided private information, Fey and Ramsay (2011) are able to use the mechanism design approach to identify the aspects of private information that do and do not necessitate a risk of war in any equilibrium to a large class of games. The key is whether knowing about the other state's type

is relevant for predicting one's own war payoff. If it is then the problem is said to exhibit interdependent values and the kind of game exhibited in the last paragraph cannot prevent the occurrence of war.<sup>7</sup>

Taking a step back then, simple, explicit, finely detailed models have value and general treatments have value. The former can be especially useful when trying to provide clarity and insight about possible intuitions or relationships. But conclusions about what is and is not possible can be misguided when they derive from the particulars of a model, and if one only analyzes a particular model it can be hard to determine what particulars drive which conclusions. For conclusions about what must or cannot obtain, approaches that cover larger classes of problems are needed.

### ***Testing Consistency of Explanations***

Another type of analysis that is largely aimed at theory building is one that looks to put existing conventional arguments on solid rigorous foundations. Most sciences start with intuition and observation, but eventually apparent contradictions emerge and it becomes necessary to become more rigorous when making arguments. Some arguments turn out to have solid foundations, some are false and some are incomplete. Formal theoretical work contributes by determining which is which.

Take the example of mutual optimism as a cause of war. For quite some time, going back at least to Blainey (1988), scholars have argued that two states can agree to fight a costly war because their private information about the probability of victory makes them both optimistic about a war's favorable outcome. On the face of it, such an argument makes sense, but upon more careful consideration the link between mutual optimism and war is quite complicated. First, formalizing the most straightforward argument,

Fey and Ramsay (2007) show that if countries must agree to fight, that is, have mutual optimism and mutual agreement to forego an efficient settlement and proceed to war for war to occur, then there is no war with rational or even boundedly rational decision-makers.<sup>8</sup> Slantchev and Tarar (2011) respond by showing that when there is bargaining with one-sided incomplete information, mutual optimism can be both necessary and sufficient for war. Fey and Ramsay (2016) show that with two-sided uncertainty and bargaining, mutual optimism, by many possible definitions, is neither necessary or sufficient for war, yet in that environment war is extremely prevalent. Smith and Stam (2004) consider a model with subjective prior beliefs that do not originate from private information and show that in some cases mutual optimism returns as a cause of war. Bilal et al. (2017) show that extreme divergence in subjective beliefs brings us back to peace.

Another intuition that surfaces in conflict studies pertains to the necessity of fighting for learning. Wagner (2000) argued that because talk is cheap, it is only when disputants meet on the battlefield and see each other's capabilities that learning can occur. Wagner draws a sharp distinction between the type of learning in bargaining models that feature in economics and the type of learning that happens in conflict. In the former, bargaining costs allow for screening and in the latter, a key feature is that information is revealed on the battlefield. Powell (2004) develops a model that allows for direct learning while fighting and shows that in equilibrium there is still strategic information transmission from screening, that is, the standard channel survives. The basic insight which cuts against Wagner's seemingly compelling intuition can be seen by a very minor change to our running example. We walk through this exercise to show how a minimal change can shed light on a very different question. Although this model shares some similarities with Powell's, it is purposefully starker and simpler to analyze.

Return to our setting in which both players know  $k$  but only B knows  $c$ . Again the common prior is that A views  $c$  drawn from the uniform on  $[0, 1]$ . Because our analysis is focused on challenging a logic and not developing a model that has all of the relevant moving parts, there is little cost to just assuming that  $k = 0$ . The key change that we need to make is to assume that the game starts with A and B fighting. In addition we want to allow for war termination to be endogenous, and so there needs to be more than one possible period in which fighting occurs. A simple way to accomplish this is to assume that the game lasts for 3 periods. In period 1, A gets to make an offer,  $x^1$ . B can then accept ending the war, in which case the payoffs are  $p + 2x^1$  and  $1 - p - c + 2(1 - x^1)$  respectively, or reject. Following rejection another period of fighting happens and A once again makes an offer,  $x^2$ . B can either accept, resulting in payoffs  $2(p) + x^2$  and  $2(1 - p - c) + 1 - x^2$ , or reject, resulting in payoffs  $3p$  and  $3(1 - p - c)$  respectively.

The analysis of this game is fairly straightforward but somewhat tedious. Begin with the conjecture that B is using a monotone strategy when evaluating offers, so that if B accepts an offer giving her  $x$  when she has cost  $c$  then she will accept if her cost is higher or the offer is higher. These strategies can be described with cutpoints. For a fixed offer in period 1, B accepts if her cost is above some level,  $c^1$ . Suppose that we reach an information set where the offer,  $x^1$ , was rejected and according to B's strategy her type must be  $c < c^1$ . The subform starting with A's second offer looks just like the take it or leave it game analyzed above, except that  $c$  is uniformly distributed on  $[0, c^1]$ . B will accept the last potential offer  $x^2$  if  $1 - p - c \leq 1 - x^2$  and so A's problem in selecting  $x^2$  is to maximize  $x^2 \frac{(c^1 - x + p)}{c^1} + p \frac{(x - p)}{c^1} + 2p$ . The first order condition and solution are similar to the standard game: the offer is  $x^2 = \frac{c^1}{2} + p$ . Because  $k = 0$ , B will make an offer that some

types will reject. Now consider the decision to accept or reject the initial offer,  $x^1$ . The key insight is to note that the type,  $c^1$ , that is indifferent between accepting the first and second offer will accept the second offer, and thus the first period offer,  $x^1$ , is accepted if  $2(1-x^1) \geq 1-p-c+1-p-\frac{1}{2}$ . So as a function of the initial offer,  $x^1$ , B rejects if  $c \leq c^1(x^1) = 2(x^1-p) - \frac{1}{2}$ . Given this, the first period offer,  $x^1$ , is chosen to maximize

$$2x^1 \left( 1 - 2(x^1 - p) + \frac{1}{2} \right) + \left( 2(x^1 - p) - \frac{1}{2} \right) \left( p + \left( x^1 - \frac{1}{4} \right) \frac{1}{2} + \frac{p}{2} \right)$$

Taking the first order condition and solving yields  $x^1 = \frac{23}{48} + p$ . And so if  $p < \frac{25}{48}$  (which is a bit more than  $\frac{1}{2}$ ), the first offer will be accepted by some but not all types of player B. Thus in equilibrium the fact that B rejects the initial offer provides information to A. Accordingly, information is gleaned by A based on whether B decides to continue fighting or acquiesce. Put succinctly, direct learning from what happens on the battlefield is not necessary; strategic players may learn from the fact that other strategic players choose to fight. Similar exercises are carried out by Nalebuff (1991) and Gurantz and Hirsch (2017) as they explore how Jervis's (1982) claim about self-fulfilling beliefs can and cannot lead to war.

**MODELING**

In our view, modeling is a slightly different exercise than theory building. If theory building is like developing our understanding of fluid dynamics, which can also allow us to understand flight, modeling is analogous to

building wings or a scale airplane to see if we can in fact make something fly.<sup>9</sup>

Modeling is an important part of the scientific process, creating a library of domain specific abstractions that bring general theoretical forces to a specific problem in a particular way. Modeling tends to be different from theory building because it tends to make domain specific assumptions that emphasize different elements of a political environment, like deciding who are the relevant players and what their preferences are, with the objective of explaining a concrete set of observable events. These models then tie specific assumptions to testable hypotheses. They also provide a means for making predictions about correlations we should see in observable data through comparative static analysis.

To the modeler, then, the task of deriving relationships between independent and dependent variables has a place of privilege. The path taken by researchers proceeding in this way needs little explanation. The author provides enough specificity so that either an explicit or implicit characterization of the equilibrium can be obtained. Then, often using differential calculus, the relationship between parameters and equilibrium quantities are explored.<sup>10</sup> But see Ashworth and Bueno de Mesquita (2005) for a review of other useful techniques. For example, we may return to the basic bargaining game from above in which state A is empowered to make a take it or leave it offer. But we might want to be more general about utility functions. Assume that  $u_i$  is strictly monotone and continuous for both players. Further assume that with  $u_i(0) \leq v_i \leq u_i(1)$  for both players, where we let  $v_i$  denote the reservation payoff to  $i$  from not reaching a settlement. Subgame perfection then requires that B accept if and only if the offer beats her reservation value and A keeps as much as she can subject to B accepting. This reduces to the following equilibrium condition

$$u_B(1-x^*) - v_B = 0.$$

The implicit function theorem then implies that  $x^*$ , the share to player A, is decreasing in  $v_B$ , the reservation payoff of B. One could parameterize  $u_A(x, \gamma_A)$  and  $u_B(1-x, \gamma_B)$  as dependent on other covariates. The above then yields

$$u_B(1-x^*, \gamma_B) - v_B = 0$$

and  $\frac{\partial x^*}{\partial \gamma_A} = 0$  and because  $u_B(1-x, \gamma_B)$  is decreasing in  $x$ , the sign of  $\frac{\partial x^*}{\partial \gamma_B}$  is the same as the sign of  $\frac{\partial u_B}{\partial \gamma_B}$ . Sometimes the comparative statics are not monotone and pointing this out can help explain why a long series of empirical papers with linear models yield different (or consistently insignificant) results. A linear model of a non-monotone relationship hinges on what part of the parameter space the data comes from. Accordingly, revising the expectations of primarily empirical scholarship to anticipate potentially non-monotone relationships can be especially valuable. Romer and Rosenthal's (1978) treatment of budgeting hinges on showing that in the spatial model the reservation utility  $v_B$  is a non-monotone function of the status quo. Very low and very high status-quo are bad for a moderate veto-player. Equilibrium offers should, then, be a non-monotone function of the status quo.

By what criteria should we evaluate these models? One criteria is its empirical consistency. The process of testing is also one that is very familiar. Here the theoretical model and the data in the world are considered to be independent objects. In this type of exercise the empirical element of the analysis tests to see if the implied correlates of the theoretical model exist in the data. In this way, the testing process is one where the 'theorist hat' comes off and the 'statistician's hat' goes on. Determining what is the best test of a theoretically derived positive or negative correlation still involves thinking through the econometric concerns that are present in any data analysis.

Examples include Benson (2012), where he develops a model of ambiguous commitments

to manage the incentive to start adventurous conflicts when they know they have the support of powerful allies. Benson tests the insights of his model on alliance data and conflict initiation, showing that ambiguous commitments do temper the aggressiveness of allies. Similarly, Ritter (2014) develops a model of leader security in office and then uses event data from 1990 to 2004 to analyze the effects of repression using a two-stage estimator. She finds executive office security decreases the likelihood that repression will occur in the first place, that is, peace inducing policy adjustments are made by secure leaders, but secure leaders are more severe in their repression when protests arise.

Furthermore, the traditional test of the null hypothesis also makes sense in this context. Specifically, it makes sense to hold as the null hypothesis that the derived comparative static *does not* exist in the world. It is only when such a position can be rejected with the appropriate confidence that we believe the analyst has found empirical evidence that their model is describing a force possibly present in the world.

It is also the case that the larger the collection of associations that can be found in the data, and the more these relationships distinguish this model's explanations from other models, the better.

## QUANTIFYING MODELS

Sometimes, and with increasing frequency, similar domain specific models are empirical in a completely different way. Researchers look to quantify the theoretical model directly using observed behavior and other data to estimate unobservable (or unobserved) theoretical quantities through the actors' revealed preferences or beliefs. Unlike in the model-testing paradigm, when quantifying a model the analyst asks: what is most likely to be true about preferences, beliefs or other theoretical unobservables in this model if it were

the process by which the data we observe is generated?

**Estimation**

Return to our running example. A robust phenomenon is that even in settings where  $v_A = v_B = 0$  and the utilities are strictly monotone in shares, we observe offers that are not close to  $x = 1$  and we observe the rejection of offers that give B substantially more than 0. A common explanation is that players tend to have other-regarding preferences. Player B can be sufficiently bothered by inequities that she will forego positive rents to rule out an inequitable split. Alternatively, even if player A thought she could get away with taking nearly all of the pie, she might feel remorse and thus offer more equitable splits. Outside the laboratory one might believe that concerns related to the fungibility of resources lead player B to have a preference for more equity, or political factors may generate altruism in A. With this idea in mind, we can trace out the structural approach. The starting point is a sample. In the extremely simple case, suppose we observe an offer of  $x$  by A and acceptance by B. Further suppose that we are inclined to parametrize  $u_A, u_B$  to capture a degree of other-regarding preferences. Namely, assume that  $u_A(x) = x - \beta_A |x - (1-x)|$  and  $u_B(1-x) = 1-x - \beta_B |x - (1-x)|$ ,  $v_A = v_B = 0$  and that A is empowered to make a take it or leave it offer. The simplest structural econometric exercise involves estimating the parameters  $\beta_A, \beta_B$  from a sample consisting of one play of the game, namely the path:  $x$  is offered by A and B accepts. It is natural to think of this as a maximum likelihood estimation problem. But we cannot yet specify the likelihood function.

First, solve the game as a function of parameters  $\beta_A, \beta_B$ : Player B will accept the offer giving A  $x \geq \frac{1}{2}$  if

$$1 - x - \beta_B(2x - 1) \geq 0.$$

The largest  $x$  that satisfies this is  $x = \frac{1 + \beta_B}{1 + 2\beta_B}$ .

The proposer’s problem is then  $\max_x x - \beta_A(2x - 1)$  subject to the constraint that  $x \leq \frac{1 + \beta_B}{1 + 2\beta_B}$ . Given that A’s utility is linear in  $x$  it is clear that if  $\beta_A$  is low then the solution is  $x = \frac{1 + \beta_B}{1 + 2\beta_B}$ . But if  $\beta_A$  is higher than  $u_A$  is maximized by selecting  $x^* = \frac{1}{2}$ .

Accordingly, as a function of the data ( $x$ , accept) the parameters are partially identified. In particular, if  $x = \frac{1}{2}$  then we infer  $\beta_A \geq \frac{1}{2}$  and any value of  $\beta_B$  is possible. If, however,  $x > \frac{1}{2}$  then  $\beta_B = \frac{1-x}{2x-1}$  and any value of  $\beta_A \leq \frac{1}{2}$  is possible. No parameters are consistent with  $x < \frac{1}{2}$ .

Although our analysis of the structural model is stark, limited to a dataset that includes one observation, it serves to flesh out the ways in which one can very closely tie the model, equilibrium analysis and econometric tests. Here, the nature of identification is interesting. Some patterns of play have more power to narrow down the set of possible deep parameters than others. In practice it is typically convenient to add more noise to the model or introduce noise that accounts for measurement error faced by the scholar.

Consider another example: suppose we were to focus on the strategic aspects of war fighting in our bargaining model. Kenkel and Ramsay (2019) consider the case where war fighting is a strategic contest in which the probability that one side wins is

$$p_A(e) = \frac{\sum_{j \in A} m_j e_j}{\sum_{j=1}^I m_j e_j},$$

for all those states exerting effort on side A. For their purposes, substantive variables affect the effort multiplier such that  $m_j = \exp(X_j \beta)$  and each participant pays a cost for

effort level  $e_j = c_j e_j$ , with the marginal cost  $c_j = \exp(Z_j \gamma)$ .

For the two country case, we can solve for equilibrium effort levels, substitute them into the contest function and get the probability that state A wins equal to

$$\frac{\exp(X_j \beta - Z_j \gamma)}{\sum_{i \in \{A, B\}} \exp(X_i \beta - Z_i \gamma)}$$

That is, the two player strategic contest function, in equilibrium, generates logit war winning probabilities where the coefficients of the estimator are the effects of variables on the marginal return to effort and the marginal cost of war. Given these estimates, Kenkel and Ramsay (2019) can back out unobserved equilibrium efforts and bargaining offers, and make inferences about the challenger's beliefs regarding the target's resolve.

In this case the model acts as a set of identifying assumptions specifying what observed actions must imply about the preferences, information or values of important theoretical variables unobservable to the analyst if the modeled strategic interaction is producing the observed data. This exercise can be based on estimation and statistical inference or calibration. The result allows both for forecasting and evaluation of theoretically motivated and empirically consistent counter-factual analysis.<sup>11</sup> Similar work has been done with respect to crisis dynamics (Signorino, 1999), territorial consolidation (Carter, 2010) and the effects of democratic audience costs on escalation (Kurizaki and Whang, 2015).

Notice that there is nothing really to test about the theory here. What the analyst does is estimate distributions of parameter values consistent with the model and the data. Unlike in the model-testing framework, in this process of bringing the model to data, the model and estimation are part of one enterprise.

So how might we assess such a model? Informally we may look to see how well the model forecasts events of interest, either in or

outside the sample data. We might also review estimated parameter values for their intuitive plausibility. But really, what you would want to do is compare this model, including its quantitative estimates, with another model and its estimates. In this framework there is no null hypothesis test: models beat other models.

Alternative methods used for model forecasting and counter-factual analysis are fundamentally different from this kind of theory based estimation. Statistical methods such as non-parametric estimation, vector autoregression, machine learning and causal inference are all aiming to estimate some version of the policy function mapping observables to outcomes, the credibility of which is determined by the flexibility of the procedure and whether the variation in treatment variables of interest is plausibly exogenous. These methods do not, however, generate estimates of the theoretical parameters, and also assume that there is a single policy function to be estimated. We know from theory – by the existence of multiple equilibria for fixed variable values or different, but unique, mappings from observables to outcomes for different values of the parameters – that these policy functions may not be unique or be useful for counter-factual analysis. This does not mean that such estimates are not useful; it just means it takes special care to determine what is being estimated and whether counter-factuals can be performed on the policy functions obtained by these means.

Structural models, on the other hand, directly estimate theoretical parameters that allow the analysis to make theoretically informed and empirically consistent counter-factual claims. But here too, questions can arise about estimation in the face of multiple equilibria, equilibrium selection and what exactly it means to have the best estimate. The difference is that one cannot proceed with the inference without explicitly making these choices, resulting in transparent, if still debatable, analysis and results.

## CONCLUSION

In the study of politics, game theory is a tool that can be useful in the performance of many different tasks. Each of these tasks contributes to a larger exercise of theory building, model creating and empirical analysis, but they do not all have the same purpose, nor are their contributions measured by the same metric. Something that might be a virtue for one endeavor, such as generality in theory building, might be too abstract to gain traction when modeling a specific political event to think about policy counter-factuals. Game theory has brought many advances to our understanding of politics, but understanding and judging individual contributions requires thinking about the purpose of the analysis.

## Notes

- 1 We mean no offense to the many other fine examples we could have chosen instead.
- 2 In some important ways our view of models is similar to that in Clarke and Primo (2012).
- 3 Readers needing additional development should consult a standard text: Fudenberg and Tirole (1991), McCarty and Meirowitz (2007) or Osborne (2004).
- 4 See also Franzese (Chapter 31) in this *Handbook* for a similar conception of models, which can be aimed at measurement, causal inference, or prediction.
- 5 As much as is possible, we will use this bargaining model as a running example to make ideas concrete.
- 6 It does not matter if the accept/veto decisions are made sequentially or simultaneously in this private values setting.
- 7 For a similar result with correlated types see Compte and Jehiel (2009).
- 8 Note that in some, if not many, settings, conflict can begin without both sides agreeing to fight. But the key conceptual debate on mutual optimism centers on an argument that both sides would want to fight.
- 9 A note on terminology: some may prefer to use the term applied modeling. We prefer to dispense with the term applied, because in a clear sense all of this is applied. Many scholars already draw a distinction between theory and applied theory, where the former is about rationality, properties of equilibrium concepts and relationships between classes of games (and more) and the latter is about using game theory to understand somewhat more specified classes of games that match up to an area of substantive research. To the extent that everything in this chapter is therefore applied, we see reference to theorizing about narrow domains as modeling.
- 10 But see Ashworth and Bueno de Mesquita (2005) for a review of other useful techniques.
- 11 In an exceptional instance of scholars agreeing on something, see also Franzese (Chapter 31) and Slantchev (Chapter 5) in this *Handbook* for compatible views on this approach.

# The Spatial Voting Model

James Adams, Samuel Merrill III and Roi Zur

## INTRODUCTION

We first discuss spatial voting models of party-centered elections<sup>1</sup> involving a continuum that is typically a broad Left–Right (liberal–conservative) ideological dimension which encompasses debates over income redistribution and government intervention in the economy, a major electoral cleavage in most western democracies. The Left–Right continuum is *positional* in that different voters prefer – and different parties advocate – different positions along this continuum. We review the assumptions that underlie the positional spatial model of elections, and then survey spatial modeling research on parties’ positional strategies in these types of elections. We describe how a fundamental spatial modeling result is that vote- or office-seeking parties are typically motivated to advocate policies near the center of public opinion, i.e., near the middle of the distribution of voters’ preferred Left–Right positions (Downs, 1957). This prediction applies most

strongly to elections between two dominant parties (as in the United States and, in earlier periods, British politics), but important elements of this prediction extend to elections featuring three or more parties, i.e., multi-party elections (as in most other western democracies). We then identify an empirical puzzle, namely that parties typically fail to converge towards the center of the voter distribution (or towards each other) to the extent predicted by basic positional spatial models.

We then discuss two possible solutions to this empirical puzzle of party positional divergence. The first extends the spatial model of *voters’ motivations* to consider election scenarios where, in addition to their Left–Right concerns, voters also weigh parties’ reputations along character-based dimensions such as party elites’ reputations for competence, integrity and leadership – i.e., to a *valence dimension* of party competition. In the case of valence issues, it is perhaps plausible to assume that voters agree about which character-based traits

they prefer, i.e., all citizens prefer that party elites possess more rather than less competence, integrity and leadership ability, and moreover all political parties seek to publicly convey positive valence attributes.<sup>2</sup> However, the parties may be differentiated on valence because voters perceive some parties' elites possessing superior character-based valence traits compared with rival parties' elites. We show how, in a spatial model that includes both a positional and a valence dimension, vote- and office-seeking parties may rationally propose radical Left–Right positional strategies that differ sharply from rival parties' positions, and also from the mainstream of public opinion. These radical strategies are not predicted by the positional spatial model that omits valence.

We next explore an extension of the spatial model that considers an alternative *party motivation*, namely that parties – like voters – have preferences over government policy outputs. We show how this assumption can prompt policy-seeking parties to advocate sharply noncentrist positions relative to rival parties, and also relative to their expectations about public opinion.

## EMPIRICAL AND THEORETICAL RESEARCH ON ALTERNATIVE DIMENSIONS OF VOTING

### *Positional Dimensions of Voting*

The spatial model of party competition is associated with the research of Harold Hotelling (1929) and Anthony Downs (1957). The simplest spatial model represents policy debates as options along a one-dimensional continuum or line, and posits that both the policies that voters prefer and the policies that parties advocate are represented by positions along this line. The best known dimension in contemporary western democracies is the Left–Right or liberal–conservative dimension, which involves disagreements over issues such

**Figure 12.1** Illustrative placements of a voter *v* and parties *A*, *B*, on Left–Right ideology

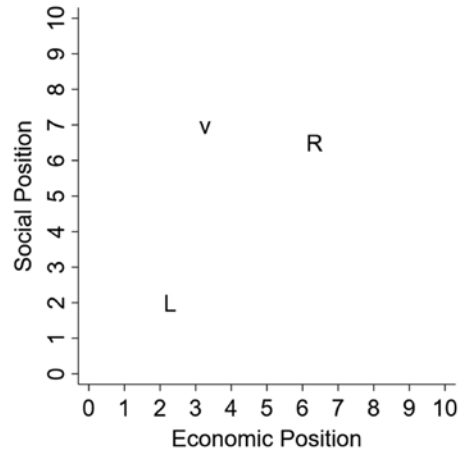

as government intervention in the economy and income redistribution. Figure 12.1 illustrates such a one-dimensional model representing the Left–Right scale, with a voter *v* located closer to party *A* than to party *B*, so we expect that, all else equal, this voter would prefer party *A* to party *B*. In this illustration the Left–Right scale runs from zero to 10, which mirrors the scale that is typically presented to respondents in national election surveys, where the convention is that higher numbers denote more right-wing positions. Empirical studies find that this Left–Right dimension is central to voter choice in western democracies, with communist, socialist and labor parties associated with leftist positions, while conservative and Christian democratic parties are associated with right-wing positions (Dalton et al., 2011).

We note that media and political elites' references to 'left' versus 'right' are shorthand for a *set of* positions on more specific issues. Thus the designation that a party (or a voter) is *left-wing* on economic issues denotes that the party advocates more progressive tax policies and expanded social welfare programs that tend to redistribute income from more to less affluent citizens, whereas *right-wing* parties (and voters) favor less progressive tax policies and a more modest social welfare safety net. These left- or right-wing labels may also encompass employment-related

issues such as the legal rights and restrictions on labor unions, the minimum wage and the degree of government intervention in the economy (Adams, 2018). Moreover, as one would expect, empirical studies find that more left-wing citizens tend to support left-wing parties while right-wing voters tend to support right-wing parties (Bølstad and Dinas, 2017; Powell, 2000).

We note that although Left–Right economic policy dominated positional debates in most western democracies at least through the 1970s, cross-cutting cleavages have emerged pertaining to debates that are not directly aligned with Left–Right economic issues. One set of debates pertains to social and moral issues including abortion, gay rights and gender equality, which cross-cut the Left–Right economic dimension because citizens’ economic views do not necessarily correlate strongly with their views on social and moral issues (Kitschelt, 1994; Marks et al., 2006). Another emerging cleavage pertains to issues involving race, religion and immigration, where, again, citizens (and parties) who share similar Left–Right economic viewpoints may disagree over issues such as affirmative action, multiculturalism and immigration policies. Well before the 1970s, the issue of civil rights in the United States, primarily associated with long-standing racial attitudes, defined a major dimension that cut strongly across the economic dimension and that split the Democratic Party into Southern and Northern branches.

Accordingly, the one-dimensional scale (from liberal to conservative or Left to Right) discussed earlier can be extended to a two-dimensional positional model, represented by a plane with  $X$  and  $Y$  axes. For example, one dimension, say  $X$ , might represent economic (traditional Left–Right) issues while the second dimension  $Y$  might represent social issues. In this two-dimensional model, a voter  $v$  has preferred positions on both the economic scale (say  $v_1$ ) and on the social issue scale (say  $v_2$ ), and is hence represented by a point  $(v_1, v_2)$  in the plane. Generally, it is

**Figure 12.2** Illustrative placement of a voter  $v$  and parties  $L$  and  $R$  in a two-dimensional space

assumed that a voter prefers a party whose expressed positions in this two-dimensional plane are nearest to their own. Figure 12.2 illustrates a voter  $v = (v_1, v_2)$  who is liberal on economic issues but conservative on social issues and is closer overall to party  $R$  than to party  $L$ , even though this voter is closer to  $L$  on the single economic dimension.

### ***A Non-Positional Dimension of Voting and Elections: 'Valence' Issues***

As discussed above, the Left–Right economic dimension – along with dimensions pertaining to social/moral issues, multiculturalism, and so on – is *positional* in the sense that voters (and parties) hold conflicting positions. Despite the continuing relevance of such dimensions, in recent years scholars have considered the effects of *valence dimensions* of voters’ party evaluations. Stokes (1963) coined this term to denote dimensions ‘on which parties or leaders are differentiated not by what they advocate, but by the degree to which they are linked in the public’s mind with conditions,

goals, or symbols of which almost everyone approves or disapproves' (Stokes, 1992: 143). Valence dimensions include such attributes as parties' (and party leaders') images with respect to honesty, competence, empathy and charisma.<sup>3</sup> These dimensions contrast with the Left–Right positional dimension, on which 'parties or leaders are differentiated by their advocacy of alternative positions' (Stokes, 1992: 143).

Valence considerations matter because although nearly all voters prefer that parties be more competent and honest, voters may perceive different parties possessing differing degrees of positive valence. In American and British politics, for instance, national political candidates including Dwight Eisenhower, Bill Clinton and Tony Blair were widely perceived as competent and likable during the periods in which they first led their parties into national elections, whereas others such as Michael Dukakis, Michael Foot, Ed Miliband and Theresa May were viewed far less positively along these dimensions. Cross-national research affirms the growing importance of valence issues across western democracies (see, e.g., Clark, 2009; Abney et al., 2013).

### **SPATIAL MODELS OF ELECTIONS WITH OFFICE-SEEKING PARTIES: THE PURELY POSITIONAL MODEL PREDICTS PARTY CONVERGENCE**

We first review purely *positional* models of party competition, while deferring valence considerations. Downs (1957) was the first to apply this framework to electoral competition, assuming, first, that both parties' positions and voters' *ideal points*, i.e., the positions voters prefer, are arrayed over a unidimensional, positional issue space. Here we illustrate the Downsian model in terms of the Left–Right continuum, but Downs' arguments apply to any positional dimension. Second, Downs assumed that voters evaluate the

parties based – as spatial modelers continue to do, at least in part – on the *proximity* of their preferred positions to the parties' positions, i.e., that voters prefer more spatially proximate parties. Third, political parties strategically announce positions that maximize their electoral prospects, i.e., parties are *office-seeking* and propose policies purely as a means of winning elected office. Downs justified this assumption by emphasizing the private benefits politicians obtain from holding office, including prestige and celebrity, their government salaries, and opportunities to distribute government jobs and contracts to political allies and family members. Hence the basic Downsian model posits that voters are purely *policy-oriented*, i.e., they invariably support the party that offers the most attractive policy positions, whereas political parties are purely *office-seeking* in that they propose policies purely as a means of winning votes, and through this winning office.

### ***Incentives for Party Convergence in the Positional Spatial Model: the Two-Party Case***

In two-party competition over a single positional dimension (here the Left–Right dimension), Black's (1948) Median Voter Theorem states that office-seeking parties converge to the *median voter's* position, i.e., the Left–Right position, such that half the electorate is located on either side.<sup>4</sup> To understand why two-party convergence at the median voter position is optimal for both parties in competition over one positional dimension, note first that, if party **A** locates at this median position and party **B** does not – say, it is at a position to the right of the median – party **B** will lose the election. This occurs because all voters to the left of the median, together with some to the right of it, will be nearer to and hence vote for party **A**, so that party **A** will win the election. However, party **B** can force a tie if it shifts in turn to also locate at the median voter position. Second, if both parties

locate away from the median voter position then either party can win the election by unilaterally shifting to the voter median (Adams, 2016).<sup>5</sup> Hence two-party, purely positional spatial competition provides centripetal incentives for parties to converge toward each other, and toward the center of the distribution of voters' ideal points.

Figure 12.3, which displays a Left–Right continuum (the horizontal axis) with a distribution of voters' ideal points (where the height of the line along the vertical axis represents the density of these ideal points at each position), illustrates this logic. In this example the voter distribution is assumed to be normal, with a median position at the center of the Left–Right scale – a distribution which, as we shall see, roughly approximates the distributions of voters' preferred positions in the electorates of many western democracies. Here we display the Left–Right scale running from zero to 10 (with higher numbers denoting more right-wing positions), which, as we discuss below, is the scale that is usually included in national election surveys to elicit respondents' ideologies. In this scenario the two political parties **A** and **B** are drawn towards the median voter position – and hence towards each other – at the center point (here 5) of the Left–Right scale.

The configuration in Figure 12.3, in which the two office-seeking parties each occupy the median voter position, constitutes a *Nash*

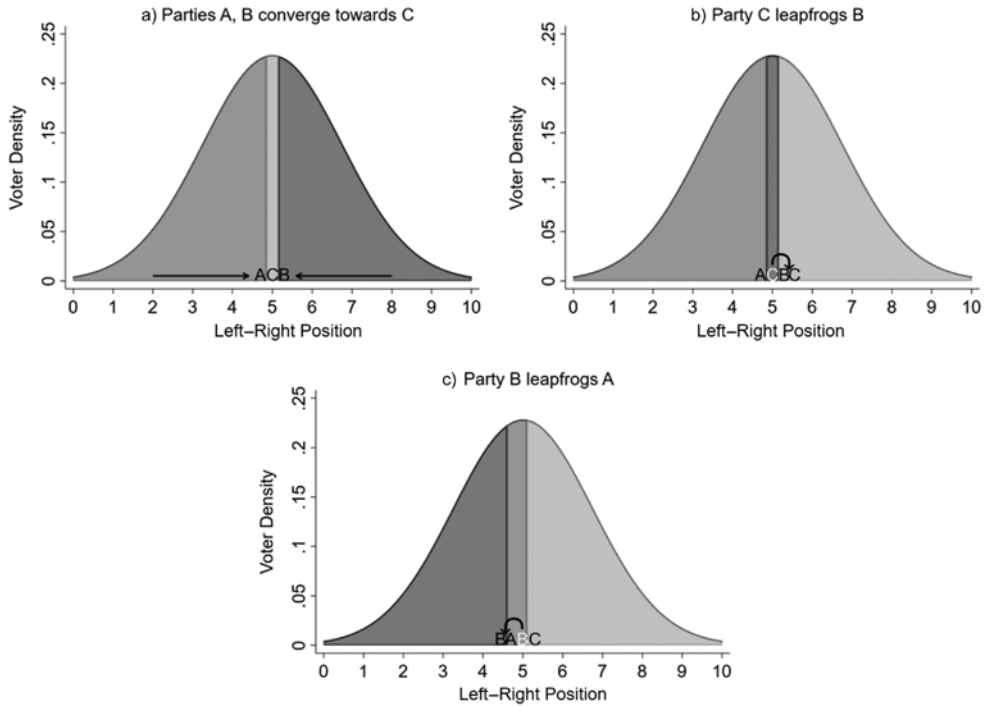

**Figure 12.3** How two-party, positional competition motivates party convergence

*equilibrium* in party strategies, i.e., a configuration of positions such that no party is motivated to unilaterally change its position, given its opponents' positions. In the Downsian two-party spatial model with a single positional dimension, the pairing of parties **A** and **B** at the median voter position constitutes a unique Nash equilibrium.

### **Extensions to Positional Spatial Competition with Three or More Parties**

Downs' arguments about incentives for two-party convergence provided an intuitive explanation for political competition in the American post-World War II party system (Downs' book was published in 1957), in which the Democratic and Republican parties both presented relatively similar and moderate Left–Right economic policies. However, virtually all western democracies outside the United States feature at least three competitive parties, i.e., they are *multi-party systems*.<sup>6</sup> The convergent Nash equilibrium for one-dimensional, two-party positional competition breaks down when additional parties compete. The research of Eaton and Lipsey (1975) – focused on competition between firms but directly translatable to elections – and Cox (1990) suggests that in multiparty elections the *centripetal incentives* motivating vote-seeking parties to converge toward similar positions – and toward the center of the distribution of voters' ideal points – are balanced by *centrifugal incentives* to differentiate their policy positions (Adams, 2018). Moreover, for the basic model we have discussed so far, a Nash equilibrium in party positions rarely exists in multiparty elections.

The above points can be grasped by considering a three-party election along the Left–Right dimension where, regardless of the distribution of voters' ideal points, the two 'peripheral' parties – i.e., the parties that announce the most left- and right-wing

**Figure 12.4 The dynamics of three-party positional competition**

positions – can increase their support by converging towards the position of the third ‘interior’ party. Figure 12.4a illustrates this incentive, with the peripheral parties **A** and **B** converging towards the interior party **C**, which causes **C** to be ‘squeezed’ and hence to win few votes.<sup>7</sup> This convergence prompts the interior party **C** to leap-frog the position of one of its rivals (Figure 12.4b), and the party that is leap-frogged will in turn be squeezed, motivating it to leap-frog another party in turn (Figure 12.4c), and so on without limit.

The centrifugal incentive described above, which counteracts peripheral parties’ centripetal incentives to converge toward the interior party’s position, implies that no Nash equilibrium is possible in three-party elections with vote-maximizing parties. Note, moreover, that in multiparty, one-dimensional positional competition with any number of parties,

the left- and right-most parties are invariably motivated to converge toward the positions of their immediate ‘neighbor’ parties along the positional continuum, because this maximizes the peripheral parties’ vote shares. Figure 12.5 illustrates this dynamic for a scenario involving four parties labeled **A**, **B**, **C** and **D**, located from left to right across the ideological spectrum, where the peripheral party **A** converges toward party **B** while the peripheral party **D** converges toward party **C**. (In this illustration we again depict a normal distribution of voter ideal points.)

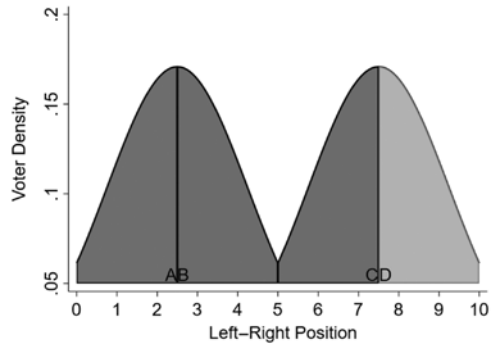

Hence for both two-party and multi-party elections with an even number of parties, the positional spatial model with vote-seeking parties predicts that either the left- and right-most parties will ‘pair’ with each other (two-party case) or “pair” with their nearest interior competitor (more-than-two-party case). In two-party elections this

implies complete party convergence to the median voter position; in multiparty elections this implies that the most extreme parties will converge towards the position of the most proximate interior party, i.e., they will ‘pair’ with an interior party if there are an even number of parties, although, depending on the number of pairs, the pairings will occur at different positions.

We briefly note that whether a Nash equilibrium exists for multiparty competition over one positional dimension depends on several technical details of the voter distribution and the number of competing parties. One condition is that, except for a uniform voter distribution, the number of parties cannot be more than double the number of ‘modes’ in the voter distribution, so that for a unimodal distribution (such as the normal distribution pictured in Figures 12.3–12.5) no Nash equilibrium exists for more than two parties, a bimodal distribution cannot support an equilibrium for more than four parties, and so on. Thus, no equilibrium in vote-maximizing strategies is possible for the scenario pictured in Figure 12.5, in which four parties compete over a unimodal distribution of voter positions. To see this, note that even if peripheral parties **A** and **D** ‘pair’ with the interior parties **B** and **C**, respectively, this cannot constitute a Nash equilibrium since the interior

**Figure 12.5 Centripetal incentives in a four-party election: the peripheral parties converge toward their ideological ‘neighbors’**

**Figure 12.6 Example of four-party Nash equilibrium configuration in competition over a bimodal voter distribution**

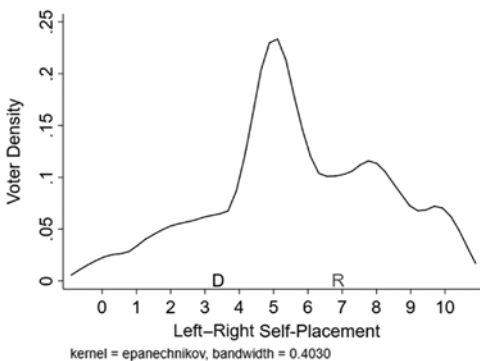

parties can increase their support by unilaterally shifting their positions towards the center of the voter distribution. On the other hand, Figure 12.6 illustrates a bimodal distribution of voters’ ideal points, where one mode is at 2.5 and a second mode at 7.5. In this case, parties **A** and **B** locate at the left-wing mode and parties **C** and **D** locate at the right-wing mode. Note, again, that these positions will constitute a Nash equilibrium only under a set of specific conditions that are beyond the scope of this chapter (but see Eaton and Lipsey (1975) for the conditions that support a multiparty equilibrium for one-dimensional competition).

### **AN EMPIRICAL PUZZLE: REAL WORLD PARTIES’ POSITIONS DO NOT CONVERGE**

The central qualitative prediction associated with the Downsian model of two-party positional competition, namely that the competing parties will offer similar, if not identical, policy positions that reflect the central tendency of public opinion,<sup>8</sup> matched the party dynamics of postwar American and British politics up through the mid 1970s. These patterns featured the Democratic and Republican parties – along with the Labour and

Conservative parties, which dominated British politics throughout this period – presenting similar, moderate Left–Right positions with respect to social welfare policy and government intervention in the economy.

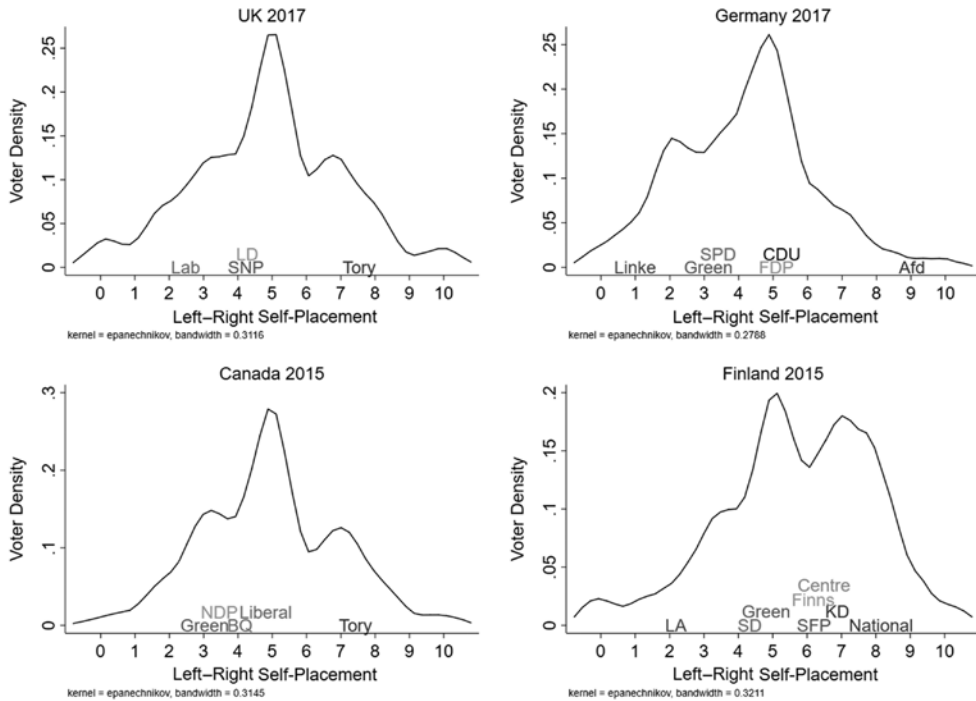

However, beginning in the late 1970s, party politics in both countries diverged from the centripetal logic of the two-party spatial model, with the British Conservatives led by Margaret Thatcher (and her successor John Major) and the American Republican Party under Ronald Reagan (and his successors) shifting their policies sharply to the right, away from their opponents' positions and from the center of public opinion (see, e.g., Adams et al., 2012). Moreover, contra the Downsian prediction that radical policy positioning is electorally damaging, both conservative parties' rightward shifts met with electoral success. And the policy divergence between Republican and Democratic Party elites has continued to widen since the 1980s – indeed, party polarization (at both the elite and mass levels) is one of the most widely studied features of contemporary American politics (see, e.g., McCarty et al., 2006).<sup>9</sup> Figure 12.7 displays this pattern based on survey responses from the 2016 American National Election Study in which survey respondents were asked to place themselves along a Left–Right scale running from 0 ('extremely left-wing') to 10 ('extremely

**Figure 12.7** Distribution of American survey respondents' Left–Right self-placements and their mean party placements, 2016 National Election Study

right-wing'), and also to place the Democratic and Republican parties similarly.<sup>10</sup> The figure displays the distribution of respondents' self-placements, which very roughly resembles a normal distribution centered near the midpoint of the scale, and also displays respondents' mean placements of the Democratic and Republican parties. These mean placements are sharply differentiated, with the Democrats' mean perceived position (3.34) well to the left of the center of the voter distribution, and the Republicans' perceived position (6.92) well to the right of the center.

At the same time that the Downsian positional spatial model appeared to illuminate two-party US and British party politics at least up to the mid 1970s, empirical patterns of party positioning in multiparty systems – which constitute the vast majority of western party systems outside the United States – have rarely displayed the degree of party convergence predicted by the Downsian model. In particular, the party systems of multiparty western democracies often feature the anomaly of radical 'peripheral' parties that present positions far more extreme than those of their nearest competitor. Figure 12.8, which displays the distributions of voter positions and of parties' (mean perceived) positions for several western party systems (the UK, Canada, Finland and Germany), illustrates this phenomenon. (The data are based on the 2017 post-election surveys in the UK and Germany and the 2015 national election surveys in Canada and Finland.<sup>11</sup>) In every country we observe at least one peripheral party whose position is perceived as substantially more extreme than that of its nearest competitor.<sup>12</sup> Yet despite the fact that the logic of the Downsian positional model implies that parties will not adopt these unduly radical strategies – and that those that do initially adopt such strategies will eventually converge towards their nearest competitor – the empirical pattern we actually observe is one where radical peripheral parties maintain stable positions over time (see, e.g., Dalton and McAllister, 2015).

**Figure 12.8** Distributions of citizens' Left-Right self-placements and their mean party placements in the UK, Germany, Canada and Finland

### A POSSIBLE SOLUTION: SPATIAL MODELS THAT INCORPORATE VALENCE DIMENSIONS

It was in the context of Left-Right party polarization in the UK and the United States that spatial modelers began exploring whether valence dimensions of party evaluation could explain this empirical puzzle. As discussed above, valence dimensions differ from positional dimensions in that nearly all voters share the same preferences with respect to valence, i.e., voters prefer that party elites display higher degrees of competence, integrity, unity, compassion and leadership ability, and moreover all political parties strive to publicly project these positive valence-based qualities. However, not all parties succeed in conveying positive valence images to the public: some parties – but not others – become enmeshed in scandals; some

parties' elites appear internally divided, while others appear united; and different parties' leaders may be more or less successful at publicly conveying competence and leadership ability. (Moreover, the same party leader's valence image may fluctuate over time, as has notably been true for British politicians such as Margaret Thatcher, Tony Blair and Theresa May.) As a result, some parties may enjoy valence advantages compared to their opponents. Furthermore, unlike positional dimensions where parties are free to change their positions, parties have only limited abilities to 'strategize' over their valence images: they can strive to achieve and convey to the public an image of competence, honesty and unity, but if these efforts fail, parties cannot simply 'decide' to improve their valence images. Therefore, in the short term, political parties may be considered to occupy more or less fixed (positive or

negative) positions along valence dimensions of voter evaluation (but see Serra, 2010; Curini and Martelli, 2015).

One historical example of the electoral importance of valence issues is the British Conservative Party during the 25 years following World War II, when the party consistently enjoyed a positive public image (compared to its opponent the Labour Party) with respect to competence and leadership. During this period the Conservatives converged toward Labour's long-term leftist economic and social welfare orientation (for this reason the period has been labelled 'the Postwar Settlement', due to the unusual policy consensus between the parties), but largely based their electoral appeals on their positive valence-based image as a 'safe pair of hands' that could administer these policies more efficiently than Labour could. The combination of the Conservatives' 'us too' Left-Right positions and their positive valence image earned the party the derisive nickname 'the party that has no ideas but that knows how to govern'. This strategy proved electorally successful, as the Conservatives won three consecutive general elections between 1951 and 1959, primarily due to their superior valence image. In addition, the Conservatives' later electoral successes in winning four consecutive general elections between 1979 and 1992 – a period when the party had shifted sharply rightward on economic and social welfare policy – largely reflected the

Conservatives' even larger valence advantage arising from the Labour Party's widely publicized internal divisions and weak leadership across much of this period (Norton, 2000).

The consideration of the types of effects discussed above prompted scholars to incorporate valence dimensions into their spatial models. Feld and Grofman (1991) expanded the positional model to include voters' tendencies to accord incumbent parties or candidates a 'benefit of the doubt' that was unrelated to the incumbent's positional stances, and that was conceptually equivalent to an advantage on valence issues. The authors' approach posits that voters' valence- and position-based party evaluations can be meaningfully compared. Figure 12.9 illustrates this approach by incorporating voters' valence considerations into a spatial model that also includes the positional Left-Right dimension. Here we specify that citizens choose between parties **A** and **B** that are positioned at 3 and 7, respectively, along the scale, by comparing these parties' Left-Right positions *and* their valence images. Figure 12.9a displays a scenario where the parties have equal valence, i.e.,  $V(A/B)=0$ , so that all voters prefer the party with the more proximate Left-Right position. In this case a voter with a Left-Right ideal point located at 5 is indifferent between the parties, since this voter's position is equidistant between parties **A** and **B**, so that we label 5 the 'indifference point' for this scenario. All voters located to

**Figure 12.9** How valence affects voter choice in a model with one positional dimension

the left of 5 prefer Party A, while voters to the right of 5 prefer B.

Figure 12.9b displays a different scenario, where party A has a superior valence image. Specifically, citizens evaluate party A's valence advantage relative to party B as equivalent to two units of position along the 0–10 Left–Right scale, which we denote  $V(A/B)=+2$ . This implies that a voter will prefer party A to B *unless the voter's Left–Right ideal point is located at least two units nearer to party B than to A*.<sup>13</sup> In this example with  $V(A/B)=+2$ , a voter located at 6 on the positional scale is now indifferent between parties A and B – which are located at points 3 and 7, respectively – since this voter is located two units closer to B than to A on the Left–Right scale, a positional preference for B which exactly balances the voter's valence-based preference for A. All voters located to the left of 6 now prefer Party A, while those to the right of 6 prefer B.

Several spatial modeling studies explore how the introduction of valence dimensions affects parties' positional strategies (for example, Ansolabehere and Snyder, 2000; Serra, 2010).<sup>14</sup> A key insight from this literature is that valence-disadvantaged parties have incentives to diverge on position from their valence-advantaged rival(s). To grasp this strategy, note that if two parties converge on position then all voters rate the parties equally on position, and hence choose between the parties based entirely on valence

considerations. Hence if one party's valence substantially exceeds its competitor's, the valence-disadvantaged party must diverge from its opponent to win support. In this way the valence-disadvantaged party attracts voters whose ideal points are close to its position but far away from its opponent's position. For this reason, when voters' policy preferences are unimodally distributed (which, as noted above, is true in most Western democracies) valence-advantaged parties are motivated to position themselves near the center of the voter distribution, whereas valence-disadvantaged parties – particularly given proportional representation elections, where office-seeking parties seek to maximize seats and thus votes, even if they cannot win a popular plurality<sup>15</sup> – have centrifugal incentives to diverge from the centrist positions of their valence-advantaged rival(s). In two-party competition over one positional and one valence dimension, the valence-advantaged party can assure victory by locating at the median voter position (or even some distance from this position).

Figure 12.10a illustrates such a configuration for the strategic scenario pictured earlier in Figure 12.9b, where party A's valence advantage relative to party B is equivalent to two units of Left–Right position, i.e.,  $V(A/B)=+2$ , and where we assume that the median voter position is located at 5. Here we picture party A located at the median voter position, which forces party B to locate

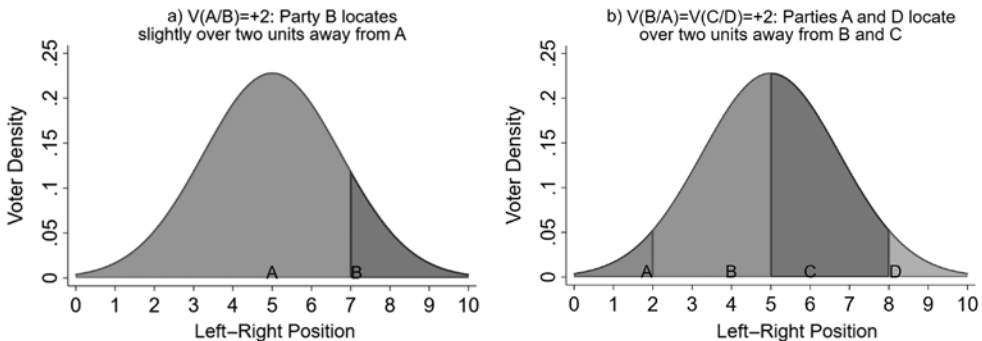

Figure 12.10 Party strategies in elections with one positional and one valence dimension

more than two units away from this position in order to attract any support at all; in this example, with **A** positioned at 5 and **B** positioned just to the right of 7, party **A** wins the election while attracting support from all voters located at or to the left of 7, while **B** wins support from voters located to the right of 7. Note, moreover, that in this example party **A** is assured of victory so long as its position is sufficiently moderate relative to the center of the voter distribution – in this case provided that **A** locates anywhere inside the Left–Right interval [3, 7] – and that regardless of **A**'s strategy, Party **B**'s optimal strategy will be to locate slightly more than two units away from **A**.

Figure 12.10b illustrates how valence considerations may play out in a four-party scenario involving parties **A**, **B**, **C**, **D**, where the two interior parties **B** and **C** each possess a two-unit valence advantage over their peripheral rival parties **A** and **D**, i.e.,  $V(B/A)=+2$   $V(C/D)=+2$ , and where we additionally assume that **B** and **C** have equal valences, i.e.,  $V(B/C)=0$ . With the valence-advantaged parties **B** and **C** located at the moderate positions 4 and 6, respectively, the peripheral parties **A** and **D** are no longer motivated to converge towards their ideological neighbors; instead they locate just over two units away from these rivals, near 2 and 8, respectively.<sup>16</sup>

## THE CONSEQUENCES OF POLICY-SEEKING PARTY MOTIVATIONS

To this point we have reviewed spatial models where parties single-mindedly seek political office. We have seen how, when we incorporate a valence dimension into the standard positional model, valence-disadvantaged parties may rationally present sharply noncentrist positions, away from their valence-advantaged opponents (and from the center of the voter distribution). While this logic illuminates the positional strategies of small, radical parties, there are many real-world

examples of large, valence-advantaged parties that also present sharply noncentrist positions – such as the British Conservatives under Margaret Thatcher and the Republicans under Ronald Reagan, discussed above. In fact, many contemporary democracies feature two large mainstream parties, one located on the center left and one located on the center right. This is true in two-party polities such as the United States, and for much of its history, the United Kingdom, as well as in many multiparty democracies, including Germany, the Netherlands, and Norway. Why might these large, mainstream parties take positions sharply different from each other and from the center of public opinion, particularly – in light of the median voter theorem – when they are the only parties present?

Donald Wittman (1973, 1977, 1983) suggested a possible solution to the above puzzle, which involved extending the model of party motivations. Wittman analyzed situations involving *policy-seeking* politicians who attach utilities to the policies that the winning party implements after the election. Wittman motivated this policy-seeking perspective by noting, first, that elected officials face pressures to implement the policies they promised during the election campaign, since to do otherwise would undermine the credibility of their promises in future elections. Second, Wittman observed that party elites – in common with rank-and-file voters – experience the ‘public good’ of government policy outputs. Wittman therefore analyzed the logic of party strategies when parties have preferences over the policies they are committed to implementing if they win office.

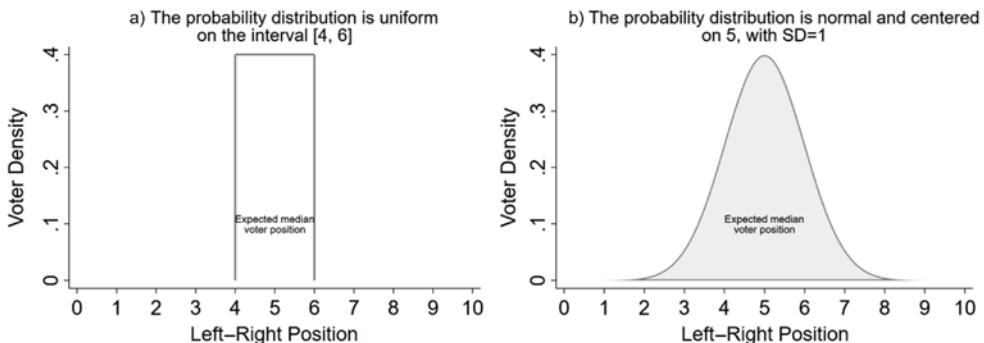

Spatial models with policy-seeking parties assume that each party, like each voter, has an ideal point which is the policy position it would prefer to implement. But this does not imply that a policy-seeking party – in attempting to optimize its policy expectations – should advocate its ideal point in elections. Party elites must still consider the electoral consequences of their policy promises, since

they must win office in order to implement these promises (and to prevent the implementation of disagreeable policies if a rival party wins). For a two-party election involving one positional dimension without valence, and where the rival parties' ideal points fall on opposite sides of the median voter's position, then, provided that party elites have perfect knowledge of this position, the positional spatial model implies that policy-seeking parties will converge towards the median voter's position – the same outcome as for office-seeking parties. To see this, note that when a party with sincere left-wing policy preferences relative to the median voter position competes against a party whose elites hold sincerely right-wing views, then if the left-wing party takes a position to the left of the median voter, the right-wing party need only choose a position to the right of the median – but nearer to that median voter – to win office and implement a policy which it prefers to its opponent's position. Since the same logic applies to the left-wing party's strategic reaction to any right-of-the-median position its opponent announces, it follows that the unique Nash equilibrium in policy-seeking party strategies is the median voter position.

But now let us assume, more realistically, that politicians *are not* certain of the median voter's location in advance of the election, where this uncertainty may reflect the limitations of public opinion polling or uncertainty

over voter turnout. Suppose, instead, that leaders of each party have a general idea of where the median voter should be located, but not a precise notion. For example, assuming a Left–Right scale from 0 (most left-wing) to 10 (most right-wing), party leaders might be quite confident that the median falls somewhere in the middle part of the scale, perhaps between 4.0 and 6.0, but be otherwise unsure of just where. In other words, they would represent their uncertainty about the median location by a uniform distribution between 4.0 and 6.0 (see Figure 12.11a). Or, perhaps more realistically, they might judge that the possible locations of the median voter follow a normal distribution, with, say, a mean of 5.0 and a standard deviation of 1.0 (Figure 12.11b).

We now analyze policy-seeking parties' strategies for this type of election-related uncertainty, using more technical mathematics than we have presented so far.<sup>17</sup> We will represent the party leaders' subjective notion of where the median voter may turn out to be located by a probability distribution with density function  $f(x)$  and cumulative distribution function  $F(x)$ .<sup>18</sup> For simplicity we assume that there are two parties, that this probability function on the median position is the same for both parties, and that voters are moved entirely by positional considerations. Note that the probability distribution of possible median voter positions is distinct from (and usually much narrower and peaked than) the underlying distribution of

**Figure 12.11** Examples of probability distributions over the median voter's position

voters themselves. We will see that, given uncertainty about the location of the median voter, the consequences for office-seeking and policy-seeking parties are different. To see this, first suppose that the two parties are both purely office-seeking. Let  $M_0$  denote the median of the subjective probability distribution  $f(x)$  that the party leaders estimate for the likely position of the median voter. (Note that  $M_0$  is a median of the voter medians, not the median of the (unknown) voter distribution.) See Figure 12.12, which depicts both the density of  $f(x)$  and its median  $M_0$ . Here we again picture the probability distribution  $f(x)$  on the median voter position as normal and centered on  $M_0=5$  with a one-unit standard deviation, as in Figure 12.11b.

Figure 12.12 also illustrates possible locations of each of two parties – one that prefers leftist policies that we will call **L**, located at  $L=4$ , and another that prefers right-wing policies that we label **R**, located at  $R=7$ . In this illustration, **L** is located nearer to  $M_0=5$  than is **R**. Note that party **L** will win the election if the actual median voter position, say  $m$ , turns out to be to the left of the midpoint  $(L+R)/2$  between the two party locations; in this example the midpoint is  $(4+7)/2=5.5$ . Party **R** will win if  $m$  turns out to be to the right of this midpoint. In fact the probability that **L** wins is equal to the cumulative probability from the extreme left up to the midpoint

$M_{LR}=(L+R)/2$ ; while the probability that **R** wins is 1 minus that cumulative probability, or in symbols,  $\Pr[L \text{ wins}] = F(M_{LR})$ , while  $\Pr[R \text{ wins}] = 1-F(M_{LR})$ . In this example the probability that **L** wins is about 0.69, and **R**'s election probability is about 0.31. Thus, unlike in the positional model with certainty over the median voter position, here the party with the more advantageous position (Party **L** in this example) is no longer certain to win election.

For a policy-seeking party, utility for a party, say **L**, is a sum of the party's valuation of the two possible outcomes of the election (either a win for **L** or a win for **R**), weighted by the respective probabilities of these outcomes. Therefore, assuming that **L** prefers leftist policies and **R** prefers rightist policies, utility of **L** for the outcome may be represented by

$$U_L = -L * F(M_{LR}) - R * [1 - F(M_{LR})]^{19}$$

and utility for **R** is given by

$$U_R = L * F(M_{LR}) + R * [1 - F(M_{LR})].$$

We are then able to show that a Nash equilibrium must be given by

$$R = \frac{1}{2f(M_0)}$$

and

$$L = -\frac{1}{2f(M_0)}.^{20}$$

This result tells us that at equilibrium the positions of policy-seeking parties experiencing uncertainty about the location of the median voter are separated by a distance that is related to the degree of spread (i.e., standard deviation) of the subjective median distribution, i.e., the separation at equilibrium increases with uncertainty about where the median voter may be located. For example, if the subjective notion of the median voter is normally distributed, then the equilibrium

**Figure 12.12** How party positioning affects parties' election prospects when there is uncertainty over the median voter position

separation is equal to approximately  $2.5\sigma$ , where  $\sigma$  is the standard deviation of the uncertainty distribution. Thus, on the 0–10 Left–Right scale, if  $\sigma=1$ , and  $M_0=5$  (as in Figure 12.12), then the policy-seeking parties **L** and **R** are separated by 2.5 units at equilibrium, i.e.,  $L=3.75$  and  $R=6.25$ .<sup>21</sup>

Adams and Merrill (2006) extend this model to a setting in which, in addition to the two major policy-seeking parties, there is a small, centrist third party that has no realistic chance of winning election. This model may apply to the British party system in recent decades, in which the Liberal Democrats ran on a platform that was often considered to lie between those of Labour on the left and the Conservatives on the right. By extending the arguments above, Adams and Merrill show that such a centrist party – if it itself prefers that a centrist policy be implemented – effectively shoots itself in the foot twice by entering the competition. This is because, first, the Nash equilibrium positions of the two major parties are even farther apart than would have been the case had the centrist party not competed, so that whichever is elected is in a position to implement an even more extreme policy, and second, the entry of the centrist party increases the likelihood that the major party that is farther from its preferred position is the one elected.<sup>22</sup>

Finally, we analyze policy-seeking parties' strategic incentives when voters are moved by valence as well as policy considerations, but the location of the median voter is assumed known with precision. In a number of spatial modeling studies, a key result that obtains for such models – with an important exception noted below – is that, in contrast to valence-advantaged parties' centripetal incentives in the office-seeking case, such policy-seeking parties typically have centrifugal incentives to announce non-centrist positions relative to the voter distribution (Londregan and Romer, 1993; Adams et al., 2005). To understand this dynamic, consider the case of positional spatial competition between a valence-advantaged

party **R** with sharply right-wing policy preferences, and party **L** with sincere policy preferences at or to the left of the median voter's position (known with certainty). In this scenario, party **R**'s valence advantage gives it leeway to diverge some distance to the right of the median voter position and still be assured of winning, with this degree of divergence increasing with the size of **R**'s valence advantage. Hence the unique Nash equilibrium in policy-seeking strategies is for **L** to locate at the median voter position while the valence-advantaged party **R** locates as near as is possible to its preferred right-wing position at the same time as, by leveraging its valence advantage, it still retains the median voter's support. Indeed, if **R**'s sincere policy preference is sufficiently moderate and/or its valence advantage sufficiently large, any configuration in which **R** locates at its preferred position is a Nash equilibrium.

The above intuition about the positional motivations of valence-advantaged, policy-seeking parties provides a plausible account of the empirical puzzle of the sharply non-centrist positional strategies of the British Conservatives under Margaret Thatcher, and the US Republicans under Ronald Reagan. Both parties benefited from valence advantages vis-à-vis their main competitors during much of the periods of these leaders' tenure in office – the Republicans' advantage was due largely to Reagan's image as a strong, charismatic leader; the Conservatives' advantage was because the Labour Party throughout the 1980s was plagued by public divisions and an image of weak leadership. Lending support to this policy-seeking perspective is the fact that both Reagan and Thatcher were widely viewed as 'conviction' politicians, who were unusually focused on pursuing their policy objectives. Londregan and Romer (1993) have delineated this spatial logic of valence-advantaged, policy-seeking parties in two-party elections, while Adams and Merrill (2009) extend this logic to multi-party elections.

## CONCLUSION

Beginning with Anthony Downs' pioneering work, research on the spatial model of elections has been extended from two-party to multiparty elections; from electorates whose voters are purely policy-focused to electorates that also weigh parties' character-based valence characteristics; from competition between office-seeking parties to elections where parties have policy motivations; and from competition between parties with complete information to elections where parties experience uncertainty about the distribution of the voters' ideal points. These extensions are intended to capture real-world election contexts, and to explain why actual political parties and candidates rarely converge to identical, centrist policies – the prediction associated with the basic Downsian model of two-party, one-dimensional, positional competition.

The extensions reviewed here by no means exhaust the variations on the basic Downsian model. In particular, a growing literature analyzes the implications of 'two-stage' candidate elections in which office-seeking candidates must first win a party primary election in order to advance to the general election (for example, Owen and Grofman, 2006; Serra, 2010). In addition, Adams et al. (2005) develop an approach that unifies the Downsian positional spatial model and the behavioral voting model associated with the University of Michigan (see Campbell et al., 1960), which emphasizes the importance of voter party identification as a long-term, affective orientation, and the authors show that parties may have electoral incentives to appeal on policy grounds to their pre-existing partisans. Since voter partisanship correlates strongly with policy preference in most real-world electorates, this implies that rival parties have electoral motivations to present dispersed policies, with each party taking positions that reflect their long-term partisans' beliefs. Finally, Curini (2018) integrates valence and positional concerns into a spatial model where parties strategize over

whether to raise valence-related corruption issues during election campaigns, showing that this strategic decision may depend on the parties' locations along positional dimensions of competition relative to their opponents' positions. Curini presents a variety of theoretical and empirical analyses (the latter derived from analyses of party programs, politicians' legislative speeches and social media data) to show how this approach illuminates the rise of negative campaigning in contemporary democracies, with particular emphasis on the strategies of emerging populist parties. These ongoing research agendas illustrate how the Downsian model can accommodate theoretically interesting, empirically realistic variations in real-world election contexts.

## Notes

- 1 We frame our discussion in terms of political parties, even though in some countries, citizens cast votes for individual candidates, not parties. An extensive literature documents that even in candidate-based electoral systems, citizens' vote choices are strongly influenced by the candidates' party affiliations (see, e.g., Dalton et al., 2011).
- 2 We realize that the assumption of common valence for a party among all voters may sometimes be unreasonable. The degree to which different voters value honesty or competence may vary, and voters may disagree in their assessments of the honesty or competence of a party or its leader (see, e.g., Zakharova and Warwick, 2014). Nevertheless, there is plausibly more voter agreement over what are desirable character-based valence attributes than over desirable Left-Right positions.
- 3 We note that some researchers apply the term 'valence' to parties' reputations for successfully addressing specific issues such as education, crime, and so on (see, e.g., Clarke et al., 2009; Green and Jennings, 2012, 2017).
- 4 Technically, this position is unique only if the number of voters is odd, but with a very large electorate it is essentially unique in any case. Furthermore, for a large electorate, any significant movement by either party can be expected to cross over the positions of some of the voters.
- 5 We note, however, that predicted party convergence breaks down under various extensions of the Downsian model, including that citizens

- abstain from voting if neither party offers a sufficiently attractive position (Adams and Merrill, 2003); that parties seek to deter entry by new parties (Palfrey, 1984); that political parties select their candidates through primary elections (Owen and Grofman, 2006); and many others. Grofman (2004) reviews these explanations.
- 6 As we discuss below, the arguable exception to this generalization is the British post-World War II party system, which prior to the 1980s was similar to the United States in that it featured two dominant political parties: the Conservatives and Labour.
  - 7 The figure illustrates a scenario in which the voters' ideal points are normally distributed, but the logic extends to any type of voter distribution.
  - 8 Of course, the Downsian model of party convergence applies to two-party competition. A similar logic, as we have seen, does not imply such convergence with three or more parties. Nevertheless, a Downsian expectation of centripetal tendency has been applied to the multiparty scenario.
  - 9 British party politics has subsequently diverged from a system of two dominant parties, as the Liberals (and in later periods the Liberal Democrats) emerged as a third competitive party. However, since the 2015 elections, the Liberal Democrats have become less competitive due to the rapid deterioration of their reputation for competence and integrity (Zur, 2019).
  - 10 These respondent Left–Right self-placements and party placements are based on the following survey questions: 'In politics people sometimes talk of left and right. Where would you place yourself on a scale from 0 to 10 where 0 means the left and 10 means the right? Where would you place [PARTY NAME] on this scale?'
  - 11 The figures display the mean placements of all parties that won at least 2% of the national vote. The respondents' self-placements and their party placements in these national election studies were based on the same questions reported in note 10 above.
  - 12 We note that alternative measures of parties' Left–Right positions, such as those based on political experts' party placements from the Chapel Hill Expert Survey (Bakker et al., 2015), or based on content analyses of parties' election manifestos (Volkens et al., 2018), support the same substantive conclusion.
  - 13 We assume here that as a party's position diverges from the voter's Left–Right position the voter's utility for the party declines at a constant rate, i.e., voters have linear loss functions. There are other utility loss functions we could consider, but these would complicate our discussion.
  - 14 In addition, Aragonés and Palfrey (2002) develop a spatial model with uncertainty about the location of the median voter, where one party may enjoy an (unspecified) advantage, which appears equivalent to the valence advantages we discuss here, with probabilistic divergence and uncertainty about the winner.
  - 15 Most western democracies feature some form of proportional, multi-member district system to select representatives to the national parliament. The major alternative to proportional representation is the plurality-based, single-member district voting system which is employed in France along with most of the English-speaking democracies.
  - 16 We note that the four-party configuration displayed in Figure 12.10b is not a Nash equilibrium since the interior parties **B** and **C**, who are equally matched with each other on valence, can each increase their support by unilaterally shifting position closer to the center of the voter distribution.
  - 17 Calvert (1985), in a setting with multiple policy dimensions, analyzes these issues and shows that candidate policy-seeking alone does not induce divergence; nor does candidate uncertainty about voter response alone (as long as weak assumptions are made), but both policy-seeking and uncertainty together prompt divergence, although small departures from the classic model lead to small levels of divergence.
  - 18 The cumulative probability  $F(x)$  (from  $-\infty$  to  $x$ ) is given by  $\int_{-\infty}^x f(t) dt$ .
  - 19 Here we assume that each party has a linear policy loss function, i.e., that their utilities for various positions decrease at a constant rate as the position diverges from the party's ideal point. The negative signs for the terms in the formula for  $U_L$  occur because **L** prefers a more negative policy while **R** prefers a more positive one. We have also omitted additive constants, which drop out when derivatives are taken.
  - 20 To see this, note that at a Nash equilibrium,
 
$$\partial U_L / \partial L = -F(M_{LR}) + (1/2)(R - L)f(M_{LR}) = 0,$$
 and similarly,
 
$$\partial U_R / \partial R = 1 - F(M_{LR}) - (1/2)(R - L)f(M_{LR}) = 0.$$
 Adding and subtracting these two equations, we obtain  $2F(M_{LR}) = 1$  and  $1 = (R - L)f(M_{LR})$ . From the first of these latter equations, we conclude that  $M_0 = M_{LR} = (L + R) / 2$ , and from the other equation, we infer that  $R - L = 1/f(M_0)$ , i.e., that
 
$$R = \frac{1}{2f(M_0)} \text{ and } L = -\frac{1}{2f(M_0)}. \text{ Q.E.D.}$$

- 21 This equilibrium configuration obtains provided that each party's sincerely preferred policy output is at least as extreme as its equilibrium position.
- 22 Merrill and Grofman (2019) consider a mirror image of this problem – namely, how should policy-seeking mainstream parties react when an extreme third party enters on the flank of one of them. In this setting, they determine conditions such that – just as in the face of entry of a centrist party – both mainstream parties should move further from the new entry.

# New Directions in Veto Bargaining: Message Legislation, Virtue Signaling, and Electoral Accountability

Charles Cameron and Nathan Gibson

## INTRODUCTION

In the years since the creation of separation-of-powers (SOP) models – aimed first at courts,<sup>1</sup> then at Congress,<sup>2</sup> and finally at presidents<sup>3</sup> – much has changed though much remains the same. Needless to say, the constitutionally mandated architecture of the American government hasn't changed at all. This architecture separates the three branches and forces them to interact through a structured bargaining process of proposals and vetoes. On the other hand, the coalition structure of the political parties, the participants in politician selection and the media environment have all changed, arguably dramatically.<sup>4</sup> The causal linkages remain disputed but the net effects are striking and manifest to all: elite partisan polarization, political rancor, congressional stasis, aggressive presidential unilateralism, and puissant courts.<sup>5</sup> In the new American politics, policy outcomes are generally quite understandable using the classic SOP models, or so we assert. But

much of the action, the sound and fury of daily politics, is quite mysterious and clearly beyond the ambit of those simple frameworks. Examples include repeated fruitless attempts to pass doomed bills, hopeless vetoes, futile filibusters, lop-sided cloture votes, obviously doomed attempts at bicameral legislating, hostage-taking via government shut-downs, manifestly impossible impeachment attempts, ostentatiously illegal executive orders and more.

In this chapter we focus on the mysterious, and we offer some suggestions on how to make the murky more transparent.

We begin with a brief review of the classic separation-of-powers (SOP) models, focusing on the veto bargaining version but noting easy extensions to the filibuster. We emphasize the use of incomplete information models to study not just outcomes but process. We are terse because handy and more elaborate reviews are available elsewhere.<sup>6</sup> Then, we note the rise of several puzzling empirical phenomena. These include bizarre

vote margins on vetoed bills and during over-ride attempts; similarly weird vote margins for filibustered bills and during cloture votes; and the useless re-passage, many times, of virtually the same doomed legislation. (If space allowed, we would add more from the laundry list above.) We trace much of these phenomena to a single cause: *the desire of political agents to send credible signals to political principals about their dedication and ideological fealty, using the policymaking procedures of the SOP system*. In other words, they are variants on or consequences of what congressional scholar Frances Lee, in a seminal contribution, called ‘message legislation’ in the lawmaking context.<sup>7</sup> We dub this phenomenon ‘virtue signaling’. Virtue signaling is closely related to, complementary of, but distinct from, blame game politics.

With one exception – Groseclose and McCarty’s prescient explication of ‘blame game vetoes’ – the first-generation SOP models did not accommodate, and say nothing about, message-oriented manipulation of the SOP system’s policymaking procedures.<sup>8</sup> Instead, they assume serious policy-minded actors who pursue genuine policy goals by bargaining with one other in a straightforward and serious way. Even the blame game veto model, which takes a big step away from this paradigm, does not fully capture the new direction in American legislative politics. We assert, however, that if the SOP models are suitably modified, then new veto bargaining, pivotal politics and related models *can* make sense of the novel phenomena while retaining their broad accuracy about policy outcomes.

The trick (in our view) is to move beyond the first-generation framework by embedding the SOP games within what is now called an ‘accountability’ model of elections.<sup>9</sup> In other words: situate the SOP game in a larger model that features retrospective voting or similar action by political principals. The principals we have in mind are the high-information ‘base’ or ‘selectorate’, that is, the individuals who are critical in candidate

recruitment, fund-raising, participation in primaries, campaigning and turnout.<sup>10</sup> Without the enthusiastic support of these individuals, a member of Congress or president is in serious electoral peril. Furthermore, the selectorate will be enthusiastic only about politicians who, if circumstances permit, are willing to work hard to enact the base’s policy agenda. That programmatic agenda is, in contrast to the typically muddled and inchoate desires of less engaged citizens, usually quite definite in some particulars. Politicians’ seemingly bizarre SOP manipulations, such as fruitlessly repealing portions of the Affordable Care Act dozens of times in a legislatively hopeless configuration, can be seen as rational efforts to prove to their skeptical ‘boss’ that they are indeed the type who will bring home the policy bacon should circumstances permit in the future. And demanding such signaling is actually rational for a boss who is doubtful whether the agent possesses ‘true grit’.

To illustrate these points, we sketch a simple model that embeds a stripped-down veto bargaining game within a simple accountability model (we do not undertake a genuine formal analysis here; our discussion is merely illustrative). We hope these notes-to-a-theory suggest the potential for a new direction for SOP models.

We conclude with some observations about whether the sound and fury of phony legislating actually makes a substantive difference or is just meaningless political theater. Our simple new-style SOP model suggests it does make a difference.

## CLASSICAL VETO BARGAINING GAMES

The classical models feature bilateral bargaining between a policy proposer, Congress, or C, and a policy receiver, the President, P. Also making an appearance is the veto over-ride player, O. This player is defined as the legislator closest to the president for whom exactly

one third of the legislature has ideal points either lower or higher than the over-ride player's, depending on whether the president's ideal point  $p$  (defined momentarily) lies in the left or right portion of the policy space, respectively. In some versions another player, the filibuster pivot, appears as well. The filibuster pivot is defined similarly but only for the Senate and using 40 members (the threshold for cloture since 1975), most relevantly on the opposite side of the median from the President. The policy space is typically assumed to be one dimensional. So it is a policy evaluation space similar to the oft-used NOMINATE space in empirical studies of roll-call voting.<sup>11</sup> A critical point in the policy space is the current policy, the status quo, denoted  $q$ .

Each actor has a policy utility function defined over the policy space, with a well-identified most preferred policy, the ideal point. Call these ideal policies  $c$  and  $p$ , for Congress and President respectively, and that of veto over-ride player  $o$ . Policies increasing far from the ideal point have declining value. An example of such a utility function is the 'tent' utility function:

$$u(x, x_i) = -|x - x_i|$$

where  $x_i$  is player  $i$ 's most-preferred policy (e.g.,  $c$ ,  $p$ , and  $o$ ) and  $x$  is any policy in the policy space.

This simple apparatus was first developed to study elections and voting.<sup>12</sup> The SOP policymaking models take the apparatus in a somewhat different direction, however.

### ***The Engine: the One-shot Take-It-or-Leave-It (TILI) Bargaining Game***

The engine that makes the SOP models run is the celebrated one-shot take-it-or-leave-it (TILI) bargaining game first analyzed by Romer and Rosenthal (1978). Most of the SOP models, including veto bargaining, just make changes to this model, for example, by adding more moves, additional institutional

actors and incomplete information. In its simplest form, the sequence of play in TILI bargaining is:

- 1 C makes a proposal  $b$  (a 'bill') to change the status quo or reversion policy  $q$ .
- 2 P accepts or vetoes the offer. If P accepts the offer, the final policy outcome  $x$  is the bill  $b$ , and the game ends.
- 3 If P vetoes the offer, a vote on a motion to over-ride occurs. If O supports the motion, the bill is successful and again  $x = b$  is the new policy. If O does not support the motion, the bill fails and  $x = q$ , so the status quo remains the policy in effect.

Because the game features complete and perfect information, it is easily solved using backward induction, thereby incorporating the idea of forward-thinking strategically minded actors. The resulting subgame perfect equilibrium is unique, depending only on the configuration of ideal points and the location of the status quo. We will not go into any of the details since very clear expositions are readily available. However, several points are worth noting. The first three are substantive; the last two are theoretical.

First, the basic model reveals a *prominent advantage for Congress relative to the President*. The presidential veto acts as a check on congressional power, but Congress's ability to force an unamendable offer on a president who can only say 'yes' or 'no' (and who might not be able to make 'no' stick) gives a huge, constitutionally entrenched power advantage to Congress.

Second, given much policy disagreement between the legislature and the executive or across the parties, *moving the status quo usually requires supermajorities* in the legislature. Given the Constitution's veto override provisions and the Senate's privileging of the filibuster, this should hardly be a surprise. But it is a point of major historical importance – almost every piece of important legislation in the post-World War II era was enacted through supermajorities.<sup>13</sup> It also implies that the American rules of the policymaking game force narrow coalitions

of extremists to compromise if they are to accomplish anything legislatively. Moderates will see this as highly desirable normatively; passionate extremists will see it as a bug, not a feature, of American government.

Third, (and related to the second point), *often no policy movement is possible*: the status quo lies in the so-called gridlock region. In fact, the model and its variants supply the causal mechanisms behind the *status quo bias* so characteristic of American politics. We all know that status quo bias exists because there are so many choke points in the policy process. The models go beyond this cliché to show exactly how the choke points work to create policy gridlock.

Fourth, because the core model is so simple and easy to analyze, *the analysis is very extendable*. This is a lovely feature for the theoretically inclined. For example, one can add congressional committees with gate-keeping power;<sup>14</sup> filibusters and cloture votes;<sup>15</sup> a powerful Speaker of the House with gate-keeping power;<sup>16</sup> agencies that begin the game by setting a policy via regulation, so the model becomes a model of the administrative state in action;<sup>17</sup> presidents who move first via an executive order, so the model illustrates presidential unilateral action;<sup>18</sup> and more. With very simple tools requiring minimal mathematical ability, one can easily see how a great deal of national policymaking works.

The fifth point is subtle and deep and not easy to grasp on first acquaintance. In complete information models of the kind we have been discussing, policy typically moves quickly to its final resting place. There are no vetoes, over-rides, filibusters or cloture votes along the path of play; policy just adjusts. If no movement is possible, nothing happens at all. In this sense, the modern analysis of vetoes and filibusters is similar to modern analyses of wars, litigation and strikes. Complete information models of those phenomena predict changes in territorial boundaries, cross-litigant payments and wages. But they also predict no wars, no

strikes, no strikes. The reason is that the participants understand perfectly what ultimate adjustments will happen and therefore reach agreements that obviate uselessly destructive conflict. In order to get actual vetoes, filibusters, wars, trials, strikes, and so on, a model *requires a degree of incomplete information*. In other words, some actor must lack knowledge about an important variable, and this ignorance or uncertainty leads to 'mistakes' (more accurately, the rational calculations of the actors lead one or both to insist on obdurate actions that would not occur if everyone knew everything).

This fundamental point about human interactions is often met with skepticism: do you mean to say the horrific slaughter in the trenches of World War I (for instance) was caused by a lack of information, not nationalism, militarism, military technology, age-old hatreds, and so on and so on? Not exactly: nationalism and so on may have been *necessary* for the conflict, in the same way that policy disagreement is necessary for a veto. But nationalism was not *sufficient*. It took nationalism *plus* incomplete information to produce the tragic slaughter. Similarly, in SOP models, it takes policy disagreement *plus* incomplete information to produce a veto, a filibuster, an over-ride attempt, a cloture vote, a judicial strike-down of an executive order, a congressional reversal of a judicial policy, and so on.

There is a logical corollary: analysts who want to study not just policy outcomes but phenomena such as vetoes, filibusters, cloture votes and over-ride attempts need to use models that incorporate incomplete information.

### ***Bilateral Bargaining under Incomplete Information***

Early analysts of separation-of-powers politics moved to do just that. McCarty (1997), for example, studied how a president can use vetoes to build a reputation across different

policy arenas over time. This model affords one explanation for the well-known honeymoon effect in presidential–congressional relations (Congress, knowing the freshman president is hungry to build a reputation for toughness, is extremely accommodating – at least at first).

Cameron (2000) explored a model of sequential veto bargaining. Here, Congress and President go through multiple rounds of passing and vetoing the same bill, with Congress making concessions each time in an effort to produce an offer the President will accept, and the President vetoing and re-vetoing in a gamble that Congress will return with a better offer before bargaining breaks down. Perhaps somewhat surprisingly, some of the most consequential legislation of the 20th century emerged from this sequential bargaining process (e.g., welfare reform under Clinton).

Cameron (2000) also offered a very simple model of over-ride attempts. Here, in the face of uncertainty about who the critical veto over-ride player will be at the actual moment of the attempt, over-rides can occur, both successful and unsuccessful. Essentially the same model could be used to study filibusters and cloture voting.

In a particularly clever model, Matthews (1989) studied veto threats. Here, a veto threat is a little like a bid in a poker game: the President opens with a ‘bid’ (a veto threat), Congress may or may not adjust its next ‘bid’ (a bill) and then the President ‘calls’ or ‘folds’ by vetoing or accepting.<sup>19</sup> Cameron et al. (2000) take this model to data, which generally display the predicted empirical patterns.

All of these models feature bilateral bargaining between the President and Congress with uncertainty about one of the player’s preferences. In most cases, the uncertainty involves the President’s preferences, although in the simple veto over-ride model the uncertainty is about the preferences of the over-ride player. Models in which the unknown-preference President moves before

a move or counter-move by Congress are signaling games.<sup>20</sup> These games feature strategic reputation-building and require more sophisticated modes of analysis than the simple complete information models (one must model player beliefs simultaneously with player strategies, and the two must reinforce one another).

Many of the incomplete information bilateral bargaining models make rather precise empirical predictions about vetoes, overrides and so on. Data from the mid 20th century (or earlier) through to the 1980s or so strongly display the predicted patterns. As a result, this analytical endeavor has often been seen as a success for the empirical implications of theoretical models (EITM) movement in political science. Critically, however, some of the key predictions of the incomplete information bilateral bargaining models show signs of breaking down – a point we return to below.

### ***Bargaining before an Audience: Message Votes***

One of the early incomplete information models stands out from the others, because it is not a bilateral bargaining game. We refer to Groseclose and McCarty’s blame game veto model (2001). This model involves three intrinsically important players. Specifically, Congress and the President play a legislative game before an audience, a Voter. The President and Congress understand each other’s preferences perfectly, so there is no incomplete information at that point. But the Voter is somewhat uncertain about the President’s preferences; therein lies the critical incomplete information. The Voter’s uncertainty creates the opportunity for Congress to set up a policymaking sequence which, if observed by the Voter, will lead her to draw a relatively unfavorable inference about the President’s preferences (even knowing that Congress would like this to happen). And that is the whole point – not truly

legislating, but play-acting legislating in order to cast blame on the other side. Indeed, the veto-bait bill may fail miserably in enactment but still succeed as symbolic action.

The ideas in the Groseclose–McCarty model should resonate with contemporary scholars, for blame game vetoes are closely related to what Frances Lee has called ‘message votes’. According to Lee (2016: 143–4), message votes occur when

a party brings to the floor an attractive-sounding idea with the following characteristics: (1) its members support it; (2) the other party opposes it; and (3) it is not expected to become law. Former Senator Olympia Snowe offers a more detailed explanation: ‘much of what occurs in Congress today is what is often called “political messaging”. Rather than putting forward a plausible, realistic solution to a problem, members on both sides offer legislation that is designed to make the opposing side look bad on an issue and it is not intended to ever actually pass.’

The Groseclose–McCarty model works out the logic of ‘mak[ing] the opposing side look bad’ in the specific context of the presidential veto.<sup>21</sup>

An obvious question is, how frequently have blame game vetoes occurred? We take a look at some relevant data below. But Cameron (2000a) addressed this question over the 20th century, using an admittedly stringent set of criteria: the veto needed to be prominent, occur in the run-up to a presidential election, and led to a hopeless over-ride attempt (so the enactors should have known that serious legislating was off the table). The historical data on vetoes during the 20th century uncovers relatively few blame game vetoes, according to these criteria (see *ibid.*, table 5.1). Most vetoes did not look like this. To the extent that this is a fair test, the blame game model does not look like a general model of vetoes, at least over much of the 20th century. However, the data reveal that *some vetoes were clearly blame game vetoes*. An example was the Family and Medical Leave Act of 1991, passed by a Democratic Congress and presented to Republican

President George H. W. Bush immediately before the 1992 presidential election. Bush had publicly opposed the bill and his veto was entirely predictable. Given the vote margins, a successful over-ride was clearly doomed. So from a serious legislating perspective, the bill was futile. The Democrats nonetheless pressed ahead, and then used the failed bill as a signature electoral issue. Upon re-gaining the presidency, they quickly enacted family leave in 1993 and touted it as a flagship legislative accomplishment. Quintessential blame game politics!

The general phenomenon of blame game politics, presciently explored by Groseclose and McCarty in the specific context of veto bargaining, has now become routine, at least in the opinion of astute observers such as Lee and candid participants such as Snowe. In fact, a series of empirical anomalies in separation-of-power politics suggest the need for some fresh thinking.

## EMPIRICAL ANOMALIES

Recent years have seen congressional legislative behavior that is extremely difficult to reconcile with the classical SOP models. Let’s look at some of the empirical anomalies.

### ***What to Look for: Vote Margins at the Pivots and Policy Concessions***

The first question, though, is this: where should we look for legislative anomalies? The incomplete information bilateral bargaining models assume a degree of uncertainty about the preferences of a key player, but not a huge amount of incomplete information. This has important implications for vote margins at the pivots and for policy concessions in re-passed bills.

First, *vote margins at the critical pivots should be close*. To see the logic, suppose, for example, a bill is geared to beat a likely

presidential veto with the veto over-ride player as the critical pivot. Then the roll call margin on passage in both chambers should be about two-thirds. If it is much higher, the proposers have not been tough enough; they have conceded too much. If it is far shy of two-thirds then the bill is a sitting duck, doomed from day one, and the proposers are wasting their time. The margin for the over-ride attempt should also be about two-thirds. Now, suppose the president himself is the critical pivot (that is, the veto over-ride player is more extreme than the president). Then the passage margin may be lower than two-thirds but if the president does veto the bill, no over-ride attempt should follow, as the over-ride is hopeless. If an over-ride attempt did occur (anomalously), the vote margin would be well short of two-thirds. In short, unless the president is moderate relative to the over-ride pivot, passage margins for vetoed bills should be about two-third yeas and one-third nays, over-ride attempts should not occur for vetoed bills with narrow passage margins and actual over-ride margins should be about two-thirds yeas and one-third nays.

Similar ideas apply to filibusters. Suppose a bill is geared to beat a filibuster in the Senate. Then a bill that is likely to provoke a filibuster should pass the Senate with about 60 votes. If it passed with many more votes, the filibuster is pointless since cloture will be easy, hence no filibuster should occur (and the bill's proponents conceded too much to the opposition). If initially passed with a narrow majority, then cloture seems likely to fail and the bill should not have been passed in the first place – its authors should have conceded more, or just abandoned the effort. Similarly, actual cloture votes should show about 60 votes in favor of cloture. Lop-sided successful cloture votes should not occur because the filibusterers should have known they would fail; lop-sided failed cloture votes should not occur because the bill authors should have known the bill was a sitting duck and either conceded more or given up the cloture attempt.

A second anomaly can occur with re-passed, previously failed legislation: *no concessions*. (That is, for re-passage under the same configuration of players.) Under the sequential veto bargaining model, re-passage of vetoed bills can occur, but the re-passed bill should contain a compromise in the direction of the president, so either he will sign it or the veto over-ride player will support the bill. As a result, the cutting line between the yeas and nays in NOMINATE space should shift toward the president, and the aye margin should increase.<sup>22</sup> Similar logic applies to bills that die from a filibuster in the Senate: if re-passed, they should contain a compromise to the filibusterers so that either they will accept it or cloture will succeed. The same logic also applies to bills that are enacted by one chamber during split-chamber divided government, but then die in the other chamber (perhaps they are never taken up). If the first chamber re-passes the bill, it should contain concessions to the recalcitrant chamber. Cutting lines for the roll call vote in the enacting chamber should shift in the direction of the recalcitrant chamber and vote margins should increase.

In sum, the place to look for legislative anomalies are: (1) lop-sided supermajorities or, conversely, very narrow enactment votes for vetoed bills upon initial passage; (2) veto over-ride margins far from two-thirds in one or both chambers; (3) enactment votes for filibustered bills far from 60–40 in the Senate; (4) cloture vote margins far from 60–40; and (5) re-passed previously failed bills in the same legislative configuration that do not contain concessions from bill to bill.

So, how many legislative anomalies have occurred in recent decades? Has the rate of anomalies increased? Unfortunately, a comprehensive empirical analysis lies outside our writ here. However, we can present some simple data and mini-case studies that suggest anomalies now abound and have distinctive features.

### ***Veto Anomalies***

Table 13.1 presents some simple summary statistics on vetoes from 1975 to 2018. There were 167 vetoes in that period, with about half escaping an over-ride attempt. Of those that were challenged (90), about 69% were sustained (the over-ride attempt failed) while 31% succeeded. Under traditional veto bargaining models, we would expect that if a veto is challenged it should either succeed or fail by a narrow margin. Otherwise, either the president should not have vetoed it or Congress should not have challenged it. Hence, a 70% failure rate for over-ride attempts may raise an eyebrow; one might expect something closer to 50–50. In fact, Cameron (2000) reports a success rate of 45%, using earlier data (p. 56). Still, one needs to look more closely at actual vote margins to identify anomalies.

Table 13.2 takes a closer look at sustained vetoes, that is, failed over-ride attempts. It focuses on hopeless over-ride attempts. In the House, over half of the time that an over-ride attempt failed, it failed by at least 10% of the required votes (29 votes). In the Senate, some 10 of the 22 failed over-ride attempts failed by the comparable 10% margin (6 votes). Hence, the ‘hopeless over-ride’ rate among the failures was 60% in the House and 45% in

the Senate. Theory would predict something close to zero. It should also be noted that, of the 34 hopeless over-ride failures, six of these over-ride attempts failed in the Senate after success in the House (so the House success was immaterial), while the other four hopeless over-ride failures in the Senate occurred for vetoes where the House did not even attempt an over-ride (so they were truly hopeless failures). In sum, the number of hopeless over-ride attempts was not large but this phenomenon has become a notable feature of veto politics.

What type of bills did Congress typically try so hopelessly to over-ride? At least in recent cases, the bills were highly visible, highly contentious vehicles for partisan position-taking. They are similar to the bills involved in the frenetic, frenzied re-passage episodes discussed momentarily; in fact, some of them are the same bills. So, for example, bills repealing parts of ObamaCare and the Dodd–Frank financial legislation both generated vetoes and hopeless over-ride failures in the Republican Congresses facing President Obama. Hopeless over-ride failures during the Bush administration were generated by vetoed bills banning waterboarding and establishing a timeline for withdrawing troops from Iraq.

Some of the hopeless over-rides seem to follow the script of Groseclose and McCarty’s

**Table 13.1 Summary statistics on vetoes, 1975–2018**

Sustained <sup>1</sup>	62	37.1%
Over-ridden	28	16.8%
Unchallenged	77	46.1%
<i>Total vetoes</i>	<i>167</i>	<i>100%</i>

<sup>1</sup>This counts two vetoes that were over-ridden in one chamber but unchallenged in the other, technically leading to an outcome where the veto was challenged but not over-ridden. Accordingly, we classified these as sustained but exclude them from the following analysis of sustained votes.

**Table 13.2 Hopeless over-ride attempts, 1975–2018**

Sustained in House	40	Sustained in Senate	22
Failed by more than 10%	24	Failed by more than 10%	10
<i>Percent not close</i>	<i>60%</i>	<i>Percent not close</i>	<i>45%</i>

blame game vetoes. For instance, the waterboarding episode can be seen as an attempt by the Democrats to demonstrate to the public the inhumanity of the president and his administration. However, in some cases there are hints of another dynamic. Thus, reporting in *The Hill* noted: ‘Republicans say they are playing the long game with the [ACA] repeal vote, hoping it will give voters a glimpse of how they would govern if they win back the White House in November.’<sup>23</sup> We will return to this point below.

We have looked at hopeless over-ride attempts; what about hopeless vetoes? How frequently does the president get massively rolled after vetoing a bill? Given the hopeless quality of the veto, why did he veto it in the first place?

In the time period we study, the president occasionally vetoed a bill with massive support, so that an over-ride was virtually certain. Of the 28 over-ridden vetoes during this time period, Congress overrode nine of them by at least 10% in each chamber. Six of these massive rolls came during the first 12 years of the data (during the Ford and Reagan Administrations). Since then,

massive rolls of vetoes have occurred only about once per decade. Table 13.3 provides a brief overview of these vetoes.

At the time of writing, the most recent massive roll of a presidential veto involved President Obama’s veto of the Justice Against Sponsors of Terrorism Act (JASTA). This bill would have allowed private individuals to pursue legal action against foreign companies in US courts, primarily in response to the victims of the 9/11 terrorist attack. President Obama veto message cited foreign policy concerns.<sup>24</sup> President Bush’s lone massive roll came from his veto of the Water Resources Development Act of 2007. Bush claimed the bill was too pork-ridden to serve the nation’s interests.<sup>25</sup> Finally, a bill canceling Clinton’s line-item veto of military construction projects was also overridden by large margins.<sup>26</sup> As with Bush’s veto, the concerns behind the veto seem primarily centered on pork.<sup>27</sup>

In each of these examples, the president had genuine policy concerns, but the veto – a hopeless endeavor from the get-go – seems to have been undertaken partly or primarily for position-taking. Perhaps the president wanted

**Table 13.3 Massive rolls of presidential vetoes, 1975–2018**

<i>Bill Number</i>	<i>Bill Name</i>	<i>Date of Veto</i>	<i>House Vote</i>	<i>Senate Vote</i>	<i>Reason for Veto</i>
S.2040	Justice Against Sponsors of Terrorism Act	9/23/16	348–77	97–1	International concerns
H.R.1495	Water Resources Development Act of 2007	11/2/07	361–54	79–14	Too much pork
H.R.2631	Line Item Veto Cancellation	11/13/97	347–69	78–20	Too much pork
H.R.1	Water Quality Act	1/30/87	401–26	86–14	Too much spending and federal oversight
H.R.2409	Health Research Extension Act	11/8/85	380–32	89–7	Too much red tape and bureaucracy
H.R.6198	To amend the manufacturing clause of the Copyright Law	7/8/82	324–86	84–9	Free trade concerns
H.R.7102	Veterans’ Administration Health-Care Amendments	8/22/80	401–5	85–0	Spent money on VA physician bonuses instead of helping veterans
H.R.5901	Education Division and Related Agencies Appropriation Act	7/25/75	379–41	88–12	Fiscal irresponsibility
H.R.4222	National School Lunch and Child Nutrition Act	10/3/75	397–18	79–13	Fiscal irresponsibility/personal responsibility

to signal his frugality and good stewardship to a national audience (or, in Obama's case, an international one). Or, the president may have wanted to highlight Congress's fiscal imprudence, a sort of *reverse* blame game veto. In all three of these examples, both chambers of Congress were controlled by the other party.

### ***Filibuster Anomalies***

Discussion of the filibuster may seem somewhat odd in an essay on veto bargaining, but we argue that the anomalies are similar in both cases and likely to have a common origin. Therefore, let us quickly examine 'strange' patterns in filibusters, focusing on cloture vote margins.

Figure 13.1 displays vote margins in all cloture votes in the 111th to 115th Congresses (2009–18). Recall that the required quota for success was 60 votes in this period; in the figure, a margin of 0 corresponds to 60 votes for cloture. The thin vertical line shows the average margin in these Congresses: about 7.3 votes (in the 94th through 98th Congresses, the average margin was almost exactly 0). Two features stand out in the figure.

First, and most noticeable, is the very long and rather flat right-hand tail, that is, successful cloture votes. As shown, some cloture votes succeeded with absolutely spectacular margins, suggesting that the filibuster in question was a hopeless endeavor. Unfortunately, this inference is clouded by the changing vagaries of senatorial procedure. As explained by CRS experts: 'In recent times ... Senate leadership has increasingly made use of cloture as a normal tool for managing the flow of business on the floor, even when no evident filibuster has yet occurred.'<sup>28</sup> Thus, cloture is now used pre-emptively and as a device to restrict non-germane amendments. This change in procedure probably accounts for some of the huge positive margins in cloture voting. Some

filibusters may have been fruitless efforts leading to a crushing cloture vote, but one cannot easily detect such filibusters using positive cloture margins alone.

Therefore, let us turn our focus to the left-hand tail: failed cloture motions. In the face of incomplete information about the filibuster pivot, one would expect some cloture motions to fail, but generally with margins close to zero. Yet one sees some eye-popping negative margins, some by 20 votes or more. Thus, some invincible filibusters provoked completely hopeless cloture attempts. Votes like this are hard to reconcile with classical SOP style models.

Have futile cloture efforts increased over time? Figure 13.2 addresses this question by examining the number of hopelessly failed cloture votes, votes failing by a 10% margin or more (that is, six votes or more). The time period is longer, from the 94th Congress to the 115th, in order to provide more of a historic contrast (the critical cloture margin was 60 votes over the entire period). As shown in the figure, there appears to be a jump in the number of big failures starting at the 104th Congress (1995–6). Using the benchmark of a 10% short-fall in votes, the average number of futile cloture votes was 10.1 in the 94th to 103rd Congresses; it was 23.5 in the 104th to 115th Congresses. Thus, the number of futile cloture votes doubled beginning with the 'Gingrich Revolution' Congress after the 1994 mid-term election. We note that the percentage of futile cloture votes (relative to all cloture votes) did not change much over this time period, though the number of such votes seemed to increase.

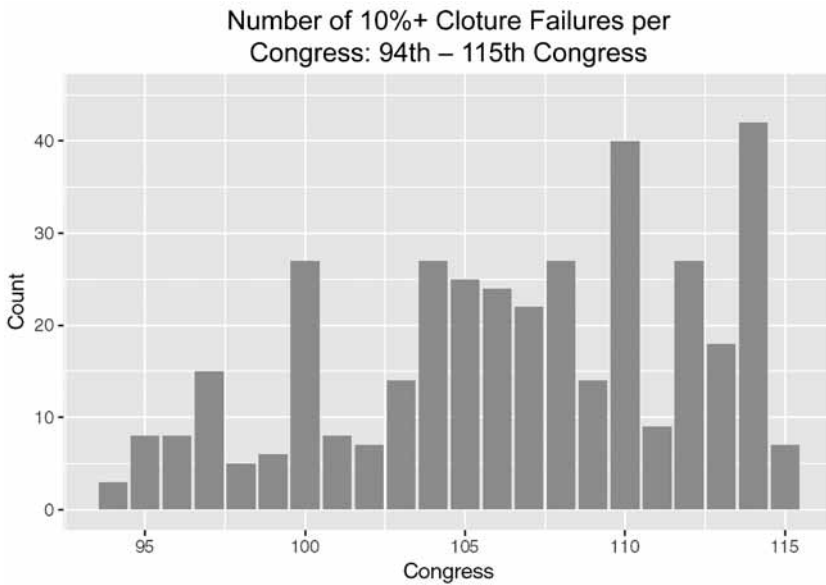

What were some examples of recent hopeless cloture votes? In the most recent period, many deal with border security, sanctuary cities, DACA and abortion – all highly visible and highly partisan issues.

We have just scratched the surface of this material but clearly some filibuster and cloture attempts look quite strange from a bilateral bargaining perspective.

**Figure 13.1** Passage margin of cloture votes, 2009–2018

*Note:* A vote margin of 0 corresponds to 60 votes for cloture. The right-hand tail of the figure captures successful cloture votes; the left-hand tail unsuccessful ones. Not every cloture motion resulted in a vote. The data exclude nominees considered under a pure majority confirmation rule.

**Figure 13.2** Futile cloture votes, 1975–2018

*Note:* Shown are counts of dramatically failed cloture votes by Congress, using the benchmark of a 10% short-fall in votes.

### ***Frenetic Failed Legislation***

One of the strangest recent phenomena in the new legislative politics is what can be called *frenetic failed legislation*. With frenetic failed legislation, one or both chambers of Congress repeatedly enact almost identical bills that all participants understand have no realistic chance of becoming law. And they do not, until the legislative configuration changes. In the traditional SOP frameworks, this spastic re-passage of doomed legislation makes about as much sense as repeatedly slamming oneself in the face with a baseball bat: it is a sign of madness. Yet, Congress has spent significant time and resources on such bills in recent Congresses. In fact, it has become a signature activity of contemporary legislative politics.

To be clear, frenetic failed legislation typically occurs under divided government, where one chamber (typically the House) passes and re-passes a bill (sometimes with minor variations) favored by the majority party in that chamber but opposed by the other chamber and/or the president. The status quo clearly falls within the gridlock interval. That is, the bill lacks the votes to overcome a filibuster or veto or both. In contrast to the sequential veto bargaining model, which envisions repeated passage of a succession of modified bills in a serious effort at policymaking, there is no effort at compromise. Instead, these repeated efforts are characterized by their intransigent and clearly infeasible nature. Let us look at a few examples from recent periods of divided government to illustrate.

The most famous example of frenetic failed legislation is of course the Republican efforts to ‘repeal and replace’ the Affordable Care Act. Recall that this landmark legislation was enacted by the 111th Congress after a historic donnybrook and signed into law by President Barack Obama in March 2010. The mid-term elections that November then saw the electorate administer a brutal drubbing to the Democrats, racking up some of the largest losses since the Great Depression – a

‘shellacking’, in President Obama’s memorable phrase. Critically, the Republican gained control of the House of Representatives, while the Democrats retained the Senate until the 2014 election, when the Republicans established a narrow majority. The Democrats held onto the presidency until the 2016 election.

The classic SOP models clearly indicate that the Republicans had no realistic prospect of repealing the ACA in the 112th, 113th and 114th Congresses. In the first two Congresses, the Democratic-controlled Senate would simply ignore House legislation. In the third Congress, Democratic filibusters or presidential vetoes would surely kill Republican bills. These were the transparently obvious outcomes predicted by the models, and that is what transpired.

Accordingly, using the SOP models, one might expect Republican legislators to focus on other legislation that might actually have a chance of enactment. Or, they might concentrate their efforts on congressional oversight, constituency service, fund-raising and just plain electioneering. Nonetheless, *The Washington Post* documented a total of 54 total or partial repeals of the ACA in the first four years of Republican control.<sup>29</sup> While these bills were far from identical, attacking the existing law from a plethora of angles, they all had the exact same chance of becoming law: zero.

The ACA wasn’t the only Obama-era statute that Republicans repeatedly attempted to repeal during this period. They also made several efforts to undo the Dodd–Frank regulations on the financial industry. For example, in 2013 alone, House Republicans passed H.R. 1256, H.R.992, H.R.2374 and H.R.1105, all of which were intended to repeal aspects of Dodd–Frank.<sup>30</sup> None of these bills were considered by the Democratic Senate.

It should be noted that Republicans held no monopoly on frenetic failed legislation. Democrats found themselves in a similar political configuration during the 109th Congress, when they had a House majority during the waning years of the Bush

administration. And they engaged in similar legislative behavior. In particular, House Democrats repeatedly attempted to restrict activities in the Iraq war, such as through requiring troop withdrawals. As noted in *CQ Weekly*: ‘In July, for example, the House passed a bill (HR 2956) sponsored by Armed Services Chairman Ike Skelton, D-Mo., that would have required troop withdrawals. But like about a half dozen other measures, it went no further.’<sup>31</sup> Furthermore, the accounts make clear that House Democrats were fully aware of the futility of their efforts:

After Republicans blocked an effort last week to require a withdrawal of U.S. troops from Iraq, Senate Democrats put the issue aside and are not expected to return to it until after the August recess. House Democrats, however, plan to do their part to keep the subject alive this week, with war-related votes possible during committee consideration of the fiscal 2008 Defense spending bill and on the floor.<sup>32</sup>

If the multitudinous ACA repeals are a sign of legislative madness, the malady, unlike much in Washington today, is refreshingly bipartisan.

But perhaps there is a method in the madness, a method outside the ambit of the classical SOP models.

### ***What Is Going on? Blame Game versus Virtue Signaling***

Our admittedly cursory review of recent empirical evidence suggests that much legislating continues to follow the script of the classical, incomplete information bilateral bargaining models. For example, in Figure 13.1 most cloture votes do fall near the 60-vote benchmark. As the same time, there appears to be a serious undercurrent of something else going on. What is it?

An obvious candidate is blame game politics. As suggested by Senator Snowe’s comment, a phenomenon like forcing a futile cloture vote in the face of an invincible filibuster may be an attempt by the chamber’s

majority to highlight the perfidy of the opposition: ‘Look, everyone! We would have this wonderful legislation but for the intransigence of these terrible people!’ So: throw the bums out!

At the same time, much of the weirdness seems somewhat distinct from pure blame game politics. For example, it may make sense to try and fail to pass a symbolically resonant bill once, in order to demonstrate that the fault for failure lies with the opposition. But why pass the same bill 60 times? How much more education in the vileness of the opposition does the public need, once the opposition is revealed to be bad via the first failure? If, as Senate Majority Leader Mitch McConnell liked to suggest, ‘There’s no education in the second kick of a mule’,<sup>33</sup> how much is there in the 40th, 50th or 60th? Similarly, even in clear blame game politics such as the veto of the Family and Medical Leave Act, part of the signaling was not just that President Bush was blocking family leave. The message was also, ‘we Democrats are really in favor of this idea and can be trusted to deliver if handed the keys to the kingdom’. In other words, the message sent to the audience is not just ‘the other side is horrible, so kick them out’ but also ‘our side is wonderful, so support us’. Virtue signaling seems as much at play as blame game.

Consequently, let’s briefly explore the politics of virtue signaling.

### **TOWARD A MODEL OF MESSAGE LEGISLATION: VIRTUE SIGNALING AND ACCOUNTABILITY**

Let’s consider a model of message legislation, legislation not intended for enactment but instead constructed *solely to send a message to outside observers*. Many obvious questions arise: who are the senders? Who are the receivers? What is the message? What gives the message meaning? What gives it credibility? Why is strategic information

transmission of this form advantageous to the parties? Many answers to these questions are possible and lead to different models. But let's sketch one set of answers, if only to suggest how to embed veto bargaining-style models of SOP policymaking within an accountability model of the electorate. We'll focus on the dramatic, frenetic failed legislation of the 'repeal and replace' variety.

First, let's assume the senders are members of a party that controls one chamber of Congress but does not control all the major veto points in the legislative process. So, the president may belong to the opposite party. Or, the other chamber may be controlled by the other party. Or, 'our' chamber may be the House while the other party controls the very constraining filibuster pivot in the Senate. Let's assume the status quo lies firmly in the gridlock region, so no enactment improving matters from the sender's policy perspective is actually possible.

Let's assume the receiver of the message is the sender's selectorate – the high-information, highly engaged portion of the party whose money, time and enthusiasm is vital for re-election. With the support of these hyper-engaged kingmakers, re-election is almost assured (the district is a safe one). But without it, the sender may well be 'primaried' and out of office. This approach is particularly compatible with the UCLA approach to parties, where parties are formed out of a coalition of policy-motivated groups which 'insist on the nomination of candidates with a demonstrated commitment to its program',<sup>34</sup> but can also fit with others in which the political marketplace is less than perfect.

Two broad classes of messages are possible. The first (as discussed above) is the *blame game message*: I will show you that the other side is terrible [so you should support me]. The second is the *virtue-signaling message*: I will show you that I am trustworthy, your faithful agent, one of you [so you should support me]. Let's consider the second class of models, since Groseclose and

McCarty already constructed an example of the former.

Virtue signaling requires the receiver (the selectorate) to have incomplete information *about the sender*, the incumbent legislator. This is in contrast to the blame game approach, where the incomplete information must be about the opposition (e.g., the opposition president or party). So, here, the selectorate is somewhat uncertain about the virtue of the incumbent representative. To make matters concrete, suppose there are two types of representatives: slackers (low virtue) and zealots (high virtue).<sup>35</sup> Slackers have no policy convictions but just value holding office. Zealots also value office but in addition they value policy, and value it similarly to the selectorate. From the viewpoint of the policy-minded selectorate, it doesn't make much difference which type holds office when policy is gridlocked. After all, no change is possible. But if policymaking becomes possible and is costly of time and effort, then it may make a great deal of difference who holds office. For on that happy day, the slacker won't do much work, but the zealot will toil like a Trojan in order to achieve the policy goal. Clearly, from the viewpoint of the policy-oriented selectorate, it will be much better to be represented by a zealot rather than a slacker on that future day.

How then can an incumbent zealot prove he is a zealot and worthy of re-election? A non-starter is, issue a raft of campaign promises. Any promise a zealot could make, a slacker could make as well. So, our model will not feature Downsian-style prospective campaign promises. Rather, it will incorporate V. O. Key-style retrospective voting. The selectorate will act in light of what has gone before, eliminating incumbents likely to be slackers and retaining those likely to be zealots. The point is to increase the chances of having a zealot incumbent when policy windows open in the future.<sup>36</sup>

Let's focus on one type of action the incumbent can undertake: frenetic failed legislation. So, pass, re-pass and continue

re-passing virtually the same bill in the face of an unbeatable veto, an invincible filibuster or just plain disregard from the opposite chamber. The resulting sequence of play is:

- 1 Nature selects the incumbent legislator's type (slacker or zealot), which is private information for the incumbent.
- 2 The incumbent engages in a futile legislative interaction with, say, the president, fruitlessly passing and re-passing the same bill with multiple vetoes and re-vetoes. Enactments are costly of time and effort that could profitably be spent elsewhere.
- 3 When either the president accepts a bill or the incumbent desists with fruitless legislating, players receive period 1 payoffs.
- 4 The voter then retains or fires the incumbent. If the voter fires the incumbent, nature selects the type of the new representative. Nature also selects a new president so that policy windows open.
- 5 The representative (either new or retained) engages in a legislative interaction with the new president.
- 6 Based on the outcome of the legislative interaction, players receive second period pay-offs.

Comparison of this sequence with that of the simple TILI game indicates a much more complex game. It features two periods, not one; incomplete information (held by the voter about the incumbent's preferences), not complete information; voter beliefs about the incumbent's preferences; costly signaling by the incumbent in period 1; retrospective voting by the voter; and, finally, serious policymaking in the second period. Still, as a costly signaling game, it is not hard to analyze using modern techniques.

We assert without proof that the virtue signaling game has two generic equilibria. In the first, a pooling equilibrium, both a slacker legislator and a zealot legislator behave the same way in period 1: they do nothing. And, in this 'incumbency advantage' equilibrium, the voter re-elects the incumbent despite the dearth of effort. Then, in the second period, a zealot legislator engages in fruitful legislating while a slacker does nothing. This

equilibrium is quite attractive for the incumbent politician regardless of type; after all, he doesn't have to do much policy work in period 1 and yet gets re-elected. But it is not so good for the voter, because when the policy window opens in the second period he may find himself saddled with a slacker as representative, resulting in a missed legislative opportunity.

The second, and more interesting, equilibrium is a separating equilibrium.<sup>37</sup> Here, in period 1 incumbent slackers and zealots behave in very different ways. The zealot engages in frantic frenetic failed legislating, fruitlessly passing and re-passing the same bill over and over and over. The slacker does nothing because imitating the furious action of the zealot would be too costly of effort. The zealot's policy-mindedness creates a wedge between him and the slacker that allows this separation to occur – but only at high levels of effort, hence the need to do a lot of futile policymaking. The voter then fires a revealed slacker and retains a revealed zealot. In the second period, when policy windows open, a zealot works hard to legislate and a slacker doesn't. This equilibrium is much worse for the legislator: a period 1 slacker gets fired, and a period 1 zealot must slave away at phony legislating in order to retain his job. But this equilibrium is much better for the voter because it boosts the chance of having a valuable zealot in place when policy windows open.

We have only sketched an analysis of message legislation and virtue signaling. But we hope we have at least suggested that the idea is worth pursuing, and that the politics of virtue signaling is distinct from but complementary to the politics of the blame game. Carefully elaborating the theory of virtue signaling may enable some parsing of the difference between the two and lead empirical work in new directions, for example, the effect of message votes on fund raising, primary challenges and citizen voting – all new directions for SOP-style models. In addition, further theoretical development might well

tackle the question: why the rise in message legislation? The new media environment, partisan polarization of elites, the rise of groups such as the Tea Party on the right and ‘the opposition’ on the left, partisan sorting geographically and across the parties, and the increase in competition to control the government are probably all implicated. But how exactly? In a related way, in the context of the virtue signaling model one might ask, across different issues, when should we expect the pooling equilibrium to prevail, and when the separating equilibrium (the difficult question of equilibrium selection)?

### **DOES BARGAINING BEFORE AN AUDIENCE MAKE A DIFFERENCE?**

We have suggested ways to modify classical SOP models, such as the veto bargaining models, in order to better capture the new American legislative politics. The new politics on which we have focused results from blame game politics but also (we suggest) from politicians’ virtue signaling to an attentive audience of ideological extremists. But is modifying the classical models to incorporate message legislation really worth the effort? After all, the classic SOP models more or less get it right with respect to policy outcomes: when they say policy windows are shut, relatively little is enacted. When they identify the key veto players, they are generally correct. And when they suggest the political evaluation needed for enactment – that is, the spatial position of viable legislation in something like NOMINATE space – usually they are close to the mark. So, one may well ask, does all the noisy action attendant on message legislation actually make a substantive difference? Or does the sound and fury signify nothing?

Our sketch model of message legislation and virtue signal suggests that the politics of bargaining before an audience does make a difference for outcomes, though a

fairly subtle one. The separating equilibrium in our proto-model involves considerable information transmission between the sending congressperson and the constituent. The constituent learns something about the congressperson and – critically – then uses the information in choosing either to support or oppose the incumbent. The result is an ideological filter applied to incumbents, resulting over time in greater retention of representatives who are zealous in pursuit of the electorate’s ideological goals. The result is not quite the same thing as ideological polarization *per se*. But because the key constituents who follow and respond to the political theater tend to be high-information ideologically consistent extremists, the net effect is to build a more extreme legislature over time. In essence, there is an enhanced feedback loop between incumbent position-taking and constituent response, leading to a legislature responsive to relatively extreme blocks within the electorate. Or so the model suggests. An obvious question is: is this actually happening?

There is another element, outside our sketch model, but of potential importance and concern. In the pooling equilibrium, zealous incumbents who face gridlock don’t undertake any policymaking effort since it won’t accomplish anything substantively and they will get re-elected anyway. But in fact, case studies show zealous policy-minded congressmen doing a lot of policy work during down periods. In particular, congressional policy entrepreneurs hone their legislative proposals and lay the foundation for future legislative coalitions. For instance, Senator Bill Bradley spent years working on tax reform before policy windows opened creating the opportunity for a big policy innovation.<sup>38</sup> Similarly, famed policy entrepreneur Representative Henry Waxman labored long and hard, often for years, to build carefully crafted bills well aimed at specific health policy problems.<sup>39</sup> The result was (arguably) high-quality bills ready to go, when the gridlock region narrowed and legislative opportunity presented itself.

In contrast, in the separating equilibrium, zealous legislators work extremely hard during the gridlock period, acting out a laborious pantomime of legislating – ‘repeal and replace’, for instance. All that effort devoted to phony legislating must come from somewhere. One obvious candidate is real legislating of the Bradley–Waxman variety: low-profile, under-the-radar preliminary work without which high quality enactments are impossible, or at least far less likely.<sup>40</sup> From this perspective, one consequence of the era of message legislation may be a reduction in the quality of actual enactments. In addition, the dearth of high-quality ready-to-go bills may suppress legislative productivity when policy windows open, again as suggested by the failure of the ACA repeal. Obviously, this possibility is speculative. But is it true? Is the quality of enactments down, is there a dearth of high-quality draft bills, and does legislation fail despite open windows because no one did the preliminary work of crafting a high-quality bill? These are troubling but compelling questions.

Changes in American politics create opportunities and challenges for empiricists and theorists both: for the first, to document what has happened, for the latter to explain it. Then, there is a challenge at the interface of theory and data: does the new theory really afford an understanding of the new patterns? Or has it missed the mark? In this chapter, we have reviewed some of the big changes in American legislative politics and offered a proposal on how to craft new theory for the new politics. Whether that new theory will be forthcoming, and whether it will prove successful in explaining the new politics, remains to be seen.

# Models of Coalition Politics: Recent Developments and New Directions

Lanny W. Martin and Georg Vanberg

## INTRODUCTION

Coalition bargaining is at the heart of politics in most parliamentary democracies, particularly those operating under proportional representation electoral rules. Elections in such systems usually leave no single party in control of a majority of legislative seats. At the same time, governments must maintain the support of a parliamentary majority to survive votes of (no-)confidence and to pass legislation.<sup>1</sup> As a consequence, the formation of a government typically involves bargaining among multiple parties to produce a joint policy program and to distribute the various ‘spoils’ of office, such as cabinet ministries, among its members.<sup>2</sup> Given the prevalence of multiparty governments, it is not surprising that the study of coalition politics has been a central research program in political

science for several decades, which has led to the development of a rich tradition of formal, deductive models of coalition bargaining. Our aim in this chapter is to survey recent developments in the study of coalition politics, to provide a typology of approaches and to sketch potential avenues for further theoretical development.

To preview, we argue that recent developments can best be understood as the result of the arrival of the ‘new institutionalism’ in coalition politics. Early models of coalition formation and bargaining focused primarily on the size and ideological compatibility of political parties, but abstracted away from the institutional context within which coalitions operate (e.g., Riker, 1962; Axelrod, 1970; De Swaan, 1973). These theories were concerned with predicting the types of coalitions that would form, but did not speak directly to the more nuanced policy and distributional

aspects of coalition bargaining. Theoretical developments in the 1990s moved these latter questions to the fore, and in so doing greatly enriched theories of coalition politics by incorporating institutional features that structure the bargaining process.

Recent contributions to coalition theory can usefully be grouped into two overarching frameworks. One is a research tradition rooted in non-cooperative game theory. This tradition has tended to focus on the strategic bargaining process among potential coalition partners, and has relied on explicit assumptions about actor preferences and the bargaining protocols that structure their interaction. A second approach, which has been characterized by greater methodological heterogeneity, has shied away from making strong assumptions about bargaining protocols, focusing instead on the background constraints that limit the viability of coalition governments (such as, most obviously, the requirement to maintain majority legislative support as well as the support of all coalition members). As we discuss, and as one might expect, each approach has its advantages and limitations.

## THE NEW INSTITUTIONALISM IN COALITION POLITICS

Early coalition theories focused on characteristic features of potential coalitions that party elites might take into account as they bargain over government formation. One such feature is the *size* of a coalition: to maximize their share of distributional payoffs, party elites should not form coalitions that include members who are not necessary to reach the relevant ‘winning threshold’, that is, coalitions should be minimal winning (Gamson, 1961; Riker, 1962). Second, to the extent that coalitions must make policy, and as doing so is easier when parties are ideologically compatible, party elites should prefer coalitions that

are ideologically connected and compact (Axelrod, 1970; De Swaan, 1973). These considerations significantly narrow the set of coalitions that are attractive to party leaders, and generate powerful predictions of coalition formation outcomes. As Martin and Stevenson (2001) have shown, these predictions have considerable empirical support. But importantly, approaches focusing on the ideological compatibility of parties and the minimal winning status of a coalition have been largely silent on the content of the coalition bargain. What do coalitions agree to with respect to policy and the zero-sum perquisites that governance provides (such as cabinet portfolios)?

One of the major developments in coalition theory over the past 30 years has been the emergence of models that aim to provide a fuller picture of coalition politics by addressing both *which* kinds of coalitions are likely to form and *what* it is that coalition partners will agree to. There are, of course, multiple paths into this literature. For our purposes, a useful starting point is the game-theoretic approach proposed in a seminal paper by Baron and Ferejohn (1989), which focused on the way in which coalitions might allocate a fixed prize (such as cabinet ministries) among their members.<sup>3</sup> Their non-cooperative approach launched an influential modeling tradition in coalition politics that has been stated in its most general form by Snyder et al. (2005). The central logic of this tradition is to extend the famous Rubinstein bargaining model (Rubinstein, 1982) to a setting in which acceptance of a proposal requires the agreement of a winning coalition (instead of a single player). The essential features of the Baron–Ferejohn (hereafter, BF) approach consist of the following:

- a set of legislative parties, none of which controls a decisive number of seats;
- a legislative process that requires approval by a coalition of decisive size (typically, a majority) to accept a proposal;
- a fixed amount of a good that a proposal must divide among the parties;

- a random recognition rule that selects one party – the formateur – to make a proposal for a division of the good, which is then subjected to a legislative vote;
- if the proposal is approved, the implementation of the proposed division, and if it is not approved, a new random selection of a formateur.

While the BF model is a general model of legislative decision-making, BF explicitly suggested that their approach can be understood as a model of coalition formation in parliamentary systems, as well as the allocation of ministerial portfolios among coalition members. Their model (and extensions of it) have since occupied a central place in coalition theory. The key implication of the BF approach is that in equilibrium, the formateur (the party selected to form a government) will construct a minimal winning coalition by making an offer that attracts the agreement of the ‘cheapest’ set of partners available and allocates the lion’s share of the good to itself. A simple example can illustrate the intuition behind this result. Suppose there are three parties, with each party controlling  $\frac{1}{3}$  of the seats in the legislature. Further assume that parties are chosen as formateur with a probability that equals their seat share. Finally, assume that if a proposal fails, and bargaining moves to a new round (where, once again, each party is chosen as formateur with probability  $\frac{1}{3}$ ), parties discount their payoff by  $\delta \in (0, 1)$ . Suppose party A has been selected as formateur. Party A knows that if its proposal is rejected, all parties (being perfectly symmetrical) have the same *ex ante* expectation about their future payoff. Denote this continuation value (which each party expects to receive in the next period) by  $c$ . To secure a majority for its proposal, party A must thus offer one other party  $\delta c$  to secure its vote, keeping the remainder of  $1 - \delta c$  for itself. Given the symmetry of the parties, this implies a payoff of  $1 - \frac{\delta}{3}$  for the formateur and a payoff of  $\frac{\delta}{3}$  for its chosen partner. The (left-out) opposition party receives no payoff.<sup>4</sup>

Like earlier models, the BF approach yields the prediction that coalitions will be minimal winning. But the seminal contribution lies in characterizing the *distribution* of spoils among the coalition partners – with the key expectation that formateur parties are able to exploit their privileged position to secure a particularly favorable outcome at the expense of their partners. Applied to the formation of coalition governments in parliamentary systems, the expectation of this ‘formateur advantage’ has given rise to an extensive empirical literature that has examined the degree to which formateur parties are able to secure additional payoffs unavailable to ordinary coalition members.

Much of this literature has focused on one of the most salient and easily observable ‘zero-sum’ payoffs: the numerical allocation of cabinet ministries among coalition partners. The overarching conclusion that has emerged is that there is no formateur bonus in payoffs (see, e.g., Warwick and Druckman, 2006). Rather, these studies suggest that portfolios are distributed in a matter that is largely proportional to the seat contribution of parties to the coalition (with a small bonus for small parties) – a regularity frequently referred to as ‘Gamson’s Law’ that had already been established in much earlier work (Gamson, 1961; Browne and Franklin, 1973). Put differently, it appears empirically that formateur parties are not able to ‘extract’ portfolios beyond the number they would be expected to receive purely on the basis of their size – a finding that stands in obvious tension with the theoretically influential BF paradigm.

### **Critiques of BF**

This disjuncture between the empirical regularity of Gamson’s Law and the theoretical prediction of BF-style models has been the lynchpin of critical assessments of this modeling approach for understanding multiparty governments in parliamentary systems. The formateur advantage that is central to the BF

model (and to models that extend this approach, such as that of Snyder et al. (2005)) is rooted in two ‘institutional’ assumptions: (1) there is a strict order in which proposals can be made; and (2), once made, the proposal is subjected to an ‘up-or-down’ vote.<sup>5</sup> This is critical, because it implies that only one offer is on the table at any one time and that rejection of this offer is costly, since it implies delay and reversion to a new round of bargaining in which any individual party is uncertain about its position. The formateur can exploit this fact to make an offer that is minimally acceptable to its prospective partners, and thereby secure a favorable payoff for itself. Put differently, it is the rigid bargaining protocol which restricts who can make proposals, and how those proposals must be dealt with, that generates the privileged position of the formateur.

It is precisely this feature of the BF framework that has recently come under theoretical and empirical attack in a series of significant papers by Laver et al. (2011) and Cutler et al. (2016). While proponents of the BF approach argue that its bargaining protocol ‘is consistent with the empirical pattern found in the formation of coalition governments’ (Snyder et al., 2005: 982), these critics charge that applications of the BF bargaining model to coalition politics are problematic because the bargaining protocol – which drives the central results of the model – does not accurately characterize the context within which real-world coalition negotiations take place.<sup>6</sup> As Laver et al. (2011: 300) point out, coalition negotiations are not subject to a rigid, enforceable protocol that approximates the BF model:

*Lack of structure* is of the essence because negotiations over government formation involve the most experienced and sophisticated politicians playing for the highest possible stakes. Rather than assuming such people adhere to an unenforceable norm under which they make public offers in an exogenously choreographed sequence and engage in no backroom discussion, it is far more reasonable to assume that *nothing* can

prevent *any* politician from proposing *any* deal at *any* time during government formation.

Put differently, the BF approach illuminates the dynamics of a highly structured bargaining situation. But for that very reason, it is theoretically inappropriate for understanding coalition politics in parliamentary systems.<sup>7</sup> Even if a specific party is identified as a formateur *de jure*, bargaining in these contexts is fluid and open *de facto*: all party leaders are free to negotiate with anyone, to bargain with multiple parties in parallel, and all participants can float potential offers at any time – if need be, in smoke-filled backrooms. As a result, conclusions that rest on a rigid bargaining protocol do not travel well to these contexts.<sup>8</sup>

The conclusion that Laver et al. (2011: 296) draw is that models of coalition politics must rest ‘on premises that can plausibly be argued, on substantive grounds, to have empirical relevance’. Put differently, to the extent that particular modeling assumptions are critical to substantive conclusions that emerge from a model, these assumptions should accurately reflect the context within which party elites bargain. In their view, this can be accomplished within two distinct (though overlapping) paradigms.

One approach is that of non-cooperative game theory, which rests on explicit assumptions about player preferences, the strategies available to them and the structure and timing of their interaction. For Laver et al. (2011: 301), the key to progress within this paradigm is to ensure that ‘the local institutional detail that structures such models ... come[s] from genuinely binding institutional constraints in the substantive environment modeled, not from “institutions” that are, when all is said and done, just tools in the modeler’s box’.

A second avenue is to move away from models rooted in non-cooperative game theory and the necessity of fully characterizing the bargaining protocol. Such approaches can focus on overarching constraints on

the government formation process and constraints on the characteristics of coalition outcomes, while making no particular assumptions about the underlying bargaining process. Laver et al. (2011) find this approach particularly promising for two reasons. One is that such an approach seems to capture the notion that elite politicians, bargaining over the ultimate prize in politics, are unlikely to be constrained by fixed formal rules that govern the bargaining process. The second is that even if such rules exist, they would vary tremendously over time and place, making a focus on overarching constraints that are common across many bargaining environments more useful. We now turn to illustrative examples of each type of approach.

## ENRICHING NON-COOPERATIVE MODELS

As just highlighted, a central critique of the BF approach as a model of coalition formation in parliamentary systems is that its central result – the formateur bonus – derives from a bargaining structure that appears in tension with the process by which real-world coalitions form. Moreover, the theoretical prediction of the formateur bonus stands in clear tension to the empirical reality of Gamson's Law. A major focus of coalition theorists working within the tradition of non-cooperative game theory has therefore been to consider alternative bargaining models that can resolve this discrepancy between theory and empirics, and offer more substantively grounded accounts of coalition bargaining. Doing so has typically involved moving away from the alternating offer framework of BF. We briefly highlight several such approaches.

The seminal – and relatively early – contribution to these efforts was the 'demand competition' model of Morelli (1999). The Morelli model introduces two important variations to BF-style bargaining. The first

is that parties bargain not only over a divisible good (such as portfolios), but also over a common coalition policy position. The second is that bargaining does not proceed through a series of sequential take-it-or-leave-it offers, but rather a series of (sequential) *demands*: the head of state chooses a formateur, who in turn determines the order in which parties will make demands. When it is a party's turn, the party proposes a coalition policy, and makes a demand for a share of the private good. If, at some point, a winning coalition emerges because its members agree on policy, make compatible demands and have the backing of a legislative majority, the coalition takes office. If no coalition emerges, a new formateur is chosen and the game begins again (with a caretaker government taking office and leaving parties with no share of the divisible good after a set number of failed negotiations).

Critically, in the Morelli model *any* (winning) collection of parties that makes compatible demands can take office – *even if this coalition leaves out the initial formateur* (or other parties whose demands have been made). This bargaining protocol induces an implicit competition among the parties because any party's demand can be ignored – there is no power to make take-it-or-leave-it demands. (This feature also ensures that the order in which demands are made does not matter.) The result is that the formateur advantage is eliminated. Instead, 'the ex post equilibrium distribution of payoffs is proportional to the ex ante distribution of bargaining power (within the majority coalition)' (Morelli, 1999: 817).

To see the intuition, return to a three-party example. For simplicity, suppose that failure to agree on a coalition leads to the formation of a caretaker government after one round, and that parties only care about the divisible good.<sup>9</sup> Note that the bargaining power of the parties is equal: each party can form a majority coalition with any other party. What demand should the first party make? Suppose it demands a share  $p_1 < \frac{1}{2}$ . The second

party now faces a choice. It could accept  $1 - p_1$  and form a coalition with the first party. Or it could issue a demand for  $p_2 = p_1 - \varepsilon$ . Should it do so, Party 3 has three options. It could form a coalition with Party 1, form a coalition with Party 2 or let negotiations fail (leading to a caretaker government). Since  $1 - (p_1 - \varepsilon) > 1 - p_1 > 0$ , Party 3 chooses a coalition with Party 2. In words, Party 1's initial demand has backfired, because the other parties are able to ignore it. Demanding more than half of the divisible good leaves Party 1 empty-handed. What about demanding  $p_1 < \frac{1}{2}$ ? Party 2 would immediately accept such an offer, and form a coalition with Party 1. (To see this, note that demanding a larger share than  $1 - p_1$  would lead Party 3 to accept Party 1's offer, leaving Party 2 out of the coalition.) But Party 1 could have gotten a better deal by increasing its demand slightly. Thus, the equilibrium demand by Party 1 – which will be accepted immediately by Party 2 – is for half the divisible good. The implicit competition between the parties leads to an even division between the members of the coalition, given that all are (essentially) in the same bargaining position: each party can form a majority coalition with any other party. More generally, competition between potential coalition partners limits the ability of any party to extract 'extra' concessions – and because the degree of competition a party faces depends on its bargaining power (loosely speaking, the proportion of winning coalitions of which it is a part), the equilibrium distribution of payoffs is proportional to parties' bargaining strength.

The significance of the Morelli contribution does not lie only in proposing a model of coalition bargaining that reconciles the tension between theory and empirics by predicting a payoff distribution that approximates Gamson's Law (as long as seat distributions and bargaining power are reasonably highly correlated). The more important contribution is methodological. Staying within the paradigm of non-cooperative game theory – which requires a clear articulation of the

game form, including players' strategies and the timing of actions – the model captures our intuitions about 'real-world' coalition bargaining in the sense that the competitive logic of the model provides a close analogy to a free-form bargaining process in which any party is able to float a potential coalition deal, parties are able to ignore some potential partners and any group of parties can 'get together' to form a government. In other words, while there is, as in the BF approach, a strict order of play in the Morelli model, this order does not affect the central equilibrium result.<sup>10</sup> Instead, the equilibrium outcome is driven by what is, intuitively, the critical aspect of real-world bargaining: the extent to which a party is in a powerful position (because it is central to many winning coalitions) or in a weak spot (because it can easily be ignored by other parties in forming a winning coalition). In this sense, the Morelli model represents precisely the kind of non-cooperative approach that Laver et al. (2011) suggest.

Of course, Morelli's (1999) is not the only non-cooperative approach that provides an alternative to the BF tradition. While a full review of all these models is beyond the scope of this chapter, we briefly highlight two additional contributions here. Bassi (2013) proposes a model in which parties bargain over a divisible good in a process in which parties auction off the right to act as formateur. As in the Morelli model, in equilibrium, no formateur bonus emerges: the competition among parties for the role of formateur ensures that potential rents to securing this position are dissipated in equilibrium.<sup>11</sup> Second, building on Austen-Smith and Banks (1988), Baron and Diermeier (2001) offer a model that integrates voter decisions in an election with a subsequent government formation process among parties that care about policy and office-holding. A formateur selects a proto-coalition, which bargains efficiently over policy (using office benefits as side payments). Because bargaining over policy is assumed to be efficient, government policy

does not depend on the (BF-style) bargaining protocol in the model. But the distribution of office benefits and the identity of the proto-coalition does, exposing the model to the critiques identified above.<sup>12</sup>

## BEYOND NON-COOPERATIVE GAME THEORY

The models we have just reviewed illustrate approaches that expand on the BF approach within the paradigm of non-cooperative game theory. The Morelli (1999) model in particular captures the competitive nature of the open-ended and essentially unconstrained process in which potential coalition partners bargain, thus addressing the limitations of the rigid alternating offer protocol of BF. Nevertheless, it still employs its own rigid bargaining protocol. As we argued above, a second approach in coalition theory has been to move away from explicit assumptions about the structure of bargaining, and instead toward frameworks that focus on assumptions about background constraints on coalition bargaining. We review two examples of such approaches, beginning with the seminal ‘ministerial autonomy’ model proposed by Laver and Shepsle (1996).

### *Laver and Shepsle’s Ministerial Autonomy Model*

This model, which also occupies a central place in coalition theory, applies the logic of the structure-induced equilibrium approach developed by Shepsle (1979) in the context of US congressional committees to coalition governments in parliamentary systems. It rests on three key assumptions:

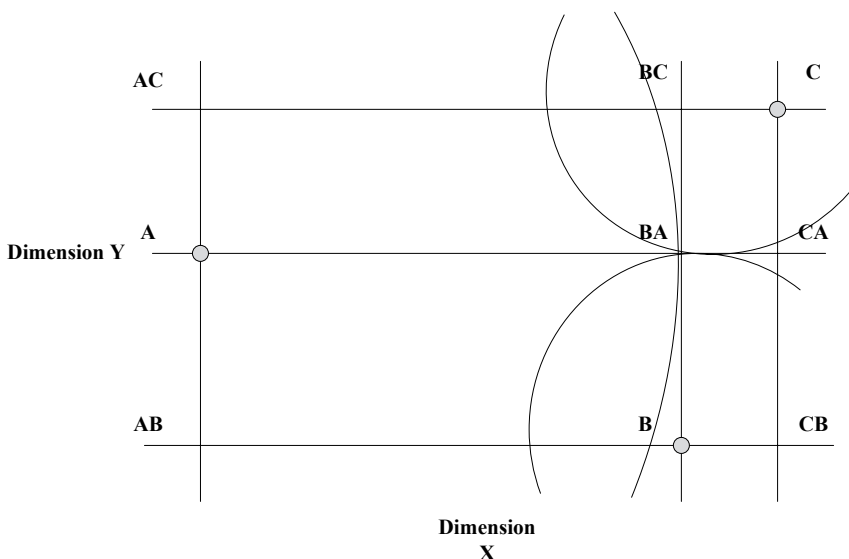

- coalition politics involves government parties agreeing on a government policy package in a multi-dimensional policy space;

- each ministry in a coalition government has jurisdiction over a single issue dimension;
- within each issue dimension, the party that controls the relevant portfolio enjoys autonomy to determine policy.

The consequence of these assumptions is to transform a collective choice problem with no (preference) equilibrium under majority rule (McKelvey, 1976) into one with well-defined properties. The combination of radically reducing the relevant policy space by associating each dimension with one ministry and assuming that each ministry has autonomy within its sphere serves to ensure that any allocation of portfolios among a specific set of parties implies a particular policy outcome. Specifically, in each jurisdiction, the ministerial party implements its preferred policy, and the collection of these policies across all jurisdictions constitutes the coalition’s policy program.

Put more provocatively, the Laver–Shepsle (hereafter, LS) model essentially assumes away the possibility of meaningful bargaining among coalition partners, and assumes instead that – given the central role of cabinet ministers in drafting and implementing policy within their jurisdiction – each party acts as dictator within its portfolios, implements its preferred policy and expects all other parties to do so. Consider the example in Figure 14.1, taken from Diermeier (2006), consisting of three parties in a two-dimensional policy space, that is, a policy space with two ‘ministries’. Assume that no party controls a majority of seats (implying that any pair of parties does). The ideal points of each party are given by the points *A*, *B* and *C*. In this scenario, a government consists either of a single-party government, which receives both portfolios, or a two-party coalition in which each party receives one portfolio.

Given the assumptions above and the assumption that party preferences are given by Euclidean distance, the two-dimensional policy space is reduced to the ‘lattice points’ implied by any particular allocation of

**Figure 14.1** Laver–Shepsle ministerial autonomy model

portfolios. For example, a coalition of parties *A* and *B*, in which party *A* controls the portfolio for dimension *Y* and party *B* controls the portfolio for dimension *X*, implies policy outcome *BA*. If the parties reverse the assignment of portfolios, the resulting coalition policy becomes *AB*. The nine possible government policy positions are indicated by the lattice points in the figure, and labeled according to the allocation of portfolios associated with each.

Which of these potential governments (characterized by a specific distribution of portfolios) is likely to emerge? To answer this question, a fully game-theoretic approach would require detailed specification of the bargaining process by which a government forms (and that specification would have to incorporate the LS background assumptions about policymaking). The structure-induced equilibrium approach takes a different tack. Rather than ask *how* potential coalition partners bargain toward the formation of a coalition, the question that Laver and Shepsle ask is which governments are viable or stable, in the sense that they cannot be replaced

by another feasible government. Given the constraints on formation of a government in parliamentary systems, this requires two conditions: there cannot be an alternative feasible government that is preferred to the current government by a *majority* of the legislature, and by *all* the members of the alternative government.

In Figure 14.1 (taken from Diermeier, 2006:167), the feasible alternative governments are indicated by the lattice points. Consider the government in which party *A* controls the portfolio for dimension *Y* and party *B* controls the portfolio for dimension *X* (with resulting policy *BA*). This government constitutes a structure-induced equilibrium in the sense that no feasible government (that is, none of the lattice points) lies within the win-set of *BA*; that is, no alternative feasible government is preferred by a majority to the existing coalition. In contrast, consider a coalition in which party *C* controls the *X*-ministry and party *A* controls the *Y*-ministry, with resulting coalition policy *CA*. This coalition is *not* viable: Parties *A* and *B* both prefer the government associated with policy outcome

BA, and could vote to replace the existing government.

The LS approach offers a number of important contributions. On the conceptual level, the model explicitly integrates a theory of coalition policymaking into a theory of coalition formation. A critical component of what makes a coalition viable or vulnerable in this approach is the expectation about the policy position the coalition will adopt, compared to those policy outcomes that would be produced by other feasible governments. While the logic that policy expectations feed into coalition formation is implicit in much of coalition theory, the LS approach was one of the first to explicitly connect these two features.<sup>13</sup>

A second contribution is related to the Laver et al. (2011) critique of the BF framework. The ministerial autonomy model does not focus on the bargaining process among potential coalition partners, and for this reason requires no assumptions about a rigid bargaining protocol. Rather, it rests on a twin foundation:

- 1 a bedrock constraint that any government in a parliamentary system must respect, namely, that there cannot be an alternative government that is preferred to the incumbent by all of its members and a parliamentary majority, and;
- 2 an assumption about the coalition policymaking process, namely, that ministerial parties are able to set policy within their jurisdictions autonomously.

Given this foundation, the model generates predictions about which coalitions are viable, the portfolio distribution associated with such governments and the resulting policy outcomes.

While the LS model constitutes a seminal and highly influential contribution, the approach is subject to at least three limitations. One is that viable cabinets (i.e., cabinets that constitute structure-induced equilibria) do not exist in all circumstances. Unlike models that rely on Nash equilibrium solution concepts (which always exist), the LS model will

thus not yield a solution in all circumstances (Austen-Smith and Banks, 1990). Perhaps more seriously, the LS approach is designed to identify a set of viable governments (i.e., governments that are stable in the sense that no alternative feasible government is preferred to it by a legislative majority, and by all its members). But the approach is silent on the choice *among* viable governments if more than one exists. In other words, Laver and Shepsle offer no theory of government selection in the face of multiple feasible alternatives. How to think about this limitation is not clear. On the one hand, theories (including game-theoretic approaches) that incorporate particular bargaining protocols do yield implications regarding government selection. On the other hand, if such selection is (as in the BF framework) driven by bargaining protocols that do not have a strong substantive grounding, an agnostic approach (such as the LS framework) may be preferable.

The final limitation, in our view, is the most serious. The core logic of the ministerial autonomy model is to identify viable governments by reducing the set of feasible alternatives. The key to doing so is to assume that ministers act as policy dictators within their jurisdiction. It is this assumption that implies a one-to-one mapping between a portfolio allocation and the (multi-dimensional) policy position adopted by a coalition government. Put in the context of the Laver et al. (2011) critique, the problem is not so much that Laver and Shepsle impose a rigid bargaining protocol. Rather, it is that they *replace* the bargaining process with strong and rigid assumptions about policy-making. Because the only incentive-compatible policy choices are for ministers to pursue their (unique) ideal policy within their jurisdiction, there are no opportunities for meaningful bargaining among parties. Policy positions that do not correspond to the lattice points associated with ministerial autonomy cannot be achieved. Just as the key results of the BF model are driven by its (rigid and, in the context of coalition formation, implausible)

bargaining protocol, so the key results of the LS model are driven by the strong assumption of ministerial autonomy.

As a result, the empirical relevance of this assumption becomes central: do ministers – and by extension, coalition parties – enjoy considerable discretion within the policy areas under their jurisdiction? Over the past decade, a number of scholars have argued that the answer depends on the institutional framework within which coalition governments make policy. For example, the presence of junior ministers who can ‘keep tabs’ on their coalition partners may allow parties to rein in the discretion of cabinet ministers (Thies, 2001). Similarly, legislative institutions (such as strong committee systems) that allow for effective scrutiny and amendment of ministerial proposals can effectively limit the ability of ministers to act as policy dictators (Martin and Vanberg, 2005, 2011). There is strong evidence that such institutions limit the discretion of ministerial parties, and allow for genuine compromise agreements (Martin and Vanberg, 2014a). With respect to legislative institutions, in particular, recent empirical work has shown that in environments where committee systems and legislative procedures allow for effective scrutiny of government ministers, real-world policy outcomes tend to reflect the preferences of the coalition *as a whole*; in contrast, where committee systems do not permit such scrutiny, policy tends to reflect the preferences of the party controlling the relevant ministry (Martin and Vanberg, 2019a). These findings suggest scope conditions on the LS approach. If parties are able to limit ministerial discretion, and to pursue genuine compromise policies, the radical reduction of the policy space that is required for the emergence of structure-induced equilibrium governments no longer holds. Thus, the LS approach is most applicable in contexts in which ministers enjoy considerable unilateral power, but is less informative in contexts in which coalition parties can reach – and enforce – compromise agreements.

### ***The Zero-intelligence Model of Government Formation***

The LS framework combines a specific policymaking assumption (ministerial discretion) with the premise that cabinet stability requires that a government cannot be beaten by a feasible alternative that is preferred by a majority and all of its members to identify a set of viable governments. A second approach is even more radical in pursuing Laver et al.’s (2011) call to move away from the rigid bargaining protocols of non-cooperative game theory. The ‘zero-intelligence’ model of government formation developed by Golder et al. (2012) aims to investigate how the outcomes of coalition bargaining are structured by two foundational constraints on government formation in parliamentary systems. These constraints are that (1) there is always a status quo government, and (2) to replace a status quo government, a prospective new government must be preferred to the status quo by a legislative majority and all of its members. As we just saw, this requirement also plays a prominent role in the LS approach. But unlike LS, who add a particular assumption about the policy process, Golder, Golder and Siegel (hereafter, GGS) aim to impose no additional features beyond the requirement that a government not be vulnerable to being replaced by an alternative. The outcomes of the coalition formation process that GGS seek to explain are the types of governments that form (minority, minimal winning and supermajority), the allocation of portfolios across coalition partners and delays in government formation.

To explore how the two foundational constraints shape these outcomes, GGS investigate a model in which parties compete in a two-dimensional policy space. Governments are characterized by a policy position, and a distribution of portfolios among the coalition partners. Parties care about the share of portfolios they receive and the divergence between government policy and their own position. The model proceeds as follows.

At the outset, parties are assigned policy positions in the policy space at random, and non-strategic voters vote for the party that is located closest to their ideal point. This step results in a ‘party system’ that is characterized by parties with a particular ideological position, and a vote/seat weight that is determined by their share of the vote. At this stage, the government formation process begins in the following way:

- 1 from among all coalitions that include itself, each party randomly proposes a government, along with a randomly assigned policy position and portfolio allocation for that government;
- 2 given the collection of all proposed governments, each party compares its utility from each proposed government to the utility it derives from the incumbent government;
- 3 proposed governments that are preferred to the incumbent by (a) all of their members and (b) a set of parties that jointly control a majority of seats are deemed ‘viable’, resulting in a set of governments that are capable of replacing the incumbent;
- 4 one of the viable governments is chosen at random to replace the incumbent;
- 5 if no government is viable, then the full process repeats, and if no government has formed after 100 iterations, the incumbent remains in office.

Note that this modeling set-up imposes a background constraint on government viability, in stages (2) and (3), but does not impose a rigid bargaining protocol. To investigate the implications of this model, GGS employ a Monte Carlo approach to simulate thousands of party systems and government formation attempts, recording information on the types of governments that emerge, the distribution of portfolios and delay in government formation.

Significantly, the aggregate distributions of these outcomes bear reasonable resemblance to empirically observed distributions. That is, the model predicts the formation of minority, minimal winning and supermajority governments, ‘approaching the real-world distribution of government types’ (Golder et al., 2012: 436). It also generates a close

approximation of Gamson’s Law for portfolio allocation, as well as delays in formation.

The only systematic assumption that the model imposes is that replacement governments must be preferred to the incumbent by a majority and all of their members; all other features of the model (including the selection of governments) are *random*. As a result, GGS conclude that central dynamics of government formation are driven by the underlying constraints that are imposed on the viability of governments in parliamentary systems, rather than being a product of forward-looking, strategic behavior by political elites. As they put it (Golder et al., 2012: 443):

Overall, the results from our model indicate that the two constitutional constraints that bind in any parliamentary government formation process are sufficient to approximate many of our most robust empirical regularities, independent of the strategic behavior of party leaders and their bargaining protocols. This suggests that structure, not behavior, may be the most important thing when it comes to explaining government formation outcomes.

The zero-intelligence model is a powerful illustration of an approach that focuses on underlying constraints, while making no assumptions about a particular bargaining protocol. And yet, it is precisely this feature that is also a weakness of the zero-intelligence model. In focusing on background constraints that viable governments must conform to, the GGS model (like the LS approach) identifies a *set* of viable governments. In the face of multiple viable candidates, the key question for a theory of government formation is *which* among the many alternatives will emerge. Put differently, what is required is a theory of government selection. As we saw, LS do not address this issue. In contrast, the GGS model does include a specific theory of government selection: namely, the government is chosen at random.

As Martin and Vanberg (2014b: 875) point out, this is equivalent to a radical behavioral

assumption about party elites, namely, that *they have no preferences among alternative viable governments*. Rather than comparing potential governments to each other in order to choose the most attractive option (and to bargain if there is disagreement), elites are content to compare potential governments to the incumbent, and then to choose at random. Given that government formation is a game in which highly skilled politicians compete for the ultimate prize in their professional careers, the implausibility of this behavioral assumption is clear: party elites obviously have preferences among potential coalitions.

Critically, the ‘random choice’ assumption is not innocuous: the results of the GGS model (in particular, the fact that the model produces aggregate distributions that resemble real-world outcomes) are largely driven by the assumption of random selection. To understand why, note that if party elites have preferences over potential governments, these preferences discriminate systematically against certain types of governments. For example, a preference for maximizing distributional benefits (such as office) will steer elites away from minority or oversized coalitions. The impact of this assumption can be seen most clearly by shifting attention from the *aggregate* distribution of government characteristics to the (much more relevant) predictive power of the model in specific formation opportunities. As Martin and Vanberg demonstrate, while the zero-intelligence model can generate empirically plausible aggregate distributions of coalition characteristics, its record in predicting which particular coalition will emerge in a given formation opportunity is very poor, and it is simply no match for models that take account of elite preferences among potential governments.

### ***Beyond Zero-intelligence***

As we have just argued, the problem posed by the selection of a particular government from a set of plausible alternatives is a

challenge for models that seek to move beyond the restrictive bargaining protocols of non-cooperative game theory. In this context, a recent paper by de Marchi and Laver (2019) offers an innovative approach. Like GGS, de Marchi and Laver depart from the non-cooperative game-theoretic paradigm by imposing no rigid bargaining protocol. They also employ behavioral assumptions that depart from fully rational, strategic behavior. The core of their model is to treat coalition formation as a problem in which parties must agree on a joint policy program that is based on the often extensive election manifestos and pledges on which parties have campaigned. Given the large number of issues involved, this represents a complex bargaining problem in a high-dimensional space.

De Marchi and Laver assume that parties treat each issue as a binary choice between favoring and opposing a particular change to the status quo, and that parties attach different salience to issues. The key assumption of the model is that, given this set-up, parties treat the problem of agreeing on a coalition policy platform as a logroll. The fact that the intensity of preferences varies across issues opens up the possibility that parties can trade concessions on issues they care less about for concessions on issues that are salient to them. Naturally, in a high-dimensional issue space, such logrolling behavior can be extremely complex. Thus, de Marchi and Laver impose a behavioral assumption: parties look for ‘simple’ logrolls on issues that can be traded directly, but forego more complicated exchanges. Issues on which the parties disagree but that cannot be resolved with a simple binary logroll are ‘tabled’ and left unresolved.

A particularly novel feature of the approach – and the one we want to highlight here – is how de Marchi and Laver confront the issue of government selection. Consistent with their critique of BF-style models, they reject the notion of a rigid bargaining protocol. Of course, as we saw in our discussion of LS and GGS, this leaves the critical question of

government selection. It is here that de Marchi and Laver introduce an important innovation. Because coalition bargaining takes place in an unconstrained ‘open outcry’ environment, they focus on the following logic: while the bargaining environment is unconstrained in its *procedures*, any government that emerges must have majority support. In this context, cabinets that are Condorcet winners (i.e., are majority-preferred to any alternative government) are privileged since they are not vulnerable to other proposals. Moreover, when a Condorcet winner exists, the government formation process is – intuitively – less complex and less vulnerable to continuous bargaining. A key question for de Marchi and Laver is thus the likelihood that, in any particular bargaining environment, a Condorcet winner exists.

To identify the conditions under which that is likely to be the case, for any given formation opportunity, de Marchi and Laver examine the policy vector associated with each possible coalition after all simple logrolls have been executed and remaining issues have been tabled. This generates the set of all potential cabinets and their associated policy platforms. Given these, it is possible to ask whether there exists a cabinet that constitutes a Condorcet winner. Significantly, de Marchi and Laver demonstrate computationally that in the logrolling framework, and given the behavioral assumptions of limited rationality, Condorcet winners are more frequent than one might naively assume. They also show that their likelihood depends predictably on model parameters. In particular, in legislatures defined by Laver and Benoit (2015) as ‘top-three’ systems (where any two of the three largest parties can form a majority coalition), a Condorcet winner is especially likely to exist.

The significance of this innovation is that it offers a middle way between the precision of game-theoretic models that is often achieved through bargaining protocols that are difficult to defend on substantive grounds, and the agnosticism of models that

feature no assumptions about the bargaining process. The de Marchi and Laver approach respects the open-outcry nature of the bargaining process while offering a systematic way to narrow down the problem of government selection that is anchored in the fact that governments must enjoy majority support.

## CONCLUSION: MOVING COALITION THEORY FORWARD

In most parliamentary systems, most of the time, no single party controls a majority of legislative seats. As a consequence, coalition governance is central, and scholars have showered considerable attention on understanding how these governments form, govern and dissolve. In this chapter, we have provided a short overview of a particular subset of this literature: formal models of coalition formation. These models are concerned with two central questions:

- 1 Which parties are likely to ‘join forces’ in a government?
- 2 How do the parties that participate in a coalition distribute the spoils of office among themselves, and what kind of policy programs do they agree on?

Early coalition scholarship concentrated primarily on the first question. But with the arrival of the ‘new institutionalism’, which explicitly incorporated the institutional context within which coalitions govern, scholars have increasingly focused on the second.

One useful way to characterize the types of models that have played a central role in these developments is to distinguish between game-theoretic approaches and those approaches that forego the rigid assumptions of a particular game form. The primary advantage of the former is that in specifying a particular bargaining protocol and focusing on equilibrium outcomes, these approaches yield specific characterizations

of government selection and the distribution of payoffs among coalition partners. The primary weakness of the approach is closely related: the particular equilibrium properties are often driven by the specific bargaining protocol assumed. In the context of real-world coalition politics, which is essentially an unconstrained ‘open-outcry’ environment, this is potentially troubling since the properties of equilibrium cabinets that depend on a bargaining protocol may not carry over to this environment.

One solution to the ‘protocol dependence’ of game-theoretic models is to move toward models that do not impose a particular bargaining structure. This is the aim of the second class of models we have considered. These models typically incorporate some ‘background constraints’ (such as the need to receive majority support), but they resist more specific assumptions regarding how parties bargain over coalitions. The strength of these models is that their results appear not to depend on strong assumptions about the bargaining process. But these approaches also face two limitations. The first is that – depending on the model – the absence of a rigid bargaining protocol may be more apparent than real. Thus, as we saw in the case of the Laver and Shepsle (1996) model and the Golder et al. (2012) zero-intelligence model, equally strong assumptions regarding the policy process (ministerial autonomy) or elite behavior (random choice among viable cabinets) drive the results. The second limitation is that these models typically provide no clear answer to the question of government selection. While non-cooperative models yield specific predictions regarding which coalition will emerge, the second class of models usually identifies a *set* of viable coalitions, but has less to say about *which* of these governments will be chosen.

This tension points to an important area for future theoretical development. Making progress on understanding government selection while not falling victim to the desire to ‘solve’ this problem through the imposition of

bargaining protocols that have little substantive grounding represents one of the key challenges. The de Marchi and Laver approach of focusing on the presence of a Condorcet winner, and investigating the conditions that make this more likely, represents an important recent development in this regard. But there is clearly room for additional work.

A second important area for future development is to enrich the nature of the ‘goods’ that parties bargain over. For reasons of analytic tractability, current models typically focus on the distribution of a divisible good (a ‘divide the dollar’ game) and/or the selection of a (multi-dimensional) policy position in a spatial model as the two relevant aspects of the coalition bargain. While the insights that emerge from such models are valuable in understanding key aspects of coalition bargaining (such as the importance of bargaining weights, as revealed in the Morelli (1999) model), they also leave unexplored significant aspects of coalition bargaining that become salient when one considers the heterogeneous qualities of the goods that parties bargain over, as well as more complex features of the bargaining environment.

A brief example can illustrate the point. A recent paper by Martin and Vanberg (2019b) examines the consequences for coalition bargaining of the fact that parties must bargain before an audience of supporters. The key assumption of their model is that supporters fall into two groups: sophisticated supporters, who are capable of evaluating all aspects of a coalition bargain, and unsophisticated supporters, who only focus on the easily observable features of coalition bargains, and evaluate these by simple heuristics. As Martin and Vanberg demonstrate, the consequences for coalition bargaining are significant: parties have strong incentives to strike bargains that meet the expectations of unsophisticated voters for those outcomes these voters observe, while using those aspects of the bargain that these supporters are unaware of as *side payments* to reconcile the coalition bargain with the

underlying bargaining strength of the parties. The result is that the distribution of payoffs that is apparent for more observable features of coalition bargains is systematically different than the distribution of payoffs for more complex aspects. In other words, what voters see is *not* necessarily what they get from the bargains struck by their parties. An empirical analysis of the numerical allocation of portfolios received by parties compared with the implied policy benefits they receive from that allocation strongly supports this conclusion.

The key point we wish to emphasize with this example is that there are at least two directions in which further theoretical development can aim. The first is to consider the more complex aspects of the bargaining environment within which parties act, including the effect of outside ‘audiences’ or the need to build reputations for subsequent bargaining rounds. The second is to move beyond the relatively simple characterizations of the goods that parties bargain over to a more nuanced, and substantively grounded, understanding of the heterogeneous characteristics of ‘goods’ (e.g., their observability to outside audiences). We suspect that both developments will require a closer collaboration between more theoretically oriented scholars and those with expertise in the empirical reality of everyday coalition governance.

## ACKNOWLEDGEMENTS

We wish to thank Scott de Marchi and Kristopher Ramsay for helpful discussions and comments on an earlier version of this chapter.

## Notes

1 Of course, such support does not require that the government itself controls a majority of parliamentary seats so long as it can rely on the implicit support of (some) opposition parties to provide legislative support to the government.

- 2 Naturally, bargaining among coalition partners continues over the lifetime of a government as parties make policy decisions. While the models we focus on in this chapter primarily concern the initial formation stage, scholars over the past several years have begun to explore the ongoing process of coalition governance (see, e.g., Strøm et al., 2008; Martin and Vanberg, 2011).
- 3 Natural alternative starting points would be a paper by Austen-Smith and Banks (1988), which presented an integrated model of an election and subsequent government formation, or the ‘ministerial autonomy model’ of Laver and Shepsle (1996). We review both of these contributions below.
- 4 To see this, note that if bargaining breaks down, and the process moves to the next period, the expected payoff for each party (and thus its continuation value) is given by  $c = \frac{1}{3}(1 - \delta c) + \frac{1}{3}\delta c + \frac{1}{3}0$ , which implies that  $c = 1/3$ . There is no incentive to provide any payoff to the opposition party since its vote is not necessary to pass the proposal, and giving it a positive share would only reduce the payoff of the formateur.
- 5 Baron and Ferejohn (1989: 1195) consider an extension that allows amendments to the proposer’s offer. As they show, this possibility reduces, but does not eliminate, the formateur advantage.
- 6 See also the original statement by Baron and Ferejohn (1989: 1194): ‘The bargaining over the allocation of ministries in a coalition government, then, corresponds closely to the model of a legislature operating under a closed rule: the party asked to form a government makes a proposal for allocating ministries (the benefits) among the parties, knowing that if its proposal does not receive a majority, another party (perhaps itself) will be asked (using the same recognition probabilities) to form a government.’
- 7 Of course, this leaves open the possibility that there are contexts that approximate the structure of BF-style models.
- 8 While the major thrust of the Laver et al. (2011) critique is theoretical, they also raise a central empirical measurement issue. An evaluation of a BF-style formateur bonus requires an *ex ante* measure of a party’s formateur status that is an indication of which party is charged, initially, with forming a government (if such a party exists). But as they demonstrate, coding of such a measure is difficult, as a result of which the measure of formateur status employed is actually an *ex post* measure – basically, an indicator of the party that ultimately secures the prime ministership in the government that forms.

- 9 These assumptions simplify the example, but do not affect the substantive conclusion. See Morelli (1999) for a general statement and proof.
- 10 There is some additional nuance here when parties have policy preferences, and the 'head of state' has some discretion in selecting the formateur. In this case, the equilibrium policy (but not the distribution of the divisible good) depends on the choice of formateur, and thus on the order of play. This aspect of the Morelli model is thus subject to the same Laver et al. (2011) critique as the BF approach.
- 11 There is a common logic between the Bassi and Morelli models in that it is competition among potential coalition partners/formateurs that eliminates the formateur advantage. That said, there is a significant difference in that the competition in the Morelli model – competition over inclusion in a cabinet, and the terms on which a party would join a coalition – appears substantively closer to 'real-world' coalition bargaining than competition for the role of formateur (whose formateur status is then firm).
- 12 Diermeier and Merlo (2000) generalize the Baron and Diermeier (2001) model, focusing on the dynamics of government turnover.
- 13 The Austen-Smith and Banks (1988) model, which was developed at roughly the same time as the LS approach, also has this feature.

# Models of Interstate Conflict

James D. Morrow and Jessica S. Sun

The application of formal models to the study of international conflict has a long history, from the days of models of arms races based on systems of differential equations and the invocation of two-by-two strategic form games to the widespread use of non-cooperative game theory over the last three decades. Rather than simply survey the range of models commonly employed in the literature these days, this essay seeks to aid the researcher who is constructing a formal model in the key decisions that any modeling project requires. Our target reader is one who does not have great experience using these methods, and so can benefit from a guide to thinking of how different types of models focus attention on certain aspects of a situation at the expense of others. We survey a range of different models used to study international conflict with an eye to the strengths and limits of each of these classes of models. We hope that this survey will help readers make deliberate choices when they develop their models.

Formal modeling as a research enterprise seeks to identify a key causal process, simplify it down to its essence and then analyze that process to reveal its central logic. Any real situation has many possible causal processes active at any time. Including all of them renders analysis intractable: which one predominates? Do some cancel out others? Instead of presenting and considering all possible causal processes, the modeler focuses on one in the hope that in isolation we can understand what drives that process. With that deeper understanding of one causal process, we may be able to determine its observable consequences and how it might interact with other plausible causal processes (Powell, 1999: chapter 1).

The design of a model is critical to the enterprise. Elements of the situation that are not essential to the causal process being studied must be pared away. The actors must be defined, their choices and how they interact to produce outcomes specified, their preferences over those outcomes stated, and the information each holds when they choose, fixed.

These design choices force the modeler to consider the essence of the problem they wish to explore. In practice, we find the design process to be iterative, beginning with a first model, solving it, and then thinking about what parts should be cut away in favor of others. In the end, a good model lays out the logic of the causal process clearly, enabling the reader to grasp its essential logic.

Formal models are particularly useful tools for studying international conflict. The internal political process of governments making foreign policy is often private and only recoverable when it has become history and viewed as safe to reveal. Although international crises and war are public events, some key communications between governments in crisis are private. Given the complexity of some conflict events, important details were not collected when those events occurred and so are lost to history. While many impressive efforts have been made to collect data on international conflict, the resulting data sets often reflect only the parts of the behavior that can be easily captured. These difficulties reduce the value of a purely inductive approach to the study of international conflict and make models an attractive research tool to explore those areas that lie unobserved.

Faced with the inability to measure many important aspects of conflict behavior, theorists of international conflict have posited a wide range of arguments for why violent conflicts occur. Formal models could help us specify the logic of those arguments carefully and fully to understand the essence of these purported causal processes. We can also play out the observable consequences of a model to think about how what we can observe might allow us to judge which causal processes produce those patterns of behavior. Even if we do not use models as guides to empirical patterns, there is still value in working through the logic of the theories of international conflict to understand the essence of the causal processes advanced by those theories (Bueno de Mesquita and Morrow, 1999).

We begin by discussing models of complete information, because they were a natural

outgrowth of key questions in international conflict. Such models have important limits, however. The development of games of incomplete information opened up questions of perception and strategic communication to formal analysis that complete information assumed away. Repeated games could analyze questions of reciprocity in conflict and whether agreements could be enforced through reciprocity. Although games of complete information could address issues of commitment – whether parties would follow through on their threats and promises – stochastic games offered a superior technology for modeling commitment issues. These models could be married to models of domestic politics to study the interplay of international and domestic politics. Other classes of games, notably games of timing and Blotto games, have received less use but should be in the range of modeling tools to study international conflict.

## COMPLETE INFORMATION

Deterrence, both nuclear and conventional, was a central issue during the Cold War. Could the threat of military action dissuade the Soviet Union from expanding its influence through coercive means? An expected utility calculation lies at the heart of deterrence (e.g. Ellsberg, 1961; Russett, 1963): is the possibility of a military response sufficient to convince the other side to live with the status quo? That possibility encompasses both the chance that the deterring party will not follow through on its threat and the evaluation of the consequences of military conflict in comparison to the attractiveness of the status quo.

Deterrence was more than just a judgment by the challenging state, that is, the party to be deterred. The party seeking to deter also had judgments of its own to make. If deterrence failed, it would have to decide whether to carry out its deterrent threat by going to war. Before the latent threat by the challenging state became immediate and pressing,

the prospective deterring state had to judge how to communicate its deterrent threat through words and actions. These decisions could also be represented by expected utility calculations, but now all three decisions would be interrelated. Working backwards, whether the deterrent state will carry out its threat influences the willingness of the party being deterred to challenge the status quo. In turn, the latter's inclination to challenge the status quo affects the nature and character of the deterrent threat before any challenge is made. How the deterrent threat is made, and then backed up by actions, changes the challenger's perception about whether the deterring state will carry out its deterrent threat. In short, deterrence involves a series of interrelated decisions between the two parties, some of which may never occur. Sequence is essential to the strategic interaction of deterrence, though previous work obscured that fact by examining one of these decisions in isolation, typically the judgment of the challenger.

Sequence and interdependence of decisions are two hallmarks of games in the extensive form. These games require the analyst to be explicit about the sequence of moves and how they produce outcomes. This discipline clarifies aspects of the problem that are often left vague in non-formal analyses of deterrence. If the game was played under complete and perfect information, backwards induction would produce the *subgame perfect equilibrium* of the game (assuming no player is indifferent at any move). The character of the resulting equilibrium coincides with many of the intuitions about deterrence in the non-formal literature, such as the importance of the credibility of the threat to effective deterrence. But that equilibrium would also create some enigmas. If the equilibrium produced behavior where the deterrent threat is made but fails to deter the challenger, one might wonder why an ineffective deterrent threat would be made at all. If that situation ended in violent conflict, both sides must have preferred war to the status quo. When conflict occurs in a game of complete information,

the parties prefer conflict to the alternative outcomes; it is Pareto optimal. Further, both sides could anticipate the outcome of the crisis from the beginning because both fully understand the other's incentives in the game. Why engage in a crisis, in that case? The deterring state should just go to war or yield the stakes without making a threat that it is unwilling to carry out. But a majority of historical crises do not end in war. Thus, sequential games can yield results that appear perverse.

Models of complete information could be used to examine when commitment problems give rise to conflict. The sequence of moves would include the possibility of one or both sides reneging on a deal made earlier in the game. Backwards induction would then render an efficient bargain unattainable because at least one side preferred conflict to entering a deal that will be broken later to its disadvantage. Although such models can capture a commitment problem, the field has gravitated to stochastic games (to be discussed later in this chapter) as the preferred modeling technique for commitment problems. The extensive form games under complete information effectively assume that one party will have the incentive to break the agreement later, while the opportunity and incentive to break the agreement are not certain in any given period in the stochastic game technology, even though the conditions that lead to breakdown are very likely to occur at some point in the future.

An alternative modeling strategy that could produce a positive probability of conflict under complete information would be to assume imperfect information, that is, simultaneous moves. The classic example here is the two-by-two game of chicken with three equilibria: two in pure strategies where the players avoid conflict, and a mixed strategy equilibrium with positive probability of conflict. Models in this line (cf. Morrow, 1994: 180–6) could represent situations of the mutual fear of surprise attack. Because the risk of conflict arises in mixed strategy equilibria, models that rely on imperfect information to produce a positive probability

of conflict are open to critiques of such equilibria, such as their lack of dynamic stability.

Models of complete and perfect information are an appropriate and useful tool for studying questions of distribution and welfare, even when they do not produce a positive probability of conflict. For example, we might wish to study how different domestic politics shift the bargain between two parties, and thereby provide a bargaining advantage to one of them. The international status quo is the result of a string of past bargains from prior efforts to change the status quo. Understanding what advantages different parties have in the bargaining allows us to characterize how the status quo should reflect those advantages. Fearon (2018) examines the welfare effects of interstate competition under anarchy, where the parties arm both in the shadow of war and political competition short of war, and where military capabilities influence the outcome of both. Parties then commit resources to the military to deter war, protect their future stream of income and gain in the political competition short of war. Because these military allocations vary with the parameters of the model, we can see when they are larger, producing a greater loss to the inefficiency of military expenditures. The model then predicts patterns within military expenditures across countries and time. While the point of the model is not to predict the occurrence of war, war breaks out only under conditions where deterrence is impossible.

## REPEATED GAMES

States and their leaders often carefully cultivate reputation, valuing the ability to communicate through repeated truth-telling or to induce compliance by threatening punishment. Unlike negotiating an agreement over a single issue, establishing reputation requires repeated interaction over time. Therefore, studying a phenomenon such as reputation requires a model of an iterative process.

Repeated games offer a means to study recurring interactions, representing the ongoing relationship between states as the repetition of a *stage game* – typically a simple, simultaneous game. This repetition enables players to condition their strategies on the history of play and to threaten to play an inefficient (equilibrium) strategy to punish undesirable behavior. Therefore, counterintuitive, and often cooperative, outcomes can be sustained in repeated games when players are able to threaten to play *minmax strategies* – strategies that minimize the maximum payoff of their opponents – should cooperation break down.

Repeated games can be used to represent many types of substantive processes where relations between states depend on past behavior. They can be used to explain normatively desirable, and not obviously rational, outcomes like diplomacy. For example, in the context of a repeated interaction between countries, states that build a reputation for honesty can improve their chance of settling issues they care about in their own favor, while those that bluff, relying too often on implausible claims, can be punished by being ignored (Sartori, 2002). In this way, repeated games allow the researcher to explore questions of reciprocity and identify conditions under which such cooperative outcomes are sustainable. Alternatively, repetition can explain inefficient outcomes such as the onset of interstate war. If war is viewed as a costly process, fighting may be optimal if refusing to fight would induce an undesirable settlement where the selection of that settlement was enforced in future plays of the game (Slantchev, 2003).

A downside of repeated games is the multiplicity of equilibria that are feasible, which gives rise to a well-known set of results known as folk theorems. All Nash equilibria of the stage game can be supported by folk theorems, as well as many strategies that generate feasible payoffs that combine different outcomes of the stage game. Therefore, while a number of substantively meaningful outcomes are possible in repeated games, a large

set of less interpretable results may also hold in equilibrium. In many cases, scholars confront this problem by selecting an equilibrium that corresponds with their substantive argument (Sartori, 2002) and emphasize the conditions under which this equilibrium holds. While this approach may suffice to answer a number of questions about reputation building, in many cases this practice of selecting equilibria is unsatisfying. Alternatively, the selection of a particular equilibrium from the wide range of them hinges on the *common conjecture* – the assumption that all players share an understanding about which equilibrium they are playing (Aumann and Brandenburger, 1995). Such common understandings of how players should act could arise from a number of sources. Morrow (2014) argues that international law embodies such understandings that allow the parties to form strategic expectations about how they will act in a given situation. This approach turns the focus of the analysis away from the incentives of the players within the game and towards the shared understanding about how they play. Because the mathematical tools of equilibrium theory center on the calculation of mutual best replies, there are few tools available to model where the common conjecture comes from. We explore an alternative method for analyzing interactions with an infinite horizon – stochastic games – that avoids the multiplicity of equilibria under the folk theorems.

## STOCHASTIC GAMES

An important way in which states manage relations with each other, and use their power to avoid or initiate conflict, is through making threats or promises. This form of strategic communication, however, is plagued by a pervasive problem – it is difficult for states to commit to agreements. Even in instances where governments take concrete steps, like making concessions, when their preferences may change over time, states that want to

make promises remain unable to guarantee they will keep them. This is a classic commitment problem. In a complete information environment, as mentioned above, commitment problems limit possible agreements to only those that are reached in subgame perfect equilibrium. A more flexible way to represent issues of commitment is through a stochastic game. In stochastic games, some underlying state of the world can change, and with it the incentives of the players. In this way, stochastic games capture the endogenous process of the interaction between states over time. Stochastic games rely on *Markov strategies* and *Markov perfect equilibria* (a refinement of subgame perfection). Markov strategies condition play on the state of the world (rather than the history of the game until that point, as in a repeated game) where the state of the world provides some kind of payoff-relevant information. Strategies that comprise a Markov perfect equilibrium are both subgame perfect and require players to play the same strategies from any history that leads to a given state.

Commitment problems arise when one (or both) side(s) of a potential conflict has incentives that shift over time. They may enter a bargain wanting to honor it, but when their incentives change, they no longer wish to. In anticipation of one side reneging in the future, the other may refuse any bargain now, even in situations where both sides are better off than if they were fighting. For this reason, commitment problems are commonly given as an explanation for inefficient outcomes, like the continuation of conflict (Fearon, 2004), coups (Acemoglu and Robinson, 2001a,b) and appeasement (Powell, 1996b). The commitment problems and the inefficient results they generate in these examples can be represented by a common mechanism (Powell, 2004b). In each of these cases, the amount of benefits that each of two players would need to be assured of obtaining in an efficient equilibrium exceeds the total amount of benefits available to be divided. Therefore, it is impossible to satisfy both players' claims on

the total value of benefits at the same time. Further, as one player loses power while the other gains it, the bargaining surplus cannot be sufficiently large to satisfy one of the players. Therefore, large and rapid changes in relative power between bargaining parties imply that commitment problems will lead to only inefficient outcomes.

Stochastic games are particularly useful for examining dynamic problems where information is not the primary concern. All of the illustrative stochastic games mentioned above have complete information. As their name indicates, stochastic games do require some randomness that can generate shifts in the state of the world, but the distribution of this uncertainty is typically common knowledge for all players. In addition, stochastic games improve on repeated games in many ways by allowing the modeler to avoid the problem of equilibrium selection. As Powell (2004b) demonstrates, all stochastic models with certain characteristics generate inefficient equilibria, namely a state where one of the parties can guarantee itself more by shifting to an inefficient path for the long run than it would receive otherwise, even if the other side offers all available surplus from an efficient path in the short run. This is a significant improvement over arguments built on repeated games that suggest inefficient outcomes must be the result of dominated inefficient equilibria. Lastly, the pervasiveness of commitment problems in interstate relations makes the stochastic game a particularly useful tool for examining the long-term relations between states. Those who wish to develop an explanation for conflict based in a commitment problem can use the condition in Powell (2004b) to ensure that efficient settlements will be undermined by that commitment problem.

## INCOMPLETE INFORMATION

Another source of conflict is differences in information between states. That is, how does conflict change when one state knows

something, perhaps about its own preferences or tolerance for conflict, that another state does not. Games of incomplete information allow scholars to approach these questions in a way that provides a disciplined framework for thinking about differences in information and beliefs about another party's actions.

For many students of international relations, the most familiar setting in which incomplete information plays a crucial role is crisis bargaining. Before initiating conflict, states attempt to bargain to find some negotiated settlement short of war. However, when information is incomplete, and states have incentives to misrepresent the information they have and their adversary lacks, conflict may occur even though it is inefficient. In many cases, the relevant information relates to a privately known cost for conflict or level of resolve. This is the key insight of Fearon (1995) and has been expanded upon in a number of ways, which we will cover in this section. We begin, however, by exploring how incomplete information changes the modeling enterprise.

An incomplete information environment is one in which at least one player has private information – known to themselves but not to other players – about their preferences or their actions at the time they make strategic decisions in the game. Information, for the other player(s), is incomplete because some key feature of the strategic environment is unknown to them. The canonical bargaining model of war incorporates incomplete information of this form because the costs for war of each player is privately known. Players with incomplete information, who have some uncertainty about the preferences of their opponent(s), must make choices based on beliefs about what the other players will do.

Importantly, incomplete information is distinct from the information imperfections that arise in some extensive form games, such as those with simultaneous moves. When information is imperfect, at the outset of the game all players know the same thing, but one or more players might get private information

throughout the game. Incomplete information implies asymmetry in information between players that arises before the game is played.

There are two ways in which information can be incomplete, and each lends itself to a different type of model. First, players can make private decisions or take private actions. This is often thought of as some exertion of effort that is unobserved by the other player(s) in the game. Such incomplete information problems are typically referred to as *moral hazard* problems, represented by an interaction between a principal and an agent. Moral hazard models are common in economics and political science but are often used to study interactions between individuals rather than states. Second, players can have private information about payoffs. In the context of international conflict, this could mean players have some private level of resolve, value for winning or cost for conflict, as is the case in Arena and Wolford (2012); Fearon (1997); Morrow (1989); Powell (1996a); Slantchev (2005); and Trager (2010). This type of information is relevant to the strategic decision at hand, and the player possessing this information cannot be compelled to truthfully reveal this component of his or her payoff unless presented with a set of incentives, designed by other player(s), that make it beneficial to do so. Incomplete information problems of this form are often referred to as *adverse selection*, and lend themselves to models of screening and signaling; notable models of this form include Morrow (1992); Powell (1988); Schultz (1998); Slantchev (2010); Tarar and Leventoglu (2009); and Trager (2011).

Moving to a world with incomplete information requires a different solution concept to characterize equilibria to this type of game, and a way to represent the particular aspect of a player's payoff or action that is unknown. The information about a player that is unknown is represented by a *type*, which stands for all the possible values of that player's private information. For example, if one player has a private cost for conflict that is either high or low, that player has

two types: one high-cost type and one low-cost type (for an example with continuous types, see Fearon, 1997). There are multiple substantive interpretations for types. Bueno de Mesquita and Lalman (1990) use types to represent the magnitude of domestic political opposition to the use of force against another state. In Powell (1996b), a declining state does not know a rising state's type, where the type represents the rising state's resolve.

Because a player's type affects his or her strategy, the uninformed player would like the informed player to reveal this private information. In some cases, the informed player also finds it optimal to communicate her private information. Games where the player with private information takes some action that demonstrates her type before the strategic interaction between the informed and uninformed player are referred to as *signaling*. When some action that reveals the informed player's type is taken after the strategic interaction with the uninformed player, the uninformed player is said to be *screening*. The key distinction between these two types of models is whether the player with the private information acts, leading to signaling, or responds to an act of the uninformed party, leading to screening. In an interstate conflict context, if a leader wants to show an adversary he is resolved, he may signal his resolution by staging military exercises. In contrast, when bargaining with an adversary of unknown strength, a leader may want to choose the proposed division of resources so that by accepting, the adversary reveals whether she is a strong or a weak type.

For static games of incomplete information where the players move before any private information can be revealed, the appropriate solution concept is Bayesian equilibrium. A Bayesian equilibrium is a Nash equilibrium in which players update their beliefs according to Bayes's Rule. Therefore, a Bayesian equilibrium is a strategy profile and beliefs, for each player, about the types of the other player(s) that maximize the expected payoff for every player, given the other players' strategies and beliefs. For sequential games,

we refine this solution concept to *perfect Bayesian equilibrium*. A perfect Bayesian equilibrium is defined by a set of strategies for each type of each player and a set of beliefs or conjectures such that the chosen actions maximize conditional expected utility based on the beliefs about other players' types.

Returning to the crisis bargaining example, in the canonical crisis bargaining model articulated in Fearon (1995), there always exists a set of negotiated settlements which both potential belligerents would prefer to war. However, incomplete information about conflict-relevant factors such as military capability or resolve – and in particular, incentives to misrepresent that information in order to attain a more favorable bargain – lead to the breakdown of negotiation into war. Entering an incomplete information environment, then, is precisely what allows the modeler to develop a rationalist explanation for why wars occur when they are inefficient *ex post*.

The role information plays in leading to bargaining failure is reinforced by the take-it-or-leave-it structure of the bargaining protocol. This particular way of representing bargaining is well suited to modeling informational mechanisms (as opposed to, for example, an alternating offers protocol) because it allows the modeler to focus attention away from the dynamics of the negotiation. Further, a take-it-or-leave-it protocol has two desirable properties that align substantively with an intuitive notion of crisis bargaining. First, while the breakdown of bargaining into conflict is inefficient, there is a positive probability of bargaining failure, and thus war can arise rationally. Second, the state making the offer faces a risk–return tradeoff, which in part generates the incentive for the second state to misrepresent its cost for conflict. The offering country can give up more and reduce the odds of that offer being rejected, but that necessarily requires accepting a smaller share of the divided benefits. For the second country, misrepresenting its cost of conflict is preferred if doing so will lead to a greater share of the benefits – specifically

because the offering country then thinks it needs to offer more to avoid conflict.

Incomplete information generates a rich set of questions that can be addressed with a number of different models to treat aspects of interstate conflict ranging from the choice to go to war (e.g. Fearon, 1995) to the reaction of domestic constituents to interstate conflict (e.g. Schultz, 1998). In this section, we cover models built on the workhorse take-it-or-leave-it bargaining model, which leverage incomplete information in three different ways: models of mechanism design, games of bargaining during war and models that test the bounds of common knowledge. A number of other incomplete information models, including signaling games, are covered elsewhere in this volume.

### ***Mechanism Design***

The language of incentives is often used to explain why states choose to engage in interstate conflict. However, the precise role of these incentives, and what exactly they say about states' motivations and concerns, is often unclear. Models of mechanism design formally enumerate states' incentives and ask under what circumstances it is sufficiently beneficial for states to take some action. Moreover, mechanism design models demonstrate how an uninformed state can induce an opponent to reveal important information by taking advantage of the opponent's incentives.

While game theoretic models are designed to make predictions about strategic behavior taking the rules of the game as given, mechanism design concerns how the incentives of the situation limit what is possible under any set of rules for the game. A mechanism is a mapping from the private information of the players into outcomes. In a standard mechanism design setting, the mechanism designer proposes a mechanism that seeks to elicit truthful revelation of information from the players, each player reports its private information to the designer and then the designer

applies the mechanism to the revealed information to determine the outcome. Each player agrees to play the game and tell the truth about her private information if a set of conditions on incentives are met; these incentives reflect equilibrium strategies in some Bayesian game. An important result in mechanism design, referred to as the Revelation Principle, ensures that any set of outcomes that can be produced under a Bayesian Nash equilibrium of the game can also be produced under a mechanism which induces truthful revelation of information to the mechanism designer. More specifically, universal honesty is a Bayesian Nash equilibrium if and only if the choice of mechanism satisfies necessary and sufficient conditions on incentives (Myerson, 1979, 1983). Thus, a mechanism design approach shows the limits of what can be achieved under a set of incentives independent of the specific game being played.

Mechanism design models require that equilibrium strategies satisfy two constraints on incentives. The first is *individual rationality*. Often referred to as a participation constraint, this condition requires that the value of an action must be sufficiently high such that it is better than taking no action. The value of a player's best outside option is referred to as her reservation value, and satisfying individual rationality requires that the benefit from playing a particular strategy must equal or exceed this value.<sup>1</sup> Second, a strategy must satisfy *incentive compatibility*, meaning the strategy must be optimal given the expected costs and benefits of playing that strategy.<sup>2</sup>

Because incentive compatibility represents a condition that must be met for a strategy to be optimal, such constraints arise independently from any game form. Banks (1990) takes a 'game free' approach to understanding the role of incentive compatibility in crisis bargaining. His results therefore hold for any equilibrium of any game with incomplete information, and solely rely on incentive compatibility conditions. Considering a generic bargaining scenario in which war is possible and one side has private information

regarding its cost for war, he identifies principles of the outcomes that must be true in any game that contains those incentives. The probability of war and the expected benefits from reaching a negotiated agreement that avoids war are both increasing in the expected benefit of conflict for the informed player. More resolute types of states – that is, those with private information that increases the value of war for them – are more likely to fight interstate wars but derive higher benefits from settlement if war is averted. Importantly, this finding is only the result of requiring that states act in a manner that is incentive compatible and individually rational. Therefore, these results help scholars of interstate conflict better understand the decision-making environment of crisis bargaining, rather than decision making within the context of a particular model specification.

While the results derived from employing incentive compatibility conditions alone provide valuable insight about the likelihood of war, combining this type of result with a formalization of key features of the information environment can provide significant, general insights about the onset of interstate conflict. Fey and Ramsay (2007) use this approach to question the logic of the mutual optimism explanation for war. Mutual optimism implies that both states on the brink of war believe they are more likely to win (or, more precisely, that the sum of their subjective probabilities of victory is greater than one). This would require that war is simultaneously incentive compatible for both states, given their beliefs about their relative probability of victory. Fey and Ramsay (2007) consider a generalized negotiation procedure because, relying on the Revelation Principle, any equilibrium for any game chosen to represent the negotiation procedure can be represented by the state of the world (a distribution over the probability that one side wins a war) and the outcomes of this negotiation protocol. In this setting, they show there is no equilibrium under which war occurs due to mutual optimism, extending to cases where the states involved can be considered

only boundedly rational.<sup>3</sup> This is precisely because, as long as war's occurrence is self-evident to all players, war cannot be incentive compatible for both rational, Bayesian players at the same time.

Because the conditions under which a mechanism is optimal are not based on a particular game form, the mechanism design approach is a highly general way to examine interstate war in an incomplete information environment. As Banks (1990) and Fey and Ramsay (2007) demonstrate, models that rest on questions of mechanism design are particularly well suited to examine when interstate bargaining is individually rational and war is incentive compatible, that is, what the necessary conditions are for states to be willing to bargain over contested issues, and how high the expected benefits from war must be for war to be observed in equilibrium.

### ***Bargaining during War***

The types of incomplete information models discussed so far offer each actor only one opportunity to update their beliefs about the state of the world through a one-shot interaction such as bargaining. However, a more realistic representation of both the bargaining process leading up to war and the process of fighting wars may be to represent war as a costly process in which states have many opportunities to incrementally update beliefs about their opponents. Models that focus on learning are particularly well suited to answering questions about how war unfolds when states disagree about the distribution of power between them, rather than their private cost for war (Slantchev, 2003; Powell, 2004a).<sup>4</sup> In addition, models in which players learn over time can be used to assess the effects of shifts in power between two states. In these models, states attempt to resolve uncertainty about the relative decline and rise of their power, and its likely effect on the outcome of war (Powell, 2012; Wolford, Reiter and Carrubba, 2011).

A general result generated by models of learning through fighting is that the uncertain state makes offers intended to screen, to gain information about the informed state's type. Types with higher cost for conflict will settle sooner and accept smaller distributions of the prize than low-cost types. Thus, if war progresses as a series of battles with bargaining rounds between them, the uninformed state can develop an increasingly refined view of the informed state's privately held cost, based on the value of offers the informed state is willing to accept. This screening dynamic is captured in Powell (2004a), and arises regardless of whether the source of uncertainty is the cost of fighting or the underlying distribution of power between belligerents. However, the source of incomplete information does change the uninformed state's ability to screen when parties can make rapid offers before or between battles. When there is uncertainty over the cost of fighting, a process of rapidly made offers can avert war, whereas when uncertainty is over the underlying distribution of power, the states must fight a battle in order for the uninformed state to screen. This is because fighting reveals a different kind of information in this rapid bargaining environment. When uncertainty is over costs, each type distinguishes itself by accepting agreements it finds preferable to war. Therefore, the uninformed state can make offers such that every type agrees and war is avoided. However, when uncertainty is over the distribution of power, multiple types can have the same cost for conflict, and the uninformed state is unable to distinguish between these types without fighting.

Costly process models effectively represent learning by enabling players to update multiple times, refining their beliefs about the true state of the world. These types of model are therefore useful for thinking about how the specification of the bargaining environment shapes results. Relaxing some of the standard assumptions of the bargaining model, such as allowing for rapid offers, as in Powell (2004a), or incorporating an inability to commit to the negotiated distribution of

the prize, as in Wolford, Reiter and Carrubba (2011), generate equilibria in which war is optimal even though it is still destructive; these are qualitatively different than the equilibria in standard one-shot bargaining models.

### **Common Knowledge**

Most games of incomplete information make an assumption about the beliefs of players before the game is played, referred to as the *common priors* assumption. Common in this case implies something that every player knows, and that everyone knows that every player knows, and this mutual understanding continues infinitely (Aumann, 1976). Beliefs held before the introduction of new information are referred to as 'prior' or initial beliefs, represented by subjective probabilities of the occurrence of a given set of events. In the incomplete information context, common priors provide elements of the game that are common knowledge and are used by players to inform beliefs about types. In most models in which information is incomplete, it is this common prior that players update using Bayes's Rule.

It is not strictly necessary (though it may be technically and epistemologically desirable) to make the common priors assumption. Non-common priors convey differences in beliefs in cases where there is no difference in information between players. In Smith and Stam (2004), non-common or heterogeneous priors represent differing theories of war between bargaining states. For example, in Smith and Stam's model, conceptual differences about the role of a new technology on the battlefield or the importance of unit cohesion among troops generate divergence in beliefs about the likely outcome of war, despite the fact that both parties observe the same information, namely the outcome of battles. Smith and Stam argue that diverging from the common priors assumption better represents empirical realities. Moreover, they contend that relaxing the common priors assumption provides an opportunity to ask

questions about where beliefs come from, and how that influences decision making (Smith and Stam, 2006).

Modelers interested fundamentally in the role of information and learning, not in understanding the effects of actors having fundamentally different views of the world, are likely better off adopting the common priors assumption. It is possible to represent different world-views and produce divergence in beliefs under the common priors assumption, and thus this approach is arguably more suitable for anyone interested in questions of how knowledge and information relate to the onset of war (Fey and Ramsay, 2006).

### **MODELS LINKED TO DOMESTIC POLITICS**

Links between international conflict and domestic politics have been an important research topic for several decades now, and models are a primary research strategy for these arguments. The range of topics addressed include effects of international conflict on leader tenure in democracies and autocracies (Bueno de Mesquita et al., 2003), how those incentives influence how leaders act in crises (Smith, 1998) and how a legislature can influence foreign policy (Morrow, 1991). These models link an international game to a domestic politics game to examine how the incentives in one arena of politics affects what politicians do in the other. The key is that conflict decisions are made in part for their domestic political consequences, and domestic politics responds to the outcomes of international conflicts. We exclude those models that allude to the effects of domestic politics on international conflict but do not model the domestic politics directly (e.g. Fearon, 1994; Schultz, 1998).

Many of these models examine democratic politics because there are a wide range of accepted models to represent different aspects of democratic politics, such as elections and

legislation. Those models of domestic politics seek to show how democratic processes influence policy outcomes, which makes them suitable to link to international policies and outcomes. The mechanism linking policy to politics is often retrospective voting, giving national leaders reasons to produce successful outcomes to conflicts. Ideological models of elections, such as spatial models, are less common because foreign policy in the US has not been viewed as an ideological issue for decades.

Autocratic politics poses a challenge for this modeling strategy because of the nature of models of autocratic politics. While a range of models have been developed over the last two decades to analyze autocratic politics, they tend to focus on whether the autocrat can sustain himself (sorry, but dictators are almost always men) in power, not on the incentives of the system to produce specific policies (see Gehlbach et al., 2016 for a survey of these models). Models of autocratic politics then are quiet about why autocrats pursue the policies they pursue in office, beyond the simple desire to maintain power (e.g. Svobik, 2012). The prominent exception here is selectorate theory (Buono de Mesquita, 2003), but the application of that theory and model to international conflict requires a translation of the ends of international conflict into the dichotomy of public goods versus private benefits, where autocrats tend to produce private benefits over public goods because they answer to a small winning coalition. This general result focuses our attention on the distribution of rents as key to the maintenance of the leader's support coalition, which is common in other models that focus on the credibility problem inherent in the provision of private benefits in autocracies.

## **GAMES OF TIMING AND WARS OF ATTRITION**

Games of timing have a simple strategic structure. Each player can stop the game any time after it starts, with payoffs determined

by when the game stopped and which side stopped it. Their strategies are simply a probability distribution over stopping times. There are games of timing played in discrete time, as well as continuous time.

Wars of attrition are a particular type of game of timing where two sides vie for a prize. Once the game starts, both sides accumulate costs – the attrition of the war. The contest ends when one side yields the prize to the other. Both sides may be willing to continue the war with added costs in the hope that the other side will yield before they do. These games generalize the Dollar Auction (Shubik, 1971; O'Neill, 1986) where both sides pay their last bid in the auction. The side with the low bid may increase its bid in an effort to secure the item even to the point where the winning bid is greater than the value of the object. Because the Dollar Auction shares some features with international crises, namely that the side that backs down suffers some loss beyond the stakes, wars of attrition have been used to model international crises. Fearon (1994) modifies the continuous-time war of attrition by having only the loser, not the winner, pay its cost accumulated over the length of the game, which he famously labeled as an audience cost. Wars of attrition can be used as a model of negotiations at an impasse where the key step is which side makes a big concession to end the impasse. There is some evidence that wars of attrition represent the distribution of the duration of strikes – which have a similar strategic structure to wars – better than other models of bargaining that allow for haggling over the terms of the bargain (Kennan and Wilson, 1990).

Discrete wars of attrition have been used to model war, where each round is considered an individual battle (Smith, 1998). The two sides fight over a finite string of positions on a line; the endpoints represent the complete defeat of one side or the other, and victory in a battle pushes the outcome one position closer to the defeat of the side that lost that battle. Both sides suffer costs from each battle as well, and can

choose to quit to avoid further losses if they think their chance of winning enough battles in the future to win the war is not large enough to justify the additional costs. In equilibrium, each side has a breakpoint – a position close to their total defeat where they quit if the war reaches that position. Morrow (2014: chapter 3) provides a complete solution to this model of war and uses it as part of a model of the laws of war. These discrete wars of attrition differ from the models of bargaining while learning in two ways: one, they are played under complete information; two, the parties cannot divide the stakes.

## **BLOTTO GAMES**

Blotto games, one of the oldest types of game, concern the strategic allocation of resources in a competitive situation. Canonically, two players simultaneously distribute fixed resources, such as identical military units, across a number of locations which can be thought as battles to be fought. The side that allocates the most units to a location wins that battle, and both sides seek to win as many battles as they can. If all battles are valued equally by both sides, the resulting game is zero-sum. If a Blotto game has an equilibrium, it is in mixed strategies. If one side played a pure strategy, the other would allocate no units to some locations – conceding them – and exactly enough units to win all the other battles, doing so to maximize the number of battles it wins. But then the first side's strategy is no longer a best reply – the side playing the pure strategy has an incentive to deviate to win more battles itself. Mixed strategies produce uncertainty about how much strength each side is required to commit to a given location in order to win the battle there, which can make these mixed strategies mutual best replies. The calculation of those mixed strategies can be complicated. See Golman and Page (2009) for generalized Blotto games and

more detail on the nature of equilibria in these games.

When the same setup is played sequentially, the nature of play changes. The leading player must allocate her resources first, and the trailing player can then target the weakest locations. In equilibrium, the leading player divides its units across the locations to make them equally attractive targets, thereby leveling their values. The trailing player then mixes among the leveled locations because they are all equally attractive targets and to prevent the leading player from anticipating which locations will be targeted. Powell (2007a,b) applies the sequential Blotto setup to the problem of protecting targets against terror attacks. The government allocates its resources across targets to protect them, and then the terror group selects which targets to attack.

Blotto games offer a way to model conflicts that could be placed within a wider model of why states choose conflict. The mixed strategies that commonly are in equilibrium induce probabilities of victory, which in turn matter in both sides' continuation values for war in the prewar moves. We see this as unexploited terrain for models of conflict and why it occurs.

## **CONCLUSION**

Formal modelers have developed a rich toolbox for examining the logic of causal processes in detail. Because the discipline of modeling requires researchers to focus on one causal process in isolation from others, they should make conscious decisions about the process they wish to analyze. We have outlined how different types of models embody broad answers to questions about why international conflict occurs. Further, we have emphasized a couple key questions about the process of interest whose answers suggest some types of models are more suitable than others. The modeler must consider

who the relevant actors are (two states, many states, domestic constituencies), how much the players know about each other, whether they are motivated by short-term incentives or long-term considerations, and if are they preparing for war (or avoiding it) or in the midst of it. The decision as to the appropriate model ultimately rests with the researcher herself.

## Notes

- 1 For adverse selection problems, this is sometimes referred to as the self-selection constraint.
- 2 For a more detailed technical treatment of the basics of mechanism design, see Börgers (2015).
- 3 Bounded rationality implies that players suffer from some type of cognitive bias that impacts their strategies.
- 4 For a treatment of similar questions in a complete information environment, see Leventoglu and Slantchev (2007). Ramsay (2008) offers an empirical analysis of similar questions and tests some of the implications of models of war as a costly process.

# Models of the Judiciary

Deborah Beim

## PREFACE

This chapter provides an overview of how courts work. It focuses on American federal courts, and takes the perspective of contemporary analytical theory. In other words, it reviews game-theoretic models of American courts. The chapter's structure follows the path of a case through the courts. These paths are long (see the literary description of how long in *Jarndyce and Jarndyce* as told by Charles Dickens (1853)). As a result, the chapter necessarily skims over each step, and unfortunately leaves aside many relevant and important models, papers and treatises. My hope is that the chapter, targeted at scholars of other institutions, will provide a cursory overview of how game theorists think about courts. If the chapter is successful, game theorists who think about other ideas and other branches of government will feel equipped to join the study of judicial politics.

## INTRODUCTION: HOW COURTS RESEMBLE AND DIFFER FROM LEGISLATURES

Courts, like legislatures, are (often multi-member) institutions that 'write laws'. Political scientists have a strong theoretical grasp of how legislatures work. We can infer from that theory a bit about how courts work. But theory about legislatures is of limited use in modeling judicial behavior, because courts also differ from legislatures.

Courts differ (and are structured differently) from legislatures. A court is an institution that resolves disputes. Common-law courts, like those we have in the United States, write opinions that describe how similar disputes should be resolved in the future. They write laws *ex post*, rather than *ex ante* as legislatures do. They are often hierarchical. They do not have complete control over their agenda (or docket, in legal parlance). Their decisions are bound by precedent. And, finally, they are inherently adversarial.

It is now broadly acknowledged that courts are policy-makers (see Dahl, 1957). The consensus around this fact has many positive consequences for scholarship on the judiciary: it welcomes political scientists to study the third branch of American government, and brings to bear a *realpolitik* perspective.

But focusing too exclusively on this function is mistaken.

Fundamentally, courts resolve disputes. American courts can make policy only by deciding cases – that is, in constitutional terms, by resolving cases and controversies. In other words, although courts are policy-makers, courts (unlike legislatures) do not *only* write laws. Nearly any opinion issued by an American court is accompanied by a simultaneous resolution of a dispute.

Legislatures typically set their own agenda – they choose which issues require their attention. They then write and issue laws that govern future behavior. In principle, a piece of legislation could be passed at one day and govern behavior indefinitely (though problems such as legislative decay and drift can change how a law is actually applied – not to mention that future legislatures can change laws when and as they see fit). Some models of judicial politics conceive of courts as legislatures. This class of models is often referred to as residing in a ‘policy space’, in contrast to a ‘case space’. Such a distinction arises from the recognition that legislatures issue policy (via legislation) while courts resolve cases. But as this distinction suggests, there are two fundamental differences between judicial policy-making and legislative policy-making.

First, cases are ‘vehicles’ for policy-making. The specific facts of a case may matter. The fact that the court must resolve a dispute while issuing its policy may introduce strategic complexities into bargaining and policy-making. Second, by construction, common-law policy-making is slow, iterative and inductive. I discuss each of these differences as we follow the path of a case through the courts.

The ways in which judicial institutions differ from legislative institutions have consequences for judicial behavior. In this chapter I plan to discuss some of these institutional details, highlighting both those that have been well explored by contemporary formal models and those that I think deserve more attention. I focus almost exclusively on models written by political scientists in the field of judicial politics. I omit models from the economic analysis of law, excepting a few papers sufficiently relevant to the political science subfield of judicial politics to warrant inclusion.

Two good recent review essays cover related material. Cameron and Kornhauser’s review essay of 2017 focuses on the Supreme Court and answers two specific questions: how to model what the Supreme Court does (statutory interpretation, administrative law and constitutional review) and how to model what Supreme Court justices want. Kastellec’s review essay of the same year explores the judicial *hierarchy*, including game theoretic models. In contrast, my chapter tries to give a quicker overview of all aspects of a case’s trajectory through American courts.

### ***Background on the Court System to Which Litigants Go When They Dispute***

In principle, people who find themselves in disputes can resolve those differences without recourse to a judiciary. This system – ‘order without law’ (Ellickson, 1994; Milgrom et al., 1990) – relies on communication and behavioral norms between participants in a society. But most states provide courts for this purpose.

In the American system, the courts that are state-provided are adversarial. In other words, truth-seeking is facilitated by two advocates each arguing their own position, and an adjudicator – a judge – evaluating the strength of each’s argument.

### ***How Does the Adversarial Nature of the Judicial Process Affect its Work?***

Dewatripont and Tirole (1999) show that under most conditions an adversarial system leads to discovery of the truth more often, and at less expense, compared to an inquisitorial system. In inquisitorial systems, common in the French legal tradition, the state pays an inquisitor to discover all the relevant facts. In contrast, in the American adversarial system, each of two lawyers discovers and presents the facts that are favorable to her client's position. Priest and Klein (1984) argue that the adversarial nature of trials means plaintiffs should win about 50% of their cases. That is to say, adversarialism affects which cases enter the courts and affects truth-seeking when in court.

### **LEARNING ABOUT LAW AND STARE DECISIS**

The common-law system works by judges reasoning by analogy from previously decided precedents to new fact patterns. There is a small amount of work on reasoning by analogy – mostly one-dimensional spatial models where nearer points are more similar than further points (examples include Gilboa and Schmeidler, 1995, Callander and Clark, 2017, Fox and Vanberg, 2014, and Baker and Mezzetti, 2012, among others).

But there are very few applied models about reasoning by analogy in common-law courts. A fully fleshed out model would incorporate work on incomplete contracts and work on unawareness.

Judicial opinions are 'stickier' than legislative bills. This status quo bias is known as precedent or *stare decisis*. *Stare decisis* creates complex situations for foresighted judges who know their opinions will be applied to future, unknown circumstances. It also creates strategic complexities for judges who are

bound to follow what their predecessors have done, even when their ideologies differ.

Bueno de Mesquita and Stephenson (2002) explore the rational foundations for the institution of *stare decisis*. They argue that *stare decisis* makes doctrinal communication easier: by relying on a string of past cases, judges can communicate with greater accuracy and ensure greater compliance with doctrine. In a game-theoretic sense, the judge faces a mean-variance trade-off. Judges may value this increase in precision so highly that they are willing to sacrifice some ideological accuracy.

Other papers consider complexities surrounding the implications of *stare decisis* for doctrinal development. For example, Gennaioli and Shleifer (2007) consider the consequences of *stare decisis* in a multi-dimensional world – specifically, how a judge will craft policy knowing that policy will bind future judges but knowing that future judges may craft permanent policies on related dimensions. In another example, Callander and Clark (2017) use a Brownian motion model to understand how *stare decisis* influences similar cases without influencing dissimilar cases.

### **THE CASE SPACE INTRODUCED**

American judge-made law is made by deciding individual cases. This raises complexities in the decision-making process which have been well explored by formal theorists. The technology of the 'case space' allowed scholars to explore this formally (see Lax, 2011 for a review and discussion of the case space).

Kornhauser (1992) introduced the idea that a legal case is a point in a fact space, where each dimension corresponds to a legal question of fact. In nearly all political science models, cases are represented as points on a one-dimensional fact space. Judges *dispose of* cases by choosing between two

actions – sometimes understood as a liberal versus a conservative decision, or a decision for the plaintiff versus the defense, or a decision for the prosecution versus the defendant. All judges dispose of cases, irrespective of where they sit in the judicial hierarchy and irrespective of whether they are ‘making law’ or not. Judges’ preferences are defined by *indifference points*, where an indifference point is a case at which the judge is indifferent between his two choices. *Doctrine*, then, is a rule for future resolution of disputes: in a one-dimensional case space, a doctrine is a cutpoint that describes which plaintiffs should win and which defendants should win. Some judges have the capacity to set doctrine in addition to issuing a disposition.

This is the crux of what is unique about judicial behavior as compared to legislative behavior: the resolution of one dispute, accompanied by a statement predicting how similar disputes would be resolved in the future, is how courts make law. Legislatures make law in the abstract, without the elements of reasoning by analogy, *stare decisis* and resolution of individual disputes that typifies judicial decision-making.

## CURRENT AND FUTURE RESEARCH WITHIN THE CASE SPACE

The case-space architecture allows scholars to understand the attributes of judicial decision-making that are distinct from abstract legislative policy-making. For example, the case space makes concurring and dissenting opinions sensible. Concurring and dissenting opinions, in case-space terms, represent judicial calls (declarations) for alternative cutpoints. A *dissent* disagrees with the disposition for a particular case, because the judge argues for a different cutpoint – particularly, a cutpoint resulting in a decision for what became the losing party in a case. A *conurrence* agrees with the disposition for a case, but would have used a

different cutpoint, although one resulting in a decision for the ultimately prevailing party. In simple spaces, doctrine can be simple. For example, minors cannot be executed (*Roper v Simmons* 543 U.S. 551). Formally, adjudication under this doctrine can be modeled in simple steps: is the punishment execution? Is the defendant a minor?

The case space also allows modeling of complex doctrines. For example, consider (in somewhat simplified terms) the question of which statutes limiting individual rights pass constitutional muster. The standard according to which courts evaluate a statute varies according to various factors, including the category of individuals whose rights the statute limits. For the most part, courts evaluate only whether there is a rational basis for the challenged statute. But where the law potentially infringes on certain special rights, the court scrutinizes said law more strictly. This idea is known as ‘strict scrutiny’. Famously, infringing on a person’s rights on account of his race is strictly scrutinized. Infringing on a person’s rights on account of her gender is not *strictly* scrutinized but is also not afforded as much leeway as would be typical. This is called ‘intermediate scrutiny’.

The case space allows the formal modeling of the adjudication of a statute challenged as unconstitutionally rights-infringing: is a statute challenged? What rights does it infringe? The complexity is in an additional step, which depends on the answer to the second: is there a rational basis for the statute *or* does it pass intermediate *or* strict scrutiny? In other words, the case space can consider which rights were infringed and thus map to scrutiny levels; the scrutiny then maps to which infringements are nevertheless permissible and which fail to meet the differential standards.

A doctrine is analogous to a cutpoint (or cutline or cutplane) strategy for dispositions in most game-theoretic settings. As a result, there is perfect agreement between dispositions and doctrine. As a practical matter, however, few if any models have exploited

the case space's opportunity to simultaneously study dispositions and rule-making. There has been little to no exploration of whether a judge would choose his own strategy as his articulated doctrine – whether his chosen doctrine would be identical to the equilibrium cutpoint he chooses. This is an important opportunity for future research.

### **OTHER OPPORTUNITIES FOR FUTURE RESEARCH WITHIN THE CASE SPACE**

We have an early understanding of how case facts affect doctrine, but our understanding is incomplete. We do not have a comprehensive understanding of how a court should select the best case facts (or 'vehicle') to achieve its most preferred policy. Exceptions in this area include Bustos and Jacobi's 'Judicial Choice among Cases for Certiorari', forthcoming in the *Supreme Court Economic Review*. (I return to case selection below.)

The case-space architecture allows scholars to focus on the judicial resolution of *individual disputes*, behavior that is uniquely judicial (as compared to legislative). But the case-space model is not entirely distinct from the policy model, or, as readers of analytical political science may think of it, the standard spatial model (such as Downs, 1957). The standard spatial model of policy-making under uncertainty is very powerful and explanatory. Consider the seminal model used by Crawford and Sobel (1982) and Gilligan and Krehbiel (1987, 1990). (The policy model has more often been used to describe legislative rather than judicial policy-making.)

The policy and case-space models assume both that policy-makers (whether, e.g., legislators or judges) have preferences about outcomes and that the policy-makers cannot directly control outcomes. Rather, the policy-makers control policy. Policy influences outcomes, but so do random shocks outside of the control of policy-makers (or

others). Scholars model these assumptions as  $x=p+w$ , where  $x$  is the outcome dependent on policy  $p$  and external factors  $w$ . A policy-maker who does not know the realization of  $w$ , and is asked to choose between two policies  $p_1$  and  $p_2$ , faces a quandary identical to that of a judge evaluating the appropriate outcome for a case whose facts he does not perfectly know (as is often assumed in models of the judicial hierarchy, such as in Cameron et al. (2000) and subsequent papers).

Despite this (and other) apparent similarities, the case-space and policy models differ fundamentally. The policy model focuses on the judicial (or legislative) choice of cutpoint. The case-space models focus on the judicial choice of an outcome *for an individual case*.

### **AMERICAN COURTS CANNOT UNILATERALLY SET THEIR OWN AGENDA**

American courts – including the United States Supreme Court – cannot set their own agenda unilaterally. Most trial and appellate courts hear (virtually) all disputes litigants bring to them. Courts with a discretionary docket (such as the United States Supreme Court) nonetheless are constrained to choose between (among) disputes that litigants bring to them. In other words, discretion over its docket allows the United States Supreme Court (for example) to decline to hear certain cases, but does not allow it to select from all possible disputes, or even all disputes actively being litigated. This restriction of cases is an important corollary of the judicial focus on individual disputes discussed in the previous section.

Despite courts' lack of complete autonomy, judicial power to set the court agenda has powerful effects on judicial behavior and, appropriately, has been the subject of serious scholarship. Courts can affect who brings disputes to them in a couple of ways: by allowing more parties or suits into courts (e.g., by

changing formal rules of access or by allowing new kinds of suits), by enticing new suits into court (e.g., by creating plaintiff-friendly doctrine), and by shifting which disputes are brought into court (e.g., by excluding certain groups or by introducing legal institutions to new kinds of disputes or new legal institutions altogether).

I discuss below a few considerations with implications for the development of doctrine.

In some instances, judges may want to *attract more* (attract fewer or discourage) cases. All judges – including trial judges – can (try to) affect this. On attracting more cases, a set of models, led largely by Dan Klerman, considers how judges attract cases at all. Consider the well-known practice of ‘forum shopping’: a plaintiff chooses the venue in which to bring his case. Klerman evaluates the opportunity this creates for ‘forum selling’ – the opportunity for judges or courts to attract plaintiffs to their courthouses. In Klerman’s argument, judges and courts are incentivized to create plaintiff-friendly doctrine to increase their caseloads. This was considered in Simpson (2017) with regard to pre-modern England, and in the contemporary context in Klerman and Reilly (2016), which discusses forum selling by the Eastern District of Texas in patent cases.

Of course, the obverse also can be true as a theoretical matter (and is true in some cases as an empirical matter): courts may want to *discourage* cases in order to reduce case load (or for some other motivation). (See for example Posner, 1993.) There is an opportunity for further scholarship in modeling the circumstances under which one or more judges (and at which levels in the judicial hierarchy) may want to increase or decrease either total caseload or type of case. There is also room for scholarship on how the strategies which judges employ to attract (discourage) cases interacts with the strategies used by litigants, particularly repeat litigants, to ensure their disputes are heard in their preferred fora (e.g., by shifting certain other cases to yet other courts, simply by currying

favor with the court by following judicial signals on caseload volume, by inviting judicial decision-making on caseload-affecting factors in a zeroth step of a game, etc.: see, e.g., Baird 2007, presenting an informal argument, and Paraweswaran, 2018, discussed elsewhere in this chapter).

### **SHAPING THE DOCKET: CASE SELECTION (DISTINCT FROM ATTRACTING (OR DISCOURAGING) CASE VOLUME)**

In addition to attracting (or discouraging) cases altogether, certain American courts enjoy perhaps a more famous power to shape their dockets: case selection. The ability to shape the docket is especially pertinent for the Supreme Court, which hears a small proportion of the cases brought to it: around 7,000–8,000 new cases are filed each year, of which the Supreme Court resolves fewer than 100 (see [www.supremecourt.gov](http://www.supremecourt.gov)). Studies of *certiorari* – the Supreme Court’s decision to grant review – are many.

As outlined by H. W. Perry in his seminal book *Deciding to Decide* (1991), justices’ decisions to grant or deny *certiorari* might depend on two kinds of possible considerations: either ‘extralegal’ considerations focusing on *outcome* preferences (as distinct both from the *policy* preferences discussed in an earlier section and from preferences about law qua law), or ‘legal’ considerations about which legal *issues* need attention, or both.

In line with these possible considerations, I discuss two strategic considerations that go into case selection and shaping the docket: which cases will produce *outcomes* that policy-oriented justices seek, and which cases will produce high-quality *law* that legal-oriented justices seek? (Of course, at least as a theoretical matter, any individual justice may be both policy- and legal-oriented, simultaneously or with respect to different parts of the (potential) docket.)

First, thinking about extralegal considerations, judges may each have a preferred policy, and may care about building a winning judicial coalition around their preferred policy. And some cases may be better vehicles than others from the perspective of bargaining – some may offer more leverage for achieving a desired political goal. This induces preferences over cases and bargaining over case selection. (On the relationship of this possibility to the case-space architecture discussed, see Parameswaran, Cameron and Kornhauser, 2019; Lax and Rader, 2015.) Second, thinking about preferences on law qua law, some cases may be better vehicles than others from the perspective of learning and foresighted doctrinal development.

Of particular interest is one way in which some cases may be better vehicles: they may be more informative. This way is of particular interest if judges can learn. By ‘judges can learn’, several related claims can be meant. First, the Supreme Court must learn from lower courts. This idea is particularly relevant to the US Supreme Court because American federal courts (like most court systems) are hierarchical. So the Supreme Court needs to *learn*, in essence, what is going on in the lower courts, both in terms of whether lower courts are applying Supreme Court instructions faithfully and in terms of the practical effects of law previously announced (by the courts or by Congress).

It is important to note here that much of the existing literature on the Supreme Court assumes things are known. This assumption permeates scholarship on multiple aspects of Supreme Court behavior. So, for example, most formal models of the judicial hierarchy are principal-agent theories that assume that the Supreme Court knows what it wants in any given case and simply struggles to achieve it due to large caseloads and insubordination. Similarly, in the context of interactions among justices (judges), the focus is on bargaining. But a judge (or other player, for that matter) can only bargain rationally once she knows her preferences, the preferences of

her colleagues and the expected outcomes of their collective decisions.

The assumption that ‘things are known’ ignores that courts are structured not only as a hierarchy but also as a ‘knowledge hierarchy’ (see, for example, Garicano, 2000). Knowledge hierarchies are organizations in which subordinates deal with easier questions and superiors with harder ones. Those harder questions can be promoted by the subordinate or by others. In courts, for example, a lower court judge may ‘certify’ a case to another court, or a litigant may appeal. On this account, as applied to federal courts, the job of the district court is to resolve large swathes of ‘easy cases’. The correct resolution of difficult questions is not the proper function of the district court (or its equivalent in any other functionally structured knowledge hierarchy).

Thinking about courts in this way changes likely possibilities about judicial preferences, skillsets, and so on. Conversely, failing to appreciate the knowledge-hierarchy construction of courts leads to misperceptions such as focusing on interactions between individual courts rather than seeing the Supreme Court as supervising a collective.

There is ample game-theoretical work exploring the downsides of such a structure (i.e., standard principal–agent costs). These models tend to assume the Supreme Court has in mind an ideal disposition for every case, and seeks to ensure that lower courts – agents – enact that preference. The seminal example is Cameron et al. (2000). Kastellec (2007) and Beim et al. (2014) introduce a multi-member lower court to estimate the consequences of dissent for monitoring. Lax (2003) introduces a multi-member Supreme Court to estimate the consequences of the Rule of Four and the benefits of extremity. Clark and Carrubba (2012) and Carrubba and Clark (2012) introduce written lower court opinions into the structure.

There remain two main ideas missing from the compliance literature. First, we do not yet have a firm grasp of how the Supreme Court

monitors lower courts as a collective unit, since most models consider one higher court and one lower court. But overseeing a group of courts is fundamentally different from overseeing just one.

Two papers consider how the Court's limited resources – i.e., costly review – affect how it learns from lower courts. Clark and Kastellec (2013) describe how the Court can learn by watching lower courts' decisions. Lower courts sequentially make independent decisions about which of two doctrines is best. Sometimes they will disagree, creating an intercircuit split. Clark and Kastellec describe how long the Court should allow this process to continue, in an optimal-stopping sense: the Court must trade an intolerance of legal discord in the lower courts against the desire to learn more by allowing more courts to weigh in. Beim (2017) considers how the Court can learn from decisions that are made simultaneously, and focuses on which cases are most informative – which vehicles are best for doctrinal development. The Court can observe some elements of a lower court's decision, such as what the case is about and what the outcome was, even without reviewing it. Other elements, such as the reasoning behind the outcome, may require further review to be fully understood. But some decisions are more ambiguous than others. In particular, an unbiased judge can make a moderate decision either because of strong evidence on both sides or because of weak evidence on both sides. As a result, these 'moderate' decisions are more likely to be informative upon review. A third take considers how lower courts can evade review by competing with one another to be the least non-compliant (Cameron, 1993).

Second, we have a weaker understanding of the benefits of this hierarchical structure. The benefits likely accrue primarily from the structure of the judiciary as a 'knowledge hierarchy' (cf, e.g., Garicano and Hubbard, 2007). In particular, higher courts can save time that can instead be used to focus on challenging issues, and can adopt good doctrine instead of writing it themselves.

There are *some* models on this, discussed elsewhere in this chapter. For example, see Clark and Kastellec (2013) and Beim (2017) on the benefits of learning from percolation through various lower courts (see also Lindquist and Klein (2006) and Beim and Rader (2019) for empirical studies of the same). Cameron and Kornhauser (2006) consider the informational benefits of litigant appeals – if litigants are savvy, they will only appeal cases that were incorrectly decided. Carrubba and Clark (2012) and Clark and Carrubba (2012) look at how lower courts can buy decisions that higher courts dislike by writing very high-quality doctrine which the higher court can adopt.

If case facts impact bargaining among justices, then justices will have induced preferences about which cases are most favorable to review.

Some models illustrate the importance of case selection, but do not go so far as to model said strategy. For example, Carrubba et al. (2012) present a model of Supreme Court decision-making in which the case facts divide the court into a majority and a minority. The Supreme Court's policy decision is then set at the median of the majority coalition. As a result, each justice has severe incentives to bargain over the best possible case. Although this is not discussed in that paper, it is an immediate by-product of the strategic environment studied in the paper.

The desire to decide cases correctly and build good law is, of course, also a central element of judicial utility. This is especially true in a common-law system, as the fundamental innovation of the common law is that courts answer hard questions that could not have been properly dealt with *ex ante*. Common-law courts are more efficient institutions for developing 'good' commercial law than are legislatures, because they deal with hard questions *ex post* (see Posner, 1973).

These preferences can come into play during case selection, as well. If case facts are differentially informative, or have differential downstream consequences, then judges may

have preferences about which case is most worth their time. I discuss three examples.

First, Beim et al. (2017) consider cases that cause follow-up questions to arise, and argue that a court may delay deciding an easy case if it will raise difficult follow-up questions. Second, Baker and Mezzetti (2012) develop a model in which doctrine is built incrementally. Judges evaluate whether, in expectation, a case will be sufficiently informative for legal development to warrant the time necessary to resolve it. In their model, judges ‘gap fill’ as time progresses, issuing opinions based on the information they learn in the case they are deciding at the time. Judges need not adhere perfectly to judicial minimalism – they can issue dictatory opinions if they choose – and so there is sometimes legal inconsistency over time (see also Badawi and Baker, 2015). Relatedly, Parameswaran (2018) presents a model in which a legal rule is uncovered over time. But in that paper, judicial decisions can affect the flow of future cases.

### **JUDICIAL DECISION (THE JUDGE DECIDES OR THE JUDGES DECIDE THE CASE)**

Early work in judicial politics focused on the judge’s decision. How does a judge decide a case? Three informal models were developed in political science as summaries for how judges might behave.

The first of these, the ‘legal model’, supposed that judges followed the law and did what it said.<sup>1</sup> This is seemingly straightforward and obvious, but legal realists – the theoreticians who are the intellectual forefathers of the contemporary game-theoretic analysis of judicial decision-making – often pointed out that deciding a case correctly is rarely straightforward. Karl Llewellyn described this evocatively in his 1934 lecture ‘The Constitution as an Institution’: ‘Man (even though he learned square roots in high school) finds more than one right answer hard to conceive of.’

The second, the ‘attitudinal model’, developed by Segal and Spaeth (1993, 2002), focused on Supreme Court justices and argued that they governed their decisions by their personal preferences. That argument posits that when Supreme Court justices are making decisions on the merits, their decisions are governed solely by their wish for whom will win. ‘Simply put, Renhquist votes the way he does because he is extremely conservative; Marshall voted the way he did because he was extremely liberal’ (Segal and Spaeth, 2002: 86).

A third model, the ‘strategic model’, embraced the strategic elements of rational-choice analysis and claimed that judges and justices moderate their decisions in anticipation of other actors. (Ferejohn and Shipan, 1990 is a seminal example of work using this model.) The ‘strategic model’ is the closest to a game-theoretic tradition, since it stems from an interest in strategy and anticipating the actions of others. Because this is the oldest branch of judicial politics, there are excellent review essays discussing formal models of how judges decide cases. See Epstein and Jacobi (2010) and Cameron and Kornhauser (2017a, 2017b).

### ***Judicial Decision: the Opinion***

The judicial opinion is the closest thing to a legislative bill that the judiciary produces. As a result, there is ample game-theoretic material on the content of judicial opinions, especially on the Supreme Court. There are many legislative-like models about bargaining over opinion content. See, among others, Hammond et al. (2005), Carrubba et al. (2012) and Lax and Cameron 2007.

There are also interesting papers on author selection and opinion assignment on the Court of Appeals, where the opportunities of strategy are yet more complex. Two excellent examples include Farhang et al. (2015), which considers the interplay of gender and ideology in determining strategic author

selection, and Hazelton et al. (2016), which considers the interplay of publication and dissent.

Once a decision is issued, often accompanied by a precedential written opinion, the game begins again. Actors in the jurisdiction governed by the relevant court change their behavior in anticipation of the court's future actions. But no written opinion is perfectly complete, and so new ideas and new problems arise. Disputes follow, and some of those disputes land in court.

## Note

- 1 The 'legal model' is a term coined primarily by proponents of other models; there is no singular document that presents the argument. See George and Epstein (1992) for a good summary of the arguments.

# Wrestling with Complexity in Computational Social Science: Theory, Estimation and Representation

Scott de Marchi and Brandon M. Stewart

## INTRODUCTION

Computation is increasingly a feature of most social scientists' research. Unsurprisingly, given the breadth of social science research, the term 'computational social science' has come to mean different things to different researchers and the challenges posed by this increased reliance on computation are not well understood. In this chapter, we hope to show that computation is useful for both theoretical and empirical modeling. In both areas, computational modeling allows researchers to build and estimate more complex models than was previously possible. Instead of attempting to review what has become a vast field, the main goals of this article will be to provide answers to the following questions:

- What types of research problem have led to an increased reliance on computation?
- What hazards exist in relying on computational models?

- Has computation substantially improved the reach of our models, either theoretical or empirical?

In considering these questions, we will focus on three main topics. The first is the use of computational social science to extend the reach of *theoretical models*. Models in this tradition are often referred to as 'agent based models' or 'complex adaptive systems' and several good overviews exist of this area of research (Miller and Page, 2007; de Marchi and Page, 2008, 2014).

The second is the use of computational social science to engage in the *estimation* of a variety of statistical models, especially with the use of machine learning. As noted by Alvarez (2016: 1–2):

Because students are accustomed to having such powerful tools as probit and logit, they often do not understand just how far applied social scientific research has advanced in the past few decades... Few students today realize that back when Rosenstone and Wolfinger were estimating the

models for their paper, when probit models would take 50 minutes to run, they were likely using a mainframe computer. Accessing computer time usually required payment in the form of university research funds. These computational barriers seriously limited social science research.

This anecdote highlights the most common use of computation in applied social science – as raw horsepower to carry out tasks such as the optimization required to estimate statistical models. This has had transformative effects: one notable example is the increased capabilities of neural networks in both forecasting and the estimation of latent variables.

The last area of application that has benefited from increased computational power is *representation* and unsupervised learning, where the main payoff to the discipline has been new sources of data and approaches to measurement. Text as data serves as one central area in which computation has transformed our ability to use large bodies of text to create variables for use in applied statistical models.

In all of the above cases, the rise of computation has been a response to both increased supply of computational power and increased demand for a way to deal with complexity (broadly conceived). Almost always, we are relying on computation because our theories, statistical models or data require its use – without computation, it would be impossible to use agent based models (Kollman et al., 1992; Laver, 2005), event data (Yang et al., 2016; Nguyen and Grishman, 2018), Twitter data (Barberá et al., 2015), text as data (Roberts et al., 2013; Grimmer and Stewart, 2013), network-based models (Fowler, 2006; Dorff et al., 2018; Minhas et al., 2019; Rozenzas et al., 2019), or employ complex models for forecasting (de Marchi et al., 2004). That said, each of these applications has the same underlying cost: computational social science involves choices and the parameter spaces involved are often large.<sup>1</sup> Computational models focused on theory or applied statistics are much more difficult to understand than prior research.

In what follows, we will explore these issues for computational models that focus on theory as well as estimation and measurement. Our hope is to highlight the progress that has been made on all of these fronts, but also to highlight some of the general challenges involved in doing this kind of work. This overview will not be expansive – there is simply too much work that falls under the umbrella of ‘computational social science’. Rather, we will use highly salient examples to illustrate our general points about the use of computation for both theory and empirics.

## THEORY

The field covered in this book [*Theory of Games and Economic Behavior*] is very limited, and we approach it in this sense of modesty ... Its first applications are necessarily to elementary problems where the result has never been in doubt and no theory is actually required. At this early stage the application serves to corroborate the theory. The next stage develops when the theory is applied to somewhat more complicated situations in which it may already lead to a certain extent beyond the obvious and the familiar. Here theory and application corroborate each other mutually. Beyond this lies the field of real success: genuine prediction by theory. It is well known that all mathematized sciences have gone through these successive phases of evolution. (von Neumann and Morgenstern, 1944: 8)

The most common computational models that generate theory are named agent based models (ABM) and consist of a set of actors, called agents, represented in a computer language by behavioral algorithms (Holland and Miller, 1991). Compared to game theoretic models, agents in ABMs have a range of different behavioral rules rather than relying on the more common assumption of backwards induction on an extensive form game. ABMs can, of course, rely on backwards induction and agents may act as perfectly rational actors, but this is not always the best choice for a given context if one wants to understand human behavior. In fact, exploring different behaviors is one of the focal points of

computational models in this tradition; in most models, agents optimize with plausible limitations on memory and cognition (Kim et al., 2010). Given that agents in ABMs are not constrained to use backwards induction as an algorithm, the focus is not typically on finding equilibria. Rather, in computational models the goal is to build more complex models that have enough verisimilitude to real-world contexts to generate precise empirical results. The real distinction between purely deductive and computational approaches is whether one produces a simple model that permits an analytical solution or a more complex model that must be exercised computationally (that is, as a Monte Carlo).

The diversity of behavioral algorithms in computational models has been a source of some controversy due to many game theorists' belief that formal models should rely on rational actor assumptions and not model more complex behavior (Diermeier and Krehbiel, 2003). This ignores, however, the large role that behavior has in all models, even those in the non-cooperative game theory tradition. Equilibrium refinements such as sequential equilibrium (Kreps and Wilson, 1982), trembling hand equilibrium, subgame perfection, and so on, are themselves behavioral assumptions, as are crucial assumptions like stationarity that are not a necessary part of a best response function. Moreover, the proof is in the pudding. The original goal of game theory was to use human games such as poker and chess as a window to more complex behaviors in legislatures and bargaining between nations.<sup>2</sup> The fact, though, is that the proliferation of relatively simple games is due to a general lack of progress by game theorists to expand the complexity of games that may be examined. Poker, one of the longest studied problems by game theorists (see for example Nash and Shapley, 1950; Binmore, 1992; Rapoport et al., 1997), produced virtually no progress (that is, empirical results) until modern computational methods were used to study the problem (Billings et al., 1998; Gilpin and Sandholm, 2007; Sandholm, 2010; Brown and

Sandholm, 2018). Currently, computational models of poker can beat expert humans in two player games of Texas Hold 'em, which is an astonishing level of success compared to earlier, purely deductive approaches.

The reason why computational models have succeeded in some areas where purely deductive models have not is because the price for pure deduction is almost always a focus on simple games. One cannot study poker or other games which humans actually play within the confines of deductive models, so instead one studies radically simpler games that bear only a passing resemblance to real-world contexts. One thus has a choice as a researcher: choose to privilege deductive models, rational actors, and focus on simple games *or* instead focus on more complex games with verisimilitude to human choice contexts and explicitly model behavior with algorithms that stray from backwards induction.<sup>3</sup> Ultimately, insights from deductive approaches can be extended with computation to produce more fruitful models – computation and deduction can and should be complementary.<sup>4</sup>

The other key difference between computational social science models and game theoretic models is that computational models are concerned with behavior in like regions of the model parameter space. In game theoretic models, agents optimize perfectly and most often researchers settle on a set of assumptions designed to produce plausible equilibria. Game theorists do not often deal with dynamics, nor do they expose their models to robustness checks (that is, testing whether or not results survive perturbations to the model parameters).<sup>5</sup> Put another way, one should ask if an equilibrium result meets two criteria: small perturbations to non-essential parameters should not produce discontinuous changes to the results; human actors must be able to find equilibria given reasonable cognitive endowments. Judd and Page (2004) note that:

When we prove a theorem characterizing the set of equilibria in a model or class of models, we like to think that we have explained what will happen in that model – the likely end result. However,

there are important differences between (1) proving the existence of an equilibrium, (2) being able to solve for it, and (3) constructing a set of agents who can learn the equilibrium (p. 197).

Finding an equilibrium for any particular game is valuable, but it is not the end of the road for research. The strength of game theory is that assumptions matter for producing results; the weakness is that there is not a lot of intuition in most cases about what happens to these results if one changes the parameters of the model or if agents do not conform to the behavioral assumptions of the model (de Marchi, 2005).

In a nutshell, computational models aim to accomplish the following:

- i. relax assumptions in existing formal models to generate more general results;
- ii. include algorithms for more plausible behavior (compared to assuming backwards induction), which often means situating actors in time/space/on a network;<sup>6</sup>
- iii. examine relationships between parameters and target variables using applied statistics. This develops an equivalence class for similar models or alerts the researcher that no such class exists;<sup>7</sup>
- iv. develop a correspondence to a real-world outcome and conduct an empirical test of the model. The goal of science is not to write down a deductive model in most cases – there are many such models. The goal is to discover the small subset of deductively true models that have a mapping to real-world outcomes.<sup>8</sup>

To provide additional context for this outline, we will examine two areas where computational models are prevalent: bargaining theory and elections.

### ***Bargaining Theory and Coalition Formation***

Bargaining theory is one of the more important areas of research in economics and political science, as it concerns the allocation of a resource between strategic parties. Typical contexts include bargaining between an employer and a union, nations considering

alliances and parties forming coalitions in proportional representation systems. The most common family of non-cooperative bargaining models starts with Rubinstein (1982) and Baron and Ferejohn (1989). To be clear, these models were crucial in suggesting ways in which the complexity of bargaining might be limited to produce expectations about how human decision-making operates in these contexts. But it is worth noting that many of the key assumptions in these models – especially when generalized to n-players bargaining in coalition politics or legislatures – represent very strong (and largely unmotivated) behavioral assumptions. As Laver et al. (2011) point out, models in the Rubinstein and Baron–Ferejohn tradition have results that are driven by the following assumptions:

- i. *A particular understanding of power (for example, minimum integer weights).* For example, parties in a legislature may have raw seat totals of (10, 10, 1); the minimum integer weights representation<sup>9</sup> of this same legislature (that is, how pivotal each party is) suggests the power of these parties is (1, 1, 1). Focusing on raw seats versus pivotality has a dramatic effect on the expected payoffs (continuation values) of the parties.
- ii. *A strict sequence of play where an exogenous, uniform selection mechanism selects a single party that is able to propose a coalition at each point in time.* Changing this to an endogenous part of the game would have huge implications for the results, as would allowing for an open-outcry approach where multiple actors would be able to make offers simultaneously.<sup>10</sup>
- iii. *A reversion point of 0 for all players if negotiations fail.* This, combined with assumption ii, is largely responsible for the proposer advantage result in many models. Changing the reversion point to a status quo position (for example, a caretaker government) or a new election entirely would remove much of this advantage.
- iv. *Stationarity.* This ensures that history does not matter and that strategies remain constant given ambient conditions at each stage. Without this, the set of equilibria would in most cases be very large.

Worse, attempts to generalize these games to deal with  $n > 2$  players and the non-homogeneous

case<sup>11</sup> have led to a great deal of mayhem (Laver et al., 2010). We are not claiming that formal theorists have not produced deductive models altering or generalizing the above assumptions – multiple innovations exist in the literature (Morelli, 1999; Banks and Duggan, 2006; and Martin and Vanberg, 2019 are excellent examples). But, in the framework of purely deductive models, this process is slow and it is difficult to build intuition about how changes to any of the above parameters affects the general results of bargaining models. Put another way, the combinatorics of the above parameters are bad for modeling – one would need to write hundreds of models to cover the set of parameters listed here.

The bottom line is this: choosing assumptions to limit the complexity of the game is suboptimal if one wishes to study human bargaining. For anyone who has ever been in a faculty meeting, it is reasonably obvious that open-outcry models (to focus on assumption ii above) are a more interesting theoretical approach to understand real-world bargaining. We have equilibria in Baron–Ferejohn style games, though at a price in terms of the complexity of the games we can study. This is not to say that one should do without deductive models – there are important insights to be gained from formalizing a model – but rather that if we are interested in building theories that will map to actual human behavior, we should seek to expand the reach of these models using computation where appropriate.

In the area of coalition bargaining in proportional representation systems, de Marchi and Laver (2020) and de Marchi et al. (n.d.) provide examples of how one may use computation to generalize game theoretic bargaining models. In the first paper, logrolling is added as a way to include policy along with perquisites in the bargaining process; by doing so, Condorcet winners are generated. This purely synthetic variable (that is, the likelihood of observing a Condorcet winner in the computational model) predicts the duration of coalition bargaining in proportional

representation systems. Similarly, the second paper relaxes the assumption of a zero reversion point for all players in the case that bargaining fails and replaces it with the possibility of new elections. A new election, in addition to being the constitutionally mandated reversion point in most systems, can affect bargaining in the present – players that derive a greater advantage from holding new elections may receive higher payoffs in observed bargaining outcomes.

### ***Electoral Models***

Bargaining theory is not the only area in which computational social science has had a positive effect on generating theory. Perhaps the most extensive tradition of computational modeling concerns how preferences are aggregated by institutions into outcomes. Path-breaking work by Kollman et al. (1992, 1998) focused attention on the fact that real-world contexts feature high-dimensional policy spaces and candidates that use optimizing algorithms rather than backwards induction. Constituents are also not fixed; they may move geographically, which has implications for outcomes at the district level (Kollman et al., 1997).

While these early papers were purely theoretical models (albeit computational), empirical support was found for both the American case and the Irish case. Ensley et al. (2009) found that measures of the complexity of electoral landscapes determined the success enjoyed by incumbents. Due to experience and the fact that they had won at least one prior election (Alchian, 1950), complex electorates favor incumbents over challengers, as one would expect from Kollman et al.'s work. Laver (2005) expanded on Kollman et al.'s models and explored the interplay between the algorithms employed by parties to search for platforms and the responses by voters in elections. Relatively simple behavioral rules in Laver's agent based models recover time

series variation in public opinion polls as well as empirically observed party sizes.

Too often, the response of formal theorists to computational models is: ‘that could have been proven deductively’. This claim ignores the hard fact that formal models most often make simplifying assumptions to produce sharp results and this limits the mapping of models to empirical tests of real-world behavior. And too often, computational models ignore prior work by formal theorists. Formal models should be used to help define the actors, strategy sets and payoffs in any given context and serve as necessary starting points for building more complex models.

### *Problem 1: Multiplicity of parameter choices*

Bargaining and elections are not the only examples of computational models that have extended the reach of theory. They do, however, illustrate one of the central problems with the use of computation in theory building: many parameters underlie these models. While there are obvious problems with simply selecting one vector of parameters and generating a simple model solved deductively, building a more complex model comes at the expense of larger parameter spaces which one can only investigate with applied statistics.<sup>12</sup> Often, these parameter choices are poorly detailed in the text of papers, and few researchers in the social sciences have the time or training to read the code that forms the basis of these models.

Ultimately, replicating code at the level of reproducing tables in papers is quite easy. Replicating a computational model at the level of validating that the code does what the author says it does and coming to an understanding of the role of the salient parameters in the model is quite difficult. The main advice we offer is that researchers should produce models that are as complex as they need to be. As with machine learning models (detailed in the next section), code needs to be made available but, more important, modelers need to investigate the relationship

between the parameters in their model and outcome variables and present these relationships clearly. Crucially, instead of treating parameters in an *ad hoc* fashion, theory and the available empirical evidence should guide these choices in models. For example, whenever possible, empirical probability density functions should be used instead of atheoretic distributions being chosen for convenience.

The lesson for us is that whether one is doing non-cooperative game theory or computational models, there are risks that one is overfitting one’s model to produce a desired result.<sup>13</sup> This is, in fact, no different from the curve-fitting that exists in applied statistical models. And, for us, the answer is the same: use theory to pick parameters and expose one’s theoretical model to frequent tests against data.

### *Problem 2: Opacity of the model*

A related issue is that more complex models come at the cost of interpretability. The folk theorem aside, when one examines a simple model like the iterated prisoner’s dilemma (IPD), the highly constrained strategy space and ease of finding equilibria means that we can understand the ‘moving parts’ of the model. With computational models involving much more complex strategy spaces and behavioral algorithms, it is not always easy to grasp what is driving the results.

For example, while computational models of poker have had a great deal of success in two-player games against humans, they have had a much more difficult time generalizing to n-players. Worse, the strategies employed by these poker models are themselves often opaque.<sup>14</sup> There is – as with machine learning models, detailed in the next section – a tradeoff between predictive power and verisimilitude on the one hand and interpretability on the other. Which point on this spectrum a model sits at depends on the application (for example, a simpler model may be chosen due to a desire for policy relevance), but this remains a genuine concern and subject for future research.

To summarize, the central point is this: we understand that many readers are likely suspicious of computational models used to generate theory. These models are not purely deductive, the code is difficult to validate without using statistical models relating parameters to outcomes and computer science is not a skill that is emphasized in our discipline. All of these concerns are valid. But there are tradeoffs that make the use of computation essential, as the examples of poker, bargaining theory and elections demonstrate. Game theoretic models that study simplified games without any mapping to data (and without providing dispositive statistical tests of the implications of the models) mean we are not all that close to the human behavior that motivates our research. While we may find an equilibrium that confirms a stylized fact about politics, this is not evidence any more than a purely correlative statistical model based on observational data is causal. Theorists creating deductive models are in many cases forced, in the concluding remarks of papers, to make verbal analogies for why the IPD has a lot to say about the Vietnam war or why constituents are really just playing signaling games when choosing between candidates. All of the mathematical precision that characterizes these models is thus thrown out of the window when we are forced to bridge the gap between where the games end and the behaviors of interest begin. Computation is the glue that can narrow that gap, and in our view this narrowing is essential if theory is going to play a primary role in guiding research in the social sciences in the future.

## **MACHINE LEARNING AND ESTIMATION**

Just as with theory, increased computational power has given rise to machine learning as an alternative to and extension of traditional statistical models. While machine learning

defies succinct description, it may be easiest to think about as the science of predicting an output given a set of inputs. While models common to social science, such as Ordinary Least Squares (OLS), assume a simple additive, linear structure, in its simplest form the introduction of machine learning offers the ability to move beyond additivity and linearity to model how different features interact in complex and non-linear ways.<sup>15</sup> The introduction of these methods parallels the benefits of using computation for theory by allowing us to move beyond the simplifying assumptions of traditional estimation strategies. This leads to an increased focus on estimation in causal inference and demands a broader discussion of the role of prediction in testing and evaluating theories.

In this section we examine the role of new computationally intensive forms of estimation in causal inference and prediction. While machine learning may allow us to tackle more complicated estimation problems, the core of social science research – how do we learn about social phenomena from data – has largely remained unchanged. We discuss the strengths and weaknesses of machine learning in causal inference and prediction and offer a perspective on what has and has not changed in these fields.

### ***Machine Learning***

Much of machine learning is about estimating a function,  $f()$  which maps from an input,  $X$ , to a prediction,  $\hat{Y}$ , which approximates a target variable,  $Y$ . Many quantitative social scientists are most comfortable with this idea in terms of OLS, which predicts the outcome using a linear function of the inputs:  $\hat{Y} = f(X) = X\beta$ . The fitted function is chosen based on how well  $\hat{Y}$  approximates  $Y$  based on the squared error loss (that is, the one that minimizes the sum of squared errors). While OLS has many virtues, it, as well as other common methods in the social science toolbox, is often not the prediction method with the highest accuracy

due to constraints on functional form, overfitting when using many variables and similar concerns.<sup>16</sup> Machine learning provides alternative methods to learn functions that may be more predictive in settings with many observations. This has allowed for estimation with higher-dimensional feature spaces (more variables) and more complex functional forms (interactions and non-linearities among many variables which do not have to be pre-specified). These gains can be substantial. In Kleinberg et al. (2018), a machine learning approach using gradient boosted decision trees substantially outperformed a basic logistic regression in predicting risk of releasing a defendant on bail. Defendants predicted by the machine learning algorithm to be in the top 1% of the risk distribution committed crimes at a rate of 54%, compared to 40% for those similarly flagged by the logistic regression.<sup>17</sup> Like agent based modeling, the value of machine learning for social scientists is the ability to cope with increased complexity in estimation beyond the standard tools in the social scientist's toolkit.

Flexibility in estimation comes with two related problems: consequential tuning parameters which must be chosen by the user, and opacity of predictions. By contrast, for a given set of input variables, output variables and observations, the OLS estimator only has one solution.<sup>18</sup> The predictions made by OLS might not be very good but they are easy to understand (or at least seem easy to understand!): as we perturb the input variables, the predictions change in a predictable (linear) way. The flexibility of many machine learning methods means that small perturbations in the inputs can map to large changes in the predictions due to local effects, making it difficult to understand why two similar observations yield vastly different predicted outcomes. This flexibility can be a great thing – sometimes the world really is complex – but it also raises different challenges than the ones that are often covered in social science statistics courses.

## Causal Inference

Machine learning tools can also aid social scientists in the goals they are already pursuing, such as causal inference. A new wave of interest in causal inference over the past decade has helped bring attention to the challenges of making inferences about counterfactual situations (Angrist and Pischke, 2008; Morgan and Winship, 2014; Imbens and Rubin, 2015; Pearl and Mackenzie, 2018). Causal inference separates identification of the causal effect from estimation. Identification is the process of linking the estimand of interest (generally involving an unobserved counterfactual quantity) and a statistical estimand that describes the observed data. Estimation then involves estimating the statistical estimand from a finite sample of data. While the two steps are often conflated by practitioners, separating them is essential for deploying machine learning in causal inference. While social scientists must use their understanding of the world to focus on choosing an estimand and identifying it, machine learning helps with the estimation step.

Consider, for example, selection on observables, the identification strategy that powers most of observational social science. Suppose our interest is in the average treatment effect of some treatment  $D$ :  $\tau = E[Y_i(1) - Y_i(0)]$  (written using potential outcomes notation: see Imbens and Rubin, 2015). The treatment effect for an individual is  $Y_i(1) - Y_i(0)$ , the difference for the unit between its outcome if it had taken treatment ( $Y_i(1)$ ) and the unit's outcome if it had not ( $Y_i(0)$ ). The average treatment effect is simply the expectation of these individual effects over the units. Of course, we can never observe both of these quantities and so we appeal to two identification assumptions: (1) positivity ( $0 < p(D_i = 1|\mathbf{X}, Y(1), Y(0)) < 1$ ), which says that every unit has the chance of being treated (or not), and (2) no unmeasured confounding  $p(D_i = 1|\mathbf{X}, Y(1), Y(0)) = p(D_i = 1|\mathbf{X})$ , which says that within levels defined by a set of covariates

$\mathbf{X}$ , the assignment of the treatment  $D$  is not associated with the potential outcomes. These two assumptions allow us to rewrite our statistical estimand  $\tau$  in terms of conditional expectations over observed data  $E_X [E[Y_i|D_i = 1, \mathbf{X}_i] - E[Y_i|D_i = 0, \mathbf{X}_i]]$ . The subsequent estimation problem is fitting a function to approximate these conditional expectations in our observed data. Identification then tells us what that quantity means for us as social scientists.

Separating identification from estimation has allowed machine learning to act as a substitute for more traditional models when tackling difficult estimation problems. In theory, the conditional expectations that we use to reason about identification are arbitrarily non-linear and interactive. Historically, we may have approximated those conditional expectations using linear, additive OLS (and perhaps more recently matching or weighting: see for example Ho et al., 2007 and Hainmueller, 2012). Machine learning provides the possibility to tackle these estimation problems with more accurate tools that can handle more complex non-linearities and interactions and/or higher-dimensional confounders  $\mathbf{X}$ . The past five years has seen an avalanche of work in this space, with much of that effort going into tuning machine learning algorithms toward maximizing performance for the parameter we care about most (in this case, the average treatment effect) and working out the theoretical properties of various machine learning estimators. What the separation of identification and estimation highlights is that machine learning cannot help us with problems that are, at the core, identification issues (such as omitted variable bias).<sup>19</sup>

In practice, there are many ways to use machine learning for estimation in causal inference. For those looking to explore these methods, one approach is the augmented inverse propensity score weighting estimator (Robins et al., 1994), for which Glynn and Quinn (2010) offer an accessible introduction. Here the researcher specifies regression models for the treatment and outcome,

using the predictions for each to construct an estimate of the causal effect. There have been several advances on these methods across a variety of disciplines, but many of the core ideas are similar (Van der Laan and Rose, 2011; Athey and Imbens, 2016; Chernozhukov et al., 2018).<sup>20</sup> The advantage of estimators of these forms is that they allow the researcher to do the work that is closest to their expertise, choosing confounding variables for treatment and outcome models, while delegating the shape of the functional form (about which we generally have no strong theory) to the estimation algorithm.

## Prediction

There is a small but growing interest in prediction in the social sciences.<sup>21</sup> Some focus on the value of forecasting as a value in itself (Ward, 2016), while others have extolled the benefits of prediction for the evaluation of theory (de Marchi, 2005; Watts, 2014; Cranmer and Desmarais, 2017). Prediction also has a role in modern approaches to measurement such as text-as-data methods which replicate human content analysis coding at scale (Grimmer and Stewart, 2013), or techniques of ‘amplified asking’ which combine a relatively small survey with a much larger data source to predict what would have happened if a larger group of people had answered the survey (Blumenstock et al., 2015; Salganik, 2018).

In many of these settings our primary concern is that the predictions are accurate. When we can hold out a randomly selected test set to evaluate performance (for example, using k-fold cross validation or by applying a model to novel data), it is possible to directly estimate predictive accuracy in future data.<sup>22</sup> When would we expect to see large performance improvements from applying machine learning techniques? Machine learning excels in settings where the number of predictors is high relative to the size of the dataset and/or the features are individually relatively

uninformative, but jointly predictive. Thus, we will tend to see performance gains in settings where we have a substantial amount of data (so that it is feasible to estimate the model well), a difficult prediction problem (so that the baseline performance is poor) and noise swamping the signal in our predictors. Decades of careful work developing theory, designing measures and coding variables may mean that a parsimonious set of variables provides most of the available predictive information. However, as we transition into new sources of data – particularly those not explicitly designed by social scientists, such as administrative data or digital trace data – machine learning may become essential for identifying the predictive signal among the noise.

Similar to the discussion above on causal inference, computational methods from machine learning can help us develop the predictive algorithm, but have little to say about what the prediction actually *means*.<sup>23</sup> In causal inference, the meaning of the estimated quantity was conferred by the identification strategy. The significance of the predictive task itself seems rarely to be carefully evaluated in applied work, which can lead to dangerous results. Put simply, predictive methods will map the relationships that you have in your data, not the ones you wish you had. For example, you can use machine learning to predict whether or not a human loan officer will grant someone a loan. However, without a careful set of assumptions, akin to the identification task in causal inference, the machine learning algorithm will learn to predict like the human loan officer, replicating, for example, any racial or gender biases that the officer may have. Predictive algorithms that embed the discriminatory patterns of human decision makers have recently gained widespread attention and criticism (O’Neil, 2017; Eubanks, 2018) and as we move towards more forms of algorithmic governance, they will play an increasingly important role in how governments assess risk, allocate scarce resources and function on a day to day level.

In response to these concerns, computer scientists and economists have begun rigorous study of algorithmic fairness. Other than perfect predictions, it is impossible to simultaneously satisfy many intuitive definitions of fairness (Kleinberg et al., 2016; Corbett-Davies and Goel, 2018). These results imply that there are no easy answers and that considering the ethical implications of these tools will require substantial engagement with the social institutions within which these decision systems are embedded. This is why it is essential that more social scientists engage in these debates and study the deployment of these predictive tools in government settings.

In all of these areas of application, machine learning methods are not a panacea. They can certainly improve our ability to solve estimation problems, but that does not of itself solve the problem of connecting theory to empirics.

### *Problem 1: Multiplicity of parameter choices*

In machine learning algorithms, there are generally tuning parameters chosen by the researcher, such as the regularization penalty in Lasso regression or the number and depth of trees in a random forest. These choices can have a substantial impact on performance. When the objective is clear – for example, prediction accuracy on some target variable – a straightforward way (in simple settings) to set these parameters is through cross-validation (Hastie et al., 2009). Frustratingly, cross-validation itself has a tuning parameter (the number of folds), but the choice tends to matter less as we acquire more data.

The sensitivity of machine learning algorithms to parameters and other details of implementation varies substantially with the problem and the estimator.<sup>24</sup> This sensitivity is a challenge because researcher discretion can be harmful for the accumulation of scientific knowledge in the aggregate even if no individual researcher engages in egregious conduct (Simmons et al., 2011; King and Nielsen, 2019). While existing methods have always had space for researcher ‘discretion’,

the diversity and complexity of machine learning methods means there is considerably more space for these choices.

A second concern is computational reproducibility. Workhorse algorithms in machine learning such as Markov Chain Monte Carlo, stochastic gradient descent, the bootstrap and cross-validation rely on random number generators and can yield different results when started from different random seeds.<sup>25</sup> When the optimization problem being solved is straightforward, the observed variations may be slight. When the methods are solving complex optimization problems, the results can differ substantially (Roberts et al., 2016).<sup>26</sup> Even when using standard solutions such as fixing the random seed, reproducibility may be challenging given differences in the numerical precision of the linear algebra libraries or elements that arise for random assignment of jobs to different cores when using parallel processing. These issues are more pronounced on newer machine learning systems, but older machine learning methods such as support vector machines or Kernel Regularized Least Squares (Hainmueller and Hazlett, 2013) have a few of these issues as well. There is also an emerging exploration within statistics of a broader notion of stability in estimators (see a compelling state-of-the-research agenda in Yu, 2013).

A particularly challenging setting is when we are using machine learning to facilitate scientific discovery. For example, in causal inference we might be trying to identify subsets of the data in a randomized experiment where treatment effects are particularly strong (Imai and Ratkovic, 2013; Athey and Imbens, 2016; Grimmer et al., 2017; Ratkovic and Tingley, 2017). A promising approach in this setting is the use of a split sample (Fafchamps and Labonne, 2017; Egami et al., 2018), where we divide the data into a discovery set and an estimation set. In the discovery set, we look for interesting relationships. Once we have chosen the exact model we want to evaluate, we access the estimation set one time to produce our estimate of interest.

With well-intentioned researchers who are only accessing the estimation set *once*, this can address concerns of searching over endless sets of parameters and ultimately finding only noise. Any relationship that was random noise in the discovery set is highly unlikely to occur in the estimation set by construction. This strategy assumes a relatively straightforward randomized experiment with independent units. An important subject for future work is extending the sample splitting framework to more complex datasets (time-series cross-sectional, network and hierarchical) that we often find in political science.

While there are individual solutions to problems that arise from estimator sensitivity, computational instability and data-driven discovery, these concerns point jointly to a need to invest more heavily in scientific replications within and across research teams. Science is an iterative process and only by returning and reengaging with important problems will we be able to identify findings which are robust.

### *Problem 2: Opacity of the model*

A second concern is the opacity of the model – while regression provides us with a small set of parameters that define clear linear relationships, a modern machine learning algorithm might involve millions of parameters that control interactions and non-linear functions of thousands of inputs, obscuring the role each variable has in generating a prediction. The complexity of the model means that it is relatively difficult to guess how a small perturbation in one input of a model will affect the resulting prediction. This has led to calls in computer science for interpretable or explainable approaches to machine learning. One of the most popular methods to come out of this space is Local Interpretable Model-agnostic Explanations (LIME), which uses a simple (linear) approximation around a prediction of interest to produce an *ex post* explanation of a model (Ribeiro et al., 2016).<sup>27</sup>

Opacity of the machine learning model is only problematic if our use of the method

actually requires interpretability. In the causal inference setting, we often build up to an estimate of a single interpretable parameter (the average treatment effect) by estimating a series of functions which don't themselves need to be interpretable.<sup>28</sup> We can use as complicated a method as we want to estimate the various conditional expectations that make up our estimate of the average treatment effect  $\tau$  and the interpretation of  $\tau$  itself won't change. That is, machine learning is only being used to estimate the nuisance parameters that are necessary to focus on our real estimate of interest (Van der Laan and Rose, 2011; Chernozhukov et al., 2018). This makes explanation of the machine learning components largely unnecessary in the causal inference setting.

In fact, the opacity of some of these components might turn out to have the ancillary positive consequence that variables lacking theoretical interest in the model are not incorrectly interpreted. Interpretation of multiple parameters often requires extremely strong assumptions that practitioners do not realize they are making. Many perfectly plausible heuristics can, however, backfire spectacularly in common settings (see for example the use of heuristics for mediation models discussed in Glynn, 2012). If these parameters are unavailable to the practitioner, we may see fewer misinterpretations in practice.

In other settings, such as algorithms deployed for public policy, there may be a legal or policy requirement to be explainable.<sup>29</sup> The response to this in the machine learning community, as we alluded to above, has been to develop techniques for *ex post* explanations of the predictions. In practice, this typically means using a much simpler model to locally approximate the more complex model. This approach can be doubly misleading. First, we don't know that the simple model captures the complexities of the more complex model (even locally). Second, because the predictive model is not causally identified, explanations can appear to the untrained eye to be causal. For example,

we might observe that an actor is predicted to turn out to vote largely on the basis of the fact that they are a frequent reader of political news; however, this does not imply that if we could somehow convince a non-reader to engage more with political news, they would be more likely to vote.

If transparency of the model is important, a better alternative to *ex post* explanation is using a machine learning model that is designed to produce interpretable results by construction (Rudin, 2018). For example, Rudin's lab has developed a number of high performance machine learning algorithms based on various types of rule lists which can often be summarized in short lists of IF/AND/OR statements (Yang et al., 2017). The results from these techniques suggest that the common understanding that there is a trade-off between accuracy and interpretability may be (at least partly, and in some contexts) an illusion.

There is one subtle opacity problem that we don't have a good answer for: the issue of common support. Common support implies that for a given value of our control covariates, we have both treated and untreated observations. For example, in studying the effect of career choice on political preferences controlling for education, we may not have any doctors who only finished high school in the sample. When we lack common support, our estimates are necessarily reliant on extrapolation and thus become increasingly dependent on arbitrary modeling choices (King and Zeng, 2006). One benefit of approaches like matching is that they drop units where we lack common support, giving us more confidence in our causal estimates. This is easy enough to do with one control variable, such as education in our above example, but is much more complicated when we have more than a handful of variables. By obscuring the prediction process with black-box machine learning algorithms, we may be extrapolating beyond the common support in various regions of the data without realizing it. D'Amour et al. (2017) suggest that this lack

of common support is an inevitable and pervasive problem in the high-dimensional settings where causal inference techniques are being applied. Identifying and addressing regions where we lack common support strikes us as a valuable area of future research.

To summarize, machine learning provides an improved approach to estimation, but estimation only gets us so far. In causal inference, we must separate identification concerns (which machine learning does not currently help with) and estimation concerns (where machine learning may be a useful replacement for existing tools). Although somewhat less common in practice, a similar thought process applies to prediction, where it is necessary to think through the implication of the estimation problem rather than treating it as an end unto itself. Theory retains a central role in setting the target estimand (whether predictive or causal) and shaping the inclusion and measurement of key inputs. Even in ideal settings, machine learning methods struggle with problems that arise due to an expansion of parameter options and opacity, but these problems are limited in scope and we are optimistic about the long-term future prospects for addressing them.

## REPRESENTATION

Computation has fundamentally altered not just estimation, but also the way we think about the measurement of the variables we study. Some of these changes are conceptually straightforward and use computation to automate basic human tasks. For example, in the field of computer-assisted text analysis, machine learning algorithms are used to mimic human coders and classify documents into pre-specified categories, identify passages of copied text (Grimmer and Stewart, 2013; Wilkerson et al., 2015) and classify text based on its complexity (Benoit et al., 2018). We focus this section on approaches to measurement that leverage unsupervised

machine learning and representation learning (Bengio et al., 2013).

Unsupervised learning is an area of machine learning that is less focused on prediction and more focused on dimension reduction and classification. The mathematical goal is to compress a high-dimensional observation into a low-dimensional representation while preserving as much information as possible. For example, we might represent a legislator's voting record by a single number, which stands in for the full set of votes in a given legislative session. The social scientist then makes an important conceptual move: interpreting and naming this dimension 'ideology'. This basic idea has been cross-applied to survey analysis (latent class analysis, factor analysis), text analysis (topic models, scaling, word embedding), voting patterns (ideal points) and networks (latent spaces, community detection). The interpretation of latent structure is not new (factor analysis is more than a hundred years old) but computational power has extended the reach of these tools.

It is important to acknowledge that the label that we place on the latent structure is an *ex post* interpretation and does not necessarily guarantee verisimilitude. For example, ideal point algorithms measure 'ideology' not because they have access to a notion of what ideology is, but because the dimension which captures the most variation in votes may be related to ideology. This emphasizes the point that the interpretation is not justified by the method; rather, it is guided by theory and validated by further empirical tests. To draw an example from the text analysis literature, the Wordfish model (Slapin and Proksch, 2008) introduced a means to analyze left-right positions based on party manifestos. However, nothing in the method entails that the method captures ideology in documents; in general, it will only do so when ideology is the dimension of maximal variation in the text themselves. In demonstrating this point, Grimmer and Stewart (2013) show that applying Wordfish to a corpus of US Senate

press releases does not return a measure of ideology at all (and in fact even fails to separate press releases by party). This is not a failure of the method, just a reminder that the interpretation is a distinct and difficult step.

What then are we to do? Whether the representation involves latent classes in a survey, topics in a document or communities in a network, it is important to recognize that the phenomenon being captured by the latent structure is different than the parsimonious label we put to it. Take for example a topic model with a topic we choose to label ‘economics’. The ‘economics’ topic is actually a distribution of weights over the entire vocabulary (containing often tens of thousands of words). This is at once substantially more complex than the five to ten words that we might display in a figure for the reader and substantially simpler than a human understanding of economics as a field. The name may evoke in the reader the idea that the measurement instrument contains things the topic doesn’t capture and the topic may pick up much more than the reader believes. There are better and worse ways to handle this conceptual gap between the label and the reality, but we echo the call in Grimmer and Stewart (2013) for a substantial focus on validation (not just in text applications but in all uses of unsupervised methods). Unfortunately, as these methods have become more routinized, the extensive validations that were present in early work (for example Grimmer, 2010) have become less rigorous.

It may be helpful to think of the results of (particularly unsupervised) machine learning models for representation as producing a kind of ‘found data’. Much of the data we analyze in the social sciences comes from academics designing a data collection procedure and creating a measure (for example, designing a survey question and then fielding the survey). Increasingly, we are turning to more instances of found data – administrative records, digital trace data and other forms of data that were collected for a purpose different than our own research. These data can

be useful, but it is best to approach their use with a healthy degree of skepticism and carefully investigate and validate that they measure what we hope they measure. In much the same way, representations in machine learning models are often designed to meet a certain criterion which is different than the interpretation that we later put on it.

At some level, it is remarkable that this approach to interpretation works at all. Yet, carefully validated representations have led to numerous interesting discoveries in social science. For example, Garip (2012) discovered theoretically interesting categories of Mexican migrants using cluster analysis and Catalinac (2016) used topic models to develop a theory of how electoral reform in Japan turned national policy from a focus on pork spending to foreign policy. In both cases, the representations serve an important role as measurements of theoretical concepts. What establishes the validity of these measurements, though, is not the fact that they are produced by a machine learning algorithm, but rather the careful theoretical work and subsequent validation that supports them.

### *Problem 1: Multiplicity of parameter choices*

Unsupervised machine learning techniques, as with other computational models, have many parameter choices which impact the estimates we see. We use the example of unsupervised text analysis here, although the problem is general. Denny and Spirling (2018) show that different choices of pre-processing (stemming, stop-word removal and other data cleaning tasks for text analysis) can result in learning very different topics for the same documents. Perhaps even more disturbingly, the same topic model run on the same data can produce qualitatively different answers using different starting values due to the difficulty of the optimization problem (Roberts et al., 2016).

The problem is most acute if you believe there is a single correct representation for a given document that the model ought to be

able to recover; that is, that there is a ‘right answer’. This is not generally how we think about measurement, though. There are many possible readings of a text and many different ways of organizing a text collection. In one of the earliest applications of statistical text analysis, Mosteller and Wallace (1962) analyzed the *Federalist Papers* to determine who authored them (Hamilton or Madison). This question has a correct answer: one of those two almost certainly wrote each essay, and we would expect an authorship model to be able to correctly recover the author. But consider if we were to ask a topic model to characterize what the essays are about. There is no single correct way to characterize what the different *Federalist Papers* are about, even if some interpretations are more or less useful.

A given machine learning algorithm with a given set of parameters provides access to one possible organizational structure. Social science theory takes an analyst from a set of parameters that compress the data effectively, to a substantively meaningful measure of a social or political quantity. From this perspective, a large set of parameter choices and non-unique solutions may be an unavoidable consequence of a complex and interesting world.

### ***Problem 2: Opacity of the model***

Machine learning models for representation learning that have seen use in the social sciences are often very simple. Topic models, for instance, represent a given document as having proportional membership across a fixed set of classes; for example, a document could be 60% about economics and 40% about cooking. While the topic model assumes that the document can be represented by multiple topics, the form of those topics is additive, meaning that ‘cooking’ words look the same regardless of whether they are combined with ‘economics’ or with ‘science’. More complex models that are interactive, allowing for the words associated with a topic to be different based on the topic mixture, have existed for some time

(Larochelle and Lauly, 2012), but they have not found use in the social sciences precisely because they complicate the simple interpretation of the topics. Simplicity in a representation is an important part of its virtue because it makes the measure easily understandable.

We note that our call for simplicity in representations is in contrast to our discussion of theoretical models, where we argued that simplicity should be cast aside to more closely represent the real world. However, a lack of simplicity in representation is distinct because it threatens the conceptual homogeneity of the measurement. That is, if the topic for ‘cooking’ can vary dramatically when combined with other topics, it is no longer clear that multiple documents which share the cooking label are really about the same thing. We can add more dimensions (topics) to our measurement in order to increase the complexity of the phenomena we can represent, but to improve our understanding of what we are measuring, simplicity of the individual topics is extremely helpful.

Even though the representation of the model may be simple, the inference procedures behind these methods are often quite complex. This can make it challenging for applied scholars to know what can and cannot be inferred from the model. To give a trivial example, the ordering of the topics in most topic models is unidentified (that is, you can swap topic 1 and topic 2 without changing the objective function). Thus, we would not want to try to draw conclusions about which topic was first. Other examples abound: the question of what is and is not identified has been carefully studied for ideal point voting models (Rivers, 2003) but this has not been accomplished for newer forms of unsupervised learning. As a result, we have seen numerous examples of dubious inferences drawn from latent variable models such as conclusions about the sparsity of topics in documents, the orientation of a low-dimensional projection or the magnitude in a unidimensional scaling model. In the long

term, the field will develop a more careful study of such models, but in the short term we emphasize again that validating findings with information directly from the raw documents can help avoid these kinds of issues.

The opacity of even simple models may however blind people to a basic point about representations: they will reflect the data they are trying to represent. Word embeddings are a recently popular representation of language in modern natural language processing. The embeddings learn a vector for each word in a low-dimensional space that predicts the kinds of words that are nearby (that is, in a neighborhood – see Mikolov et al., 2013). They are well known for being able to solve analogic reasoning tasks by adding and subtracting the learned vectors. For example, the analogy ‘France is to Paris as Spain is to \_\_\_\_’ can be solved by taking the vector for ‘Paris’ minus ‘France’ plus ‘Spain’. The resulting vector will be close to the correct answer, ‘Madrid’. While these analogy tasks are interesting, the real advantage is that the representations encode similarity between words that allows information to be efficiently shared. The vectors can be quickly trained on very large corpora (for example, all of Wikipedia or the common crawl of the internet) and the information-sharing leads to substantial performance improvements in downstream models.

That said, Caliskan et al. (2017) demonstrate that word embeddings show evidence of human-like biases (such as racial and gender stereotypes). This piece attracted considerable attention and prompted a sequence of papers demonstrating other biases (Garg et al., 2018). While this was surprising to some, from a social scientist’s perspective it was inevitable. Sexism and racism are pervasive in the language people use on the internet and thus representations trained on that language will reflect those associations. That is, the representation learning does not learn an ‘objective’ property of language (if that even exists), but the associations of how that language is deployed in the training corpus. In this case the opacity of the method may

have obscured a more basic truth about how the representation was constructed and what it means.

To summarize, representation learning has become a powerful method for measurement and discovery in the social sciences. While machine learning is complex in these settings and occasionally opaque, the ever-present challenges are more about the interpretations of measures than anything else. This places the challenge firmly in the theory and substantive understanding of the problem at hand.

## CONCLUSION

The future of computation models in the social sciences is bright. Increased computation has led to improvements in theoretical models, estimation and representation, as well as an expansion of the evidence base in social science (Lazer et al., 2009). To the extent that we desire more general models, new sources of data and an increased ability to predict human behavior, there is no substitute for computation. There are, however, genuine limitations and challenges to the increased reliance on computation. Computation will not solve fundamental underlying social science problems such as the need for validation in measurement or identification in causal inference. We identified two common sets of challenges: the sensitivity to parameters and the potential for opacity. In both of these cases, substantive theory is most often the best guide to making choices and producing results that are interpretable. The best use of computation thus requires an iterative process in which theory and empirical work are more closely combined.

We are also concerned that current reproducibility standards, although vastly improved in recent years, are not always adequate for the task of validating computational models. We hope that more attention

will be devoted to these issues, with a particular focus on going beyond reproducing tables in a paper and instead understanding the logic of the procedure and the role key methodological choices have in producing results. The capacity for computation will keep increasing; let's make the best use of it we can.

## Notes

- 1 Most social scientists readily understand the parameters involved in applied statistical modeling; for example, for a Normal distribution we have two parameters, the mean and the variance. The definition of parameter spaces is broader than this, however, and includes all of the choices involved in producing a mathematical model in both applied statistics and formal theory. For example, the choice of equilibrium refinement is a parameter.
- 2 It was clear at the onset of Von Neumann and Morgenstern's work that the focus on 'simple' games was a starting point and not the end point of theory: 'the discussions which follow will be dominated by illustrations from Chess, Matching Pennies, Poker, Bridge, etc., and not from the structure of cartels, markets, oligopolies, etc.' (von Neumann and Morgenstern, 1944: 47).
- 3 Backwards induction scales poorly as the complexity of the choice context increases. As the standard algorithm for 'rational' choice, it fares poorly in most settings of interest (Russell and Norvig, 2016).
- 4 In large part, the National Science Foundation's Empirical Implications of Theoretical Models (EITM) tradition in political science has yet to come to grips with this issue. EITM's original conception was that one would write down a non-cooperative game and then test it with data (see, for example, Signorino, 1999). The difficulty that persists is that the results of games are far afield from the data, complicating empirical testing.
- 5 For more on the importance of robustness in the area of political institutions, see Bednar (2008). The point raised in this work is general, however.
- 6 Backwards induction on a tree is often conflated with 'rational choice' actors. As decision-making algorithms go, backwards induction is not very efficient and does not scale well with the size of the extensive form of the game (that is, the complexity of the game – see Russell and Norvig, 2016, for an overview).
- 7 For more on this topic, see Laver and Sergenti (2011).
- 8 For an overview of the issues involved, see the EITM report generated by the National Science Foundation: <https://www.nsf.gov/sbe/ses/polisci/reports/pdf/eitmreport.pdf>.
- 9 Minimum integer weights, such as the Shapley and Banzhaf value, focus on the pivotality of parties in a bargaining or weighted voting game. Loosely, they are the smallest vector of integers that reproduce the coalitions derived from the raw weights for each actor and represent how pivotal each actor is relative to the others.
- 10 And, even if it remains exogenous, changing this assumption on proposals to one that is a monotonic function of player strength would provide a greater advantage to players with more power.
- 11 Homogeneous games have the property that all minimal winning coalitions are of equal voting weight.
- 12 Best practice is to approach computational models of this sort as Monte Carlo – parameters are varied across many (many!) trials.
- 13 To be concrete, one can focus on the proposer advantage in bargaining models as a salient example. This advantage springs from the closed rule version of Baron and Ferejohn's model and is oft-cited in the literature. But, noting the dominant empirical expectation that parties receive a strictly proportional payoff (that is, Gamson's Law), Morelli's demand bargaining model does not produce a proposer advantage. By manipulating parameters, it is possible to produce any outcome one wants; this is not a productive way to build confidence in the actual causal mechanisms underlying real-world outcomes.
- 14 The same is true of other, related endeavors such as Google's machine learning model AlphaGo, which has been able to beat the best humans on the planet.
- 15 Many areas of social science could benefit from this flexibility. For example, the causes of war are complex and depend on multiple factors, and effects may be conditional based on the historical context (see Jenke and Gelpi, 2017). Machine learning approaches are likely dominant in such applied settings.
- 16 Easy extensions such as regularization can address some of these problems. See [https://web.stanford.edu/~hastie/glmnet/glmnet\\_beta.html](https://web.stanford.edu/~hastie/glmnet/glmnet_beta.html) for a good introduction to regularization.
- 17 The logistic regression used the same set of covariates in a linear additive form. As noted in note 28, adding all two-way interactions induced overfitting and worse test-set performance.

- 18 We are glossing over the edge cases, such as linear dependence in the predictors or a number of predictors that exceed the number of observations.
- 19 There is an area of research on using machine learning to help with identification (Spirtes et al., 2000; Peters et al., 2017) by filling in unknown edges in a directed acyclic graph. These methods still involve strong theoretical assumptions and we think they are unlikely to enter into the mainstream of social science in the near future.
- 20 In R, we recommend the grf package as a starting point (Tibshirani et al., 2018).
- 21 We are not certain why prediction is not more prominent in the social sciences. It may be due to a lack of agreement on dependent variables (Spirling, personal communication) or due to the lack of coordination between theorists and empiricists (<https://www.nsf.gov/sbe/ses/polisci/reports/pdf/eitmreport.pdf>).
- 22 It is worth emphasizing that in true forecasting situations this isn't possible. Political phenomena are dynamic in a way that means models which can predict the past effectively may perform quite poorly in predicting the future (Bowlsby et al., 2019). Similarly, when phenomena are interdependent, simple cross validation is not straightforwardly applicable anyway.
- 23 It is also worth noting that feature selection usually precedes building forecasting models and this step is most often guided by theory (see Bishop, 1995).
- 24 It can be difficult to tell when a choice is particularly important. For example, there are different ways of solving the Lasso regression problem (coordinate descent, least angle regression, etc.) which will in general converge to extremely similar solutions. However, the way in which the regularization parameter is chosen can completely change the quality of the resulting model.
- 25 Non-stochastic algorithms solving non-convex optimization problems depend on the initial starting values. This important issue is generally less about randomness in the algorithm than about the difficulty of the optimization problem to be solved.
- 26 This means that the algorithm may converge to only a local optimum and not the 'true' global solution, which would further minimize the loss function on the observed data. This is not surprising given the very large size of the parameter spaces involved. The value of reproducibility is thus lessened in cases where all one is reproducing is a local optimum.
- 27 While an improvement, local approaches such as LIME still present challenges for applying models in policy settings. It is fair to say that most interven-

- tions/programs are relatively coarse and expect that the main effects of key variables are monotonic.
- 28 Causal estimands are often written as the difference between two conditional expectation functions. The estimand itself needs to be interpretable but the two conditional expectation functions don't need to be.
- 29 For example, the European Union's General Data Protection Regulation (GDPR). More generally, if we want to make policy interventions based on a model, prediction alone is not sufficient if we cannot understand the relationship between variables in the model. It is fair to say that most policy makers expect that when they pull a lever (that is, conduct a program of intervention), it has a monotonic effect – they do not expect an effect that is conditional on other (perhaps unobserved) levers or that the effect changes based on how hard one pulls.

# Learning and Diffusion Models

Scott J. LaCombe and Frederick J. Boehmke

## **POLICY DIFFUSION**

In this chapter, we provide an overview of different methodological approaches used to study diffusion and learning. In political science, studies of diffusion seek to capture interdependence across units in the spread of an idea or action, such as the adoption of a policy by a state or country, the signing of compacts or treaties, the adoption of a norm of behavior, or the occurrence of political conflict. A variety of methods has been developed to understand how such items spread, each with its own advantages and disadvantages. We will highlight the theoretical foundations of diffusion research as well as the corresponding methodologies to understand how phenomena spread.

In American politics, diffusion research often focuses on the spread of policies across states and cities. US states make an ideal unit of analysis for diffusion studies because they all operate at the same level in the same federal system. Policy adoptions also represent

easily observable, discrete events that are conducive to large-N quantitative analysis. Research in US state policy diffusion typically asks a variety of questions: why do some policies spread widely across states, countries or cities, and others do not? What makes a government innovative? Are some governments innovative in certain policy areas but not others? How do states make decisions about what states to use as a model for policy ideas? Since Walker's (1969) foundational work on policy diffusion, political scientists have become increasingly focused on understanding how policies spread from one governing body to another. Diffusion scholars want to know what makes some policies spread widely and not others (Boushey, 2010; Nicholson-Crotty, 2009). In American politics, some states, such as California and Massachusetts, are historically innovative (Boehmke and Skinner, 2012), while others, such as Wyoming and West Virginia, usually wait for others to go first before adopting a policy. Studies of American politics have

helped scholars understand what makes policies more likely to spread and states or cities more likely to innovate.

International relations and comparative politics research also consider diffusion (Zhukov and Stewart, 2013). As with researchers in American politics, scholars of cross-national diffusion recognize the role of international interdependence in the spread of political phenomena (Gilardi, 2012): the actions of one country often influence the decisions of other actors in the international system. Countries often use a combination of carrots and sticks to explicitly influence other countries to adopt their preferred policies or trade practices, or engage in a variety of other interstate behavior (Simmons et al., 2006). Research ranges from the diffusion of macro-economic policies cross-nationally (Simmons and Elkins, 2004) to the diffusion of democratic governments (Starr, 1991), government spending levels (Lee and Strang, 2006) and conflict (Gleditsch, 2009).

The prior examples illustrate that many phenomena are influenced by diffusion. But why does diffusion occur? Researchers seeking to understand the causes of diffusion rely on four widely agreed upon mechanisms: coercion, imitation, competition and learning (Simmons et al., 2006; Shipan and Volden, 2008; Jensen and Lindstädt, 2012). In this chapter, we will focus on learning. Diffusion via learning occurs when a government or other actor uses information resulting from the policy or other choices made by other actors. If those choices prove beneficial, then other governments will tend to make similar choices (Butler et al., 2017). Learning requires that policymakers are aware of both what policies other actors are adopting and the outcomes produced by those adoptions.

The primary empirical method for studying diffusion has long been event history analysis (EHA). In recent years, however, a wide variety of alternatives have emerged that can incorporate the diffusion of multiple policies and more explicitly model and account for

interdependence among observations. We will provide an overview of the following methodological approaches that have been used to study diffusion in political science: event history analysis, dyadic event history analysis, pooled event history analysis, network analysis, latent networks and spatial regression.

## THEORETICAL BACKGROUND

This section focuses on the four mechanisms of diffusion described above and briefly traces the evolution of the literature on policy diffusion, with examples from related areas (e.g., conflict, monetary policy). We recap many of the original ideas on the diffusion of innovations, starting with Rogers in 1939, and briefly trace their development in the political science literature (Weyland, 2005; Graham et al., 2013; Karch, 2007; Meseguer and Gilardi, 2009; Berry and Berry, 2007).

Despite increased attention to understandings of how innovations spread from state to state, researchers have struggled to develop tests to isolate the four theorized mechanisms of diffusion. When they do test mechanisms, researchers rarely agree on appropriate indicators to distinguish between them. A recent survey of the literature found that the ‘same mechanisms are operationalized using different indicators, and different mechanisms are operationalized using the same indicators’ (Maggetti and Gilardi, 2016: 3). Given this, researchers have effectively focused on predicting state innovativeness rather than on specific mechanisms that may cause states to adopt policies sooner (Gilardi, 2016). Four primary theoretical mechanisms have been identified: imitation, learning, coercion and competition (Simmons et al., 2006; Shipan and Volden, 2008).

The most clearly identifiable mechanism is coercion. Coercion occurs when an actor compels another to adopt a policy (Simmons et al., 2006; Berry and Berry, 2007). In international

relations, more powerful countries could pressure less powerful ones into implementing certain reforms or taking a desired action (Henisz et al., 2005). In the American context this occurs when the federal government pushes states to adopt policies, either by using a combination of carrots and sticks (often in the form of federal funds) or via Supreme Court rulings. Diffusion through coercion, unlike other mechanisms, is a vertical relationship in the US context,<sup>1</sup> which makes it easier to observe. The federal government has a clear position above the states when coercion is used. States are horizontal actors operating at the same level within the government, so none has the authority to legally force another to take an action. A similar dynamic has been studied in which US states coerce cities to adopt preferred policies, or refrain from adopting a policy the state opposes (Shipan and Volden, 2006).

The other three mechanisms mostly focus on the horizontal spread of policies across political actors, meaning that adoptions spread from actor to actor at the same level of government. Within a country this could mean spreading from state to state or city to city; in international relations it means country to country diffusion. Learning occurs when a state observes the policy outcome(s) in another state, and uses that information to make a decision on policy adoption. If that policy produced an outcome that a state desires (e.g., reduced crime), then it learns from the policies and choices of other states that have achieved that outcome and adopts the relevant components. This mechanism often occurs when a state is faced with a new problem, and is looking for potential policy solutions (Walker, 1969). Learning can also incorporate more than just policy outcomes by providing information about a policy's political effects (Graham et al., 2013; Gilardi, 2010). Butler et al. (2017) use an experimental approach to demonstrate that even when given information on a policy's success, municipal policymakers are less likely to support policies that they

ideologically oppose. Policymakers have additional considerations when deciding to adopt a policy. Is the policy politically viable? Does it produce spillover effects or negative externalities?

Learning requires not only that policymakers are aware of what other governments are doing, but that they understand the effect of their actions. The Japanese 'Economic Miracle' provided a model for other developing countries to grow their economies. Other countries, such as South Korea and Chile, successfully learned from the Japanese case by adopting similar economic liberalization policies as Japan (Simmons and Elkins, 2004). Countries that successfully followed Japan's example had to identify which policies led to the desired outcome (increased growth and development).

The next mechanism, imitation, occurs when a state looks to another state for policy ideas, but without looking at the policy outcome (Shipan and Volden, 2008). In this case, actors are adopting policies because of the other state's attributes. Mississippi may adopt a gun law first passed in Alabama not because the policy was a success, but because Mississippi looks at shared conservatism (or another aspect) between the states and follows Alabama's lead even if the policy does not have the intended effect. Similarly, urban states may look to urban states, and wealthy states to wealthy states, for policy ideas. This is done irrespective of policy outcomes. Learning focuses on the policy outcome, whereas imitation uses actor characteristics to inform policy adoption decisions.

Finally, competition occurs when states look to gain an advantage, often economic, over other actors. Incentives to innovate frequently arise from negative externalities fueled by other states' previous adoptions (Baybeck et al., 2011). Tax rates may be lowered, business incentives increased or welfare spending altered to prevent one state from gaining a competitive advantage over the others (Peterson and Rom, 1990). While learning influences decisions to adopt

policies, competition has been found to motivate post-adoption behavior. Boehmke and Witmer (2004) argue that while competition and learning often both matter for initial adoptions, future adjustments to a policy result solely from competition. States have already adopted the policy, so they need not look to other actors for information about outcomes.

Recent work attempts to focus on developing theories and implications about learning-based diffusion. The goal is typically to offer guidance about how learning might produce specific patterns of diffusion and methodological tools that could be used to detect it. One branch of this research typically relies on conditional effects – identifying circumstances in which learning is more likely and then specifying an empirical model to test for the predicted pattern. For example, diffusion by learning might be more likely to influence those that have no experience with a given policy or behavior (Boehmke and Witmer, 2004), or it might be more likely to occur among those with resources to support more careful consideration and exploration of different options (Shipan and Volden, 2008).

Theoretical work has also attempted to clarify the conditions for learning and the patterns that might result from it. These typically create opportunities for learning by making the benefits or outcomes of policies uncertain and partially revealed only by experimenting with policy choices. Volden et al. (2008) develop a formal model of policy adoption that demonstrates an incentive for potential adopters to free-ride on others by waiting to adopt in order to see how the policy plays out in other jurisdictions. This can lead to a delay in adoptions and specific patterns of adoption based on states' underlying predilection toward the policy. A related model from Callander and Harstad (2015) finds that the incentives for free riding can be reduced within a federal structure if states expect the national government to harmonize policy after a period of time. Within the context of a single decision maker, Callander

(2011) examines optimal policy search in an environment with policy uncertainty characterized by Brownian motion. This leads to certain patterns of policy search that feature stickiness and typically end once the results seem 'good enough'. This model has clear applications for policy choices by multiple units. Finally, there have been some attempts to develop empirical estimators corresponding to game-theoretic models of strategic interaction and learning. Building on the development of Quantal Response Equilibrium estimators (Signorino, 2003), Esarey et al. (2008) develop an estimator for incomplete information games that explicitly incorporates learning. Whang et al. (2013) apply a similar estimator to determine that sanctions threats do not lead to the targets updating their beliefs about the sanctioning country's resolve but rather shape the cost-benefit calculation directly.

## EVENT HISTORY ANALYSIS

Walker's (1969) research on policy innovation was quickly met by theoretical and methodological critique from other scholars in the field (Gray, 1973). Further limiting progress in diffusion research was an inability to model both internal characteristics of states (such as legislative professionalism and demographics) and external predictors (contiguous state adopters) of policy diffusion simultaneously. Berry and Berry (1990) introduced event history analysis to the discipline and provided a framework that would allow for modeling both internal and external determinants of policy adoption in the same model.

Event history analysis typically uses a logit (or probit) estimator to model the likelihood of a state adopting a policy in a given year.<sup>2</sup> The logic of the analysis was taken from medical researchers that modeled medical survival data. The 'event' would often be death, and the model would estimate the risk

of an individual dying at different in time. In policy diffusion research, the event is the adoption of a policy, and the risk is the probability of a government adopting a policy in a given year. The risk set is the sample of units that are at risk of the event occurring to them. Once a state adopts a policy, it is no longer at risk of adopting it, and is removed from the analysis.<sup>3</sup> The definition of the event can vary from state policy adoption to signing international treaties to engaging in military conflict, and is signified by a binary variable that is 1 in the time period the policy is adopted, and 0 when it is at risk of adoption but has not done so.

Scholars must consider which units qualify to be part of the risk set, how to measure the event and when units begin to be at risk. For diffusion scholars, the risk set typically begins once any actor in the risk set experiences the event. For example, if a scholar studied the diffusion of the ballot initiative process in US states (Smith and Fridkin, 2008), the risk set would initially include all 50 states. The risk would begin once the first state, South Dakota, adopts the initiative process in 1898. In 1899 the other 49 states are still at risk of adopting the policy, whereas South Dakota is not, because it already experienced the event. Each time a state adopts the initiative, it drops out of the risk set in the subsequent year. Observations that have not adopted the policy by the time data collection ends are considered right censored – they could still adopt that policy but have not done so yet.<sup>4</sup>

The event does not have to be a policy adoption, and event history analysis has been used in a variety of studies. Lektzian and Souva (2001) estimate an event history model for when a country returns to pre-sanction levels of international trade after being sanctioned by the international community. A country is at risk once sanctions are put in place and the event occurs when trade reaches its pre-sanction level. After the event occurs a country drops out of the risk set. Countries that had not yet reached

pre-sanction levels of trade when data collection finished would be considered right censored. Note that while the concept being measured is not binary (amount of trade), the event itself is operationalized as a discrete event that either occurs or does not occur in a discrete time period.

Event history analysis has long been the workhorse method for studies of diffusion in political science and has contributed greatly to how scholars understand policy diffusion (Berry and Berry, 1990; Mintrom, 1997; Balla, 2001). As Gilardi (2016) summarizes, this literature has established that diffusion occurs in a wide variety of phenomena, both within and across countries. The challenge, as he sees it (and we agree), is to move beyond cataloguing the presence of diffusion to understanding the mechanisms behind it. The policy diffusion literature, especially in the American states, has typically accounted for diffusion by including a count of prior adoptions by contiguous states (e.g. Berry and Berry, 1990). Yet a variety of mechanisms could drive findings that find support for this effect. Given data limitations on what the relevant actors know and when, scholars have often turned to identifying conditional diffusion effects to help sort out the mechanisms. For example, Shipan and Volden (2006) find that states with greater legislative professionalism – and therefore greater capacity to learn – respond to the adoption of anti-smoking laws by cities within their borders with state-level adoptions, whereas those with lower levels do not.

In addition to challenges in sorting out mechanisms, EHA presents several other drawbacks. While early studies provided important theoretical contributions to the literature, single-policy studies are increasingly providing diminishing returns (Boehmke 2009a). Scholars hoping to produce generalizable findings about broad diffusion dynamics struggle to aggregate findings from multiple event history analyses. Finally, an EHA model only somewhat acknowledges interdependence among units by focusing

on exogenous and time-lagged outcomes in other states, while diffusion scholars are explicitly arguing that actions in one unit affect actions in another. As the study of diffusion has developed and grown, a number of new methods have been used to overcome some of the shortcomings of single-policy event history analyses.

### POOLED EVENT HISTORY ANALYSIS

Pooled event history analysis (PEHA) was proposed as a way to apply the logic of single-policy EHA to multiple policies (or multiple components of the same policy) in a unified model (Shipan and Volden, 2006; Boehmke, 2009a). PEHA seeks to address the problem of interpreting a possibly wide range of findings from single-policy EHAs by estimating a single model. This allows it to identify systematic commonalities in the determinants of diffusion and innovation across policies and reduce the idiosyncrasies of each individual policy. Analyses with a large number of policies incorporate dramatically more information, which can offer a more accurate estimate of the average effect of a variable. The unit of analysis for PEHA shifts from unit-year, as in EHA, to policy-unit-year. Each policy has a separate risk set that begins when the first unit adopts a policy, just as in single-policy EHA. The difference is that a pooled EHA stacks each policy's risk set into a single model (Makse and Volden, 2011; Shipan and Volden, 2006). The dependent variable,  $Y_{ikt}$ , is still a binary indicator, coded 1 if unit  $i$  adopts policy  $k$  in time period  $t$  and 0 when it is at risk of adopting policy  $k$  but does not adopt.

This approach can identify common diffusion trends across policies, but makes the assumption of fairly homogeneous diffusion pathways across policies. Single-policy analyses have demonstrated significant heterogeneity in diffusion pathways by policies. For example, morality policies may have distinct

patterns of diffusion from non-morality policies (Mooney and Lee, 1995) while crime and law policies may diffuse differently from education policies. Republican control of a state legislature likely predicts diffusion positively for some policies, but negatively for others. As policy databases become increasingly large (Boushey, 2010; Kreitzer, 2015; Makse and Volden, 2011; Boehmke et al., 2018), the likelihood of heterogeneity among diffusion pathways increases. If scholars fail to account for this heterogeneity, then conclusions will simply be a function of the sample of policies chosen for analysis, which is similar to the problem posed by single-policy case studies. If the coefficients differ across policies, then both the coefficient estimates and standard errors will be incorrect.

To overcome this obstacle, Kreitzer and Boehmke (2016) propose running PEHAs as a multilevel model using random intercepts and random coefficients across policies or units to model heterogeneity in the baseline rates of adoption and heterogeneous effects of variables by policy. This form of PEHA seeks to find a middle ground between running separate single-policy EHA models and a single pooled model with all policies treated identically. Scholars must decide which variables merit random (or fixed) effects. Decisions should be guided by the nature of the data being used and the covariates included in the model. These models can be computationally intense, particularly when using a large number of random coefficients. When properly constructed, a multilevel PEHA acknowledges heterogeneity in diffusion pathways while still identifying common, generalizable trends across units and policies.

PEHA's ability to capture both common effects and heterogeneity can be of value for identifying whether mechanisms of diffusion, including learning, have consistent effects in a collection of policies or just within a subset of policies in the collection. That subset may be identified by the researcher and captured in the model via interactions with unit-level covariates (Boushey, 2016; Makse and

Volden, 2011; Shipan and Volden, 2006), or it may be left unspecified and detected via the estimated distribution of a random coefficient across policies, some values of which may indicate the presence of learning while others show no such effect.

Finally, although a PEHA can identify commonalities among diffusion pathways, it still can only partially recognize interdependence among observations. Monadic analysis assumes independence among observations, yet diffusion implies interdependence. Many researchers include variables to capture adoptions in other units, most often a lagged count of the number of contiguous units that have adopted the policy. Both the single-policy and pooled EHA can include external and internal determinants of policy adoption, but the analysis still seeks to explain policy adoption or event occurrence more generally. The methods we outline next represent attempts to directly model diffusion pathways at the level at which they occur.

## DYADIC EVENT HISTORY ANALYSIS

A critical shortcoming of the previous approaches is that they fail to capture the specific sources of learning. Theories of learning and diffusion examine how one unit learns from other units, but it does not necessarily learn from all other units equally. For example, a country can learn from the experiences of countries that have adopted a policy and from those of countries that have not adopted it. It may learn more from the adoption decisions of countries that have similar demographic and political environments or that face a similar scope of the problem the policy seeks to address. Learning therefore typically occurs from one unit to another, and often from multiple units in different ways. Single-policy and pooled EHA models struggle to capture the different sources of learning since they lump the influence of other units into a single variable or series of variables

(though they may be weighted according to their likely influence). They can therefore capture whether the choices of other countries influence the outcome in a single country in the aggregate, but provide little leverage on differential impacts needed to identify sources of learning and to help distinguish them from other mechanisms.

To help address this problem, diffusion scholars have often turned from monadic to dyadic structures. These have been applied extensively in the study of international conflict (Maoz and Russett, 1993b; Leeds, 2003; Danilovic and Clare, 2007) but have more recently been adapted to the diffusion framework to explicitly model the spread of policies or behaviors through the development of dyadic event history analysis. Rather than a single country (or state, city, etc.) being the unit of analysis, a dyadic approach evaluates dyads, or pairs of units. This approach allows for modeling sender and receiver states in order to evaluate the direction of the diffusion event flow (Volden, 2006). In international relations applications, the dependent variable often measures the probability of two states going to war (Maoz and Russett, 1993a; Leeds, 2003) or signing bilateral trade agreements (Elkins et al., 2006). In the case of policy diffusion, the dependent variable shifts from 'policy adoption' to 'dyadic policy similarity' where a receiver unit is either adopting a policy already present in the other unit in the dyad (Gilardi and Füglistler, 2008) or moving its policy closer, in a possibly multidimensional space, to that in the other unit (Volden, 2006).

Importantly, dyadic EHA is directional. Each dyad consists of a sender and a receiver unit. The dyad enters into the risk set once the sender has adopted the policy (see Gilardi and Füglistler (2008) for information on how to format the data). This method allows direct modeling of diffusion pathways (Boehmke, 2009b), meaning scholars using this approach are modeling diffusion itself rather than diffusion as a part of a broader policy adoption or innovation process. Hinkle (2015) uses a dyadic logit to identify signals of policy

success or failure (in this case, being ruled unconstitutional in the courts) which states consider when learning about policy solutions. If scholars can identify cases of successful policy outcomes, a dyadic approach can allow for modeling the extent to which actors are learning from previous adoptions.

While dyadic analysis offers several advantages, scholars have found theoretical and methodological issues with this approach (e.g., Erikson et al., 2014). As noted above, the dependent variable shifts from being the occurrence of the event of interest to the convergence of one unit's outcome with another unit's existing choices. Thus information on why some units tend to experience the event earlier than others is lost in favor of explaining the choices of later adopters vis-à-vis the choices of previous adopters. This may be helpful when the focus is explicitly on learning or other mechanisms but researchers need to be cognizant of the change in interpretation. For example, Boehmke (2009b) demonstrates the need to remove observations that already have the outcome in question since they are not at risk of learning in many applications of dyadic EHA. Including them risks conflating factors that influence adoption of the underlying policy with those that influence convergence between two units.

Dyadic EHA has not yet addressed the more challenging limitation that while it can capture policy convergence between pairs of states, it cannot differentiate from among a host of potential sources. That is, the dependent variable captures whether a state moves toward a set of states but its movement toward all units with the same current policy is coded the same way. Conceptually, researchers must rely on richer measures of convergence or the inclusion of lots of data to try to tease out which of the units to which a state converges matter and which may be coincidences, e.g., since they may all be converging to a single leader state at different points in time. Statistically, this creates problems since it induces correlation between the error terms as a state must be treated as converging

to all states with similar outcomes, even if it is only converging to a subset of them. The dyadic approach therefore explicitly models some interdependence among observations, but misses and can even create other forms. Compared to a monadic analysis, dyadic models may misidentify independent observations as interdependent, and thus underestimate the effect of internal characteristics on policy adoption and overstate the role of external characteristics. Finally, researchers should also address why dyads are the proper unit of analysis, and not triads, or, as we discuss in the next section, even a full network.

The dyadic approach's ability to include characteristics of both units in a pair means that it can account for features of states seeking to learn, those they might learn from, and relative features of the two (such as similarity). While this is helpful for studying all mechanisms of diffusion, it proves particularly valuable for studying learning since it offers an opportunity to account for the performance of a policy in units that already have it. The dyadic approach therefore offers great leverage for establishing that learning occurs when such measures are available. For example, Volden (2006) analyzes convergence in US states' children's health insurance programs over six dimensions and finds that states were considerably more likely to revise their policy to more closely mirror those in states that had successfully reduced their uninsured rate among poor children. In contrast to this evidence of policy learning, Gilardi (2010) finds evidence of political learning in his study of unemployment benefits in OECD countries: right wing governments are more likely to move their policies toward those of countries in which reforms have produced electoral benefits.

## **DIFFUSION NETWORKS**

Another way for scholars to incorporate interdependence among observations is to use network analysis to model event

pathways. This approach allows for a more comprehensive incorporation of interdependence than a dyadic approach by incorporating higher ordered network processes such as transitivity (Valente, 1995). Public policy research has used network analysis for decades to understand how policies spread (Coleman and Perl, 1999; Klijn, 1996; Koppenjan and Klijn, 2004; Thatcher, 1998), and international relations research has used networks to explain topics ranging from the structure of alliance networks (Cranmer et al., 2012) to international trade flows (Hafner-Burton et al., 2009). The basic assumption behind a network approach is that the behavior of an actor, e.g., the adoption of a policy, affects the behavior of other actors in the group. Network scholars argue that events flow through a network of actors. Countries make decisions to ratify a treaty or go to war based on their own characteristics and in response to other countries. Network analysis better approximates the theoretical flow of policies (Lubell et al., 2012). When the United States makes a decision to sign an international treaty, it is likely influenced by whether allies (or competitors) have signed the treaty, and its decision to sign (or not sign) likely influences other nations.

The shift to networks now means that the focus of analysis is how an event spreads, not whether individual actors or dyads behave in a particular way. In the context of policy diffusion, a tie forms between two nodes when they adopt the same policy. So in a network of US states, after the first state adopts a policy the network would have no ties because the policy has not spread. As the policy spreads to another state, a directed tie forms from the first adopter to the second, and the network continues to build as policies go from receiver to sender states. However, scholars may struggle to identify the source of policy ties. If Florida adopts a policy previously adopted by Indiana and Wyoming, should Florida receive a tie from Indiana, Wyoming, or both states? Garrett and Jansa (2015) use bill text to identify the source of a policy and

where it spreads. Their analysis reveals that interest groups can act as a policy resource. Researchers must decide what a tie means in the network, and how to determine the source of diffusing policies. A network of directed ties better mirrors the diffusion theories that policies spread from one unit to another, but there may be cases where an undirected network is the appropriate choice. Mutual defense treaties or free trade agreements imply a reciprocal relationship. Those using networks must decide how to define a tie in the network and whether it should be directed or undirected.

Network analysis presents other advantages beyond better mirroring the structure of diffusion theories. Networks have been used to identify where policies originate and how they spread through the network (Garrett and Jansa, 2015). A variety of network statistics can be used to evaluate which units are the most or least central to a unit. For example, when two countries share a similar network position (measured by structural equivalence), they are likely to compete with each other (Cao, 2010). Unless these two units were directly connected, a non-network approach would be unable to observe this higher-order relationship between actors. For example, during the Cold War the USSR and United States were the two poles of the international alliance network. They responded to each other throughout the Cold War, but did not have direct alliance ties to each other. With a network approach, unlike monadic or dyadic analyses, scholars can model how the United States deciding to join an alliance affects the alliance network for the USSR (Chyzh and Kaiser, n.d.). Network processes and statistics can provide insights into diffusion pathways that would otherwise go unobserved in a monadic analysis (Robins et al., 2012).

Beyond network statistics, estimators such as QAP or ERGMs can be used to determine the correlates of ties between the states (Cranmer and Desmarais, 2010). These models can be very powerful for understanding

policy diffusion because they use a combination of network structure and edge-level attributes (such as population differences or trade between units) to model diffusion (Robins et al., 2012). This approach directly mirrors theories of diffusion that argue that both external and internal characteristics contribute to diffusion and policy adoption. Notably, ERGMs include the dyadic logit as a special case in which there are no network-level effects. This analysis takes a similar approach of a dyadic logit but adds network dynamics to the model of nodal, edge and system level variables. These network effects can potentially be used to distinguish between learning, emulation and competition (Maggetti and Gilardi, 2016).

ERGMs allow researchers to include features of the network structure as part of the explanatory model. For example, Thurner and Binder (2009) use an ERGM to understand how the structure of the European Union affects the network connections between high ranking bureaucrats in member states. They test if the institutionalization of the European Union replaced existing networks of communication between nation states. The ERGM they estimate includes both network statistics (reciprocity) and edge-level covariates (economic interdependence) to predict communication ties between policymakers. They find that the structural components of the network and the edge-level covariates have a significant relationship with the existence of communication ties between policymakers. ERGMs allow researchers to leverage both network structure variables and edge covariates to understand how actor characteristics and the structure in which they are nested affect diffusion pathways.

Diffusion can also be viewed as occurring within an existing network structure. Examples of this abound for exogenous networks such as contiguity, ideological similarity or trade. In monadic models, researchers often include the network-weighted sum of policies or behaviors in other states to explain occurrence in the current state. In

dyadic models such pairwise features may be included as dyadic covariates. But in some cases one might worry about coevolution of the behavior of interest and the transmission network. For example, Chyzh (2016) argues that states' human rights policies depend on their position in the international trade network, but also contends that position in the network depends on human rights policies since states often forego trade with countries whose protections they deem insufficient. To address this, Chyzh (2016) employs a coevolutionary actor-oriented longitudinal-network model (see, e.g., Steglich et al., 2010). This estimator, referred to as RSiena, models the network connections simultaneously with a behavioral outcome, such as human rights policies, at the nodal level within that network. Both equations can include features of the network. The results indicate that states that rely more on indirect trade links (trading through mutual partners rather than directly) tend to score lower on human rights and that states that score lower on human rights have few direct trade connections to other states. Thus the network shapes policy, but policy also shapes the network.

While network models have been used to study diffusion generally, to our knowledge no published research has used an ERGM to identify learning in a policy diffusion network. However, researchers could take a few approaches to identify learning in the network. Many of these will mirror the options for a dyadic logit since they share the same underlying structure of modeling links between units, but an ERGM allows researchers to study additional features related to network structure. Researchers could evaluate how signals of success or failure alter the diffusion network, e.g., do states with successful policy outcomes take a more central role in a diffusion network? Do we see a greater level of transitivity when the policy is deemed a success? Are isolates (states that do not have diffusion ties to any state) less common when a policy's success is clear? Additionally, different diffusion mechanisms imply different

network connections. Competition suggests reciprocity between nodes as they act and react to the other's behavior. Learning, on the other hand, should mostly be a uni-directional relationship because actors are responding to the policy success of a previous adoption. Researchers can include network statistics to identify these types of connections between actors. We believe a network approach could be a fruitful avenue for identifying learning in diffusion.

One of the drawbacks of the network approach in general centers on how to pool results. Almost every policy will have a unique adoption network when considering both how and when policies spread. Different policy areas may also have different policy leaders. This presents a similar dilemma to the single-policy event history analyses discussed in an earlier section. Different networks will likely result in different conclusions. Without a systematic way to aggregate findings, scholars must assume that the chosen diffusion network is representative of general trends in the diffusion network if they wish to make generalizable claims about diffusion networks.

## LATENT NETWORKS

More recently, network scholars have begun to use latent network analysis to examine diffusion pathways. Rather than studying observed diffusion networks, this approach utilizes data from a large number of such networks to estimate a single, underlying latent network that contains the ties that best explain the observed diffusion patterns. A latent network approach operates in a similar way to latent factor analysis by using observed policy cascades to infer an optimized network of ties between units (Gomez-Rodriguez et al., 2010). The network is constructed using an algorithm that infers diffusion ties based on the number of cascades in which state  $i$  adopts before state  $j$ ,

the length of time between these adoptions and how well state  $i$  adoption predicts state  $j$ 's adoption as opposed to that of other states that tend to adopt before  $j$ . Latent networks are not directly observed, but represent the most likely network of diffusion ties given the policy adoption networks used to infer the network. Rather than predicting the adoption of a single policy, researchers estimate latent diffusion ties, which can then be analyzed using appropriate models, such as dyadic logit, QAP logit or an ERGM.

Desmarais et al. (2015) apply this algorithm to a sample of more than 100 policy adoption cascades in the American states to recover a latent diffusion network. The ties represent the most likely diffusion connections between states. Their results reveal a network that evolves over time based on a 40-year rolling window of adoption data. With 100 years' worth of data, this produces 60 estimated networks. This means that scholars can estimate and then model how diffusion networks evolve over time. To study this evolution, Desmarais et al. (2015) employ a QAP logit model to find that directed ties in the latent state policy diffusion network depend on theoretically relevant dyadic features such as geographic distance, ideological similarity and political similarity. They also find that more populous states send out more ties and receive more ties.

Because the networks cannot be directly observed, scholars must carefully consider how they infer a network, including what observed diffusion events to use, how quickly the influence of an adoption should decay over time, how dense the network should be and what the appropriate universe of cases is when deciding nodes in the network. Each of these decisions will determine what the network looks like. The network will be less dense if sparse policy adoption networks are used to construct the latent network. Additionally, the longer the window of time for previous policy adoptions to influence the current diffusion network, the denser the

network. When constructed appropriately, latent networks are representative of the general diffusion network in a given era. Even though there is still only a single network produced for a given time period, scholars can feel more comfortable that the network is generalizable. Additionally, latent networks represent more than just observed adoption, but also the flow of information and other factors that predict diffusion between units.

Latent networks allow for a variety of diffusion studies. Network descriptives can be used to identify the leader and follower states, as well as the most central actors in a diffusion network. The network can be the dependent variable, where scholars analyze the determinants of ties between units in a network. This approach allows for examining the competing roles of state characteristics and network forces such as triadic closure or in-degree in the same model. Alternatively, these networks can be utilized in event history analyses as a measure of the external diffusion influences on policy adoption. In much the same way that adoptions by contiguous neighbors or ideologically similar states increase the chance of adoption in a given state – whether in a monadic, dyadic or network analysis – past adoptions by latent sources likewise predict adoption (Boehmke et al., 2017). Once the network has been produced, scholars can proceed using the same types of network analysis that they would use for other types of diffusion networks, including ERGMs, QAP and other model specifications where the latent network is used as either an independent or dependent variable to understand the structure of ties between states. Notably, in contrast to the dyadic EHA models discussed earlier, the latent network approach facilitates analysis of specific links since it leverages the spread of many policies to determine the presence of a diffusion tie between all pairs of states.

Political scientists have just begun to explore the ability to estimate latent networks for studying policy diffusion. An important next step will be using the estimated

networks to help study the mechanisms of diffusion, including learning. While they require a considerable amount of data and optimization, they also offer some advantages. Most importantly, they offer a direct estimate of a tendency for diffusion to occur between all pairs of units, possibly varying over time. Rather than relying on the information contained in the adoption of a single or small number of policies, researchers can obtain direct estimates of the item of interest: policy ties between units across a large number. These ties can then be modeled with variables intended to more directly capture the mechanisms of diffusion.

## SPATIAL ECONOMETRIC MODELS

Spatial econometrics offers a potential middle ground between dyadic analysis of ties in the diffusion network and monadic analysis of the choices by individual units. It allows the researcher to capture a variety of dependencies between units, both endogenous and exogenous. It does so by requiring the researcher to specify a spatial dependency matrix indicating how each unit connects to all other units. This matrix is essentially a representation of a continuous-valued network. In fact, most existing diffusion studies already use a version of spatial econometrics via the inclusion of a lagged count of adoptions in contiguous units or related measures. The lagged count comes from the multiplication of the contiguity matrix for all units by a vector capturing the presence of the policy in every unit. Since the presence of the policy variable is usually lagged, this is just a case of spatial regression with an exogenous lag.

Spatial econometric methods offer much more than this, however. They can accommodate any matrix of connections between units, whether geographically based or not. This feature proves critical for studying diffusion mechanisms since many of them are

not based on notions of geography: fashion may diffuse through friend networks or via social media ties; policies may diffuse via ideological or problem similarity; or conflict may spread through terrorist networks or ethnic groups that straddle international borders. One can include a sum or weighted average of any feature of other units as an exogenous influence by specifying the spatial weights matrix (Neumayer and Plümper, 2016); more than one such feature can be included via multiple weights matrices.

Even more powerfully – and much less commonly utilized in the study of diffusion – spatial econometric models permit capturing endogenous dependencies via these spatial weights matrices. Rather than include the weighted value of an exogenous covariate, one can include the weighted value of the error terms or, even better, of the outcome variable. Conceptually, the latter means that spatial autoregressive (SAR) and spatio-temporal autoregressive (STAR) models can capture the simultaneous way in which the outcome in one unit explicitly depends on the outcomes in other units and within the same unit over time (Franzese Jr and Hays, 2007). This makes them valuable for studying certain forms of diffusion, including those based on contemporaneous learning or strategic interactions.

An early application of STAR models to policy diffusion concerns the question of welfare benefits in the American states. Longstanding concerns about a race to the bottom in which states work to keep their benefits levels below those of nearby states to thereby avoid attracting too many potential recipients make this a strong candidate for spatial analysis. Rom et al. (1998) conduct just such an analysis with contiguity as their spatial weights matrix and find evidence of positive spatial correlation: an increase of \$100 in benefits per person in a state leads to a contemporaneous increase of \$27 in its neighbor (which is then compounded over time and across space). A useful comparison can be made with Volden

(2002), which conducts an EHA model for a binary measure of benefit increases and accounts for changes in neighboring states via a time-lagged exogenous variable, reaching similar conclusions. In contrast to these findings, Franzese Jr and Hays (2006) find evidence of free riding in European countries' support for labor market policy, with a negative spatial correlation that produces a drop in domestic spending when neighboring states increase their spending.

Spatial autocorrelation arises from a number of possible mechanisms (Franzese Jr and Hays, 2007): interdependence, unmodeled heterogeneity (in the form of spatially correlated random shocks or omitted variables) and selection (e.g., via homophily in the connectivity matrix). Interdependence includes the common forms of diffusion such as learning, emulation, competition and coercion. As with the other models we have discussed, it is often difficult to determine which mechanism undergirds a finding of spatial correlation (though see Mitchell (2018) for a recent proposal for how to do so). As with the EHA model and its variants, scholars often turn to conditional interactive effects to identify learning. For example, Arel-Bundock and Parinandi (2018) study tax competition in the American states and find that corporate tax policy in states with better resourced (and therefore more able to learn) legislatures more closely tracks policy in connected states.

## MOVING FORWARD

Each of the methodological approaches outlined in this chapter has its trade-offs for studying policy diffusion and innovation. There has been tremendous growth in the diffusion literature over the past 30 years, particularly after Berry and Berry (1990) introduced EHA to political scientists and noted its strengths in incorporating internal and external characteristics to determine

when events occur. This offered a way to test for the influence of diffusion mechanisms while accounting for unit-level differences in the probability of an event occurring. As the field has moved forward greater emphasis has been placed not just on understanding whether diffusion occurs, but on testing and identifying the role of specific mechanisms.

These demands have pushed researchers to develop and apply new empirical methods for studying diffusion. EHA was introduced nearly 30 years ago, but none of the other methods discussed here was used much, if at all, just over a decade ago. This new menu of estimators offers diffusion scholars a range of options for identifying and testing for these mechanisms. As we see it, they fall broadly into two groups. The first, including PEHA, dyadic EHA and latent network estimation, provides opportunities to leverage information from large data sets to identify common and possibly small diffusion effects while allowing for heterogeneity across events. The second group, including ERGMs, RSiena and spatial econometrics, provides estimators designed to explicitly capture endogenous interdependencies in diffusion networks.

On top of these differences in their orientation towards data and diffusion processes, each of these methods has its own strengths and weaknesses. The choice of which to use may therefore depend on the questions asked or the types of analyses needed. And as many of them have only relatively recently been applied to studying diffusion, work remains to be done to more fully determine their strengths and weaknesses and adapt them to diffusion applications to maximize the former while minimizing the latter. Ultimately the ability to identify the presence of a distinct mechanism of diffusion, such as learning as opposed to emulation, requires careful thinking about how theoretical concepts map into measures and which methods provide the most appropriate features for estimating them.

## Notes

- 1 While horizontal coercion is common in international politics (countries using their economic or military clout to force others to comply), the constitutional context of the United States makes horizontal coercion rare.
- 2 Continuous-time duration models like the Weibull or Cox may also be employed (Jones and Branton, 2005).
- 3 For some policies, re-adoption of a policy is possible, but generally researchers remove an actor once the event, however defined, occurs.
- 4 See Box-Steffensmeier and Jones (2004) for a guide to the application and estimation of EHA.

# Conceptualization and Measurement: Basic Distinctions and Guidelines

Gerardo L. Munck, Jørgen Møller  
and Svend-Erik Skaaning

One of the key aims of the social sciences is to describe the social world. Descriptions are one of the most powerful products of the social sciences. Based on descriptions, countries are ranked as being more or less democratic or respectful of human rights or corrupt; the level of violence over time within and between particular groups is gauged; political parties are compared on a left–right spectrum; citizens are held to have more or less liberal or religious values, and so on. Much of what we know about the social world is due to research that seeks to provide descriptions. In addition, research oriented to offering descriptions provides important input for research that aims at explaining the social world.

In this chapter, we offer an overview of the issues involved in producing the data that are used in descriptions. The overview is divided into three main sections. We begin by focusing on the task of conceptualization. *Concepts* play a fundamental but frequently unappreciated role in the production of data.

We clarify the components of concepts, discuss how concepts can be organized and distinguish among different kinds of conceptual systems. We next turn to measurement, distinguishing between the production of *data on indicators* and *data on indices*. The notions of indicators and indices are sometimes used interchangeably. However, the tasks and choices involved in producing data on indicators and indices, respectively, are distinct and better addressed one at a time. Thus, in the second section we focus on data on indicators, and address the task of selecting indicators, designing measurement scales and collecting data. Subsequently, in the third section, we turn to data on indices, where we develop a key distinction between two kinds of indices – those that combine data on multiple units and those that combine data on multiple indicators measuring different properties in one unit – and discuss key options concerning these two kinds of indices.

Data can be good or poor, and we are also concerned with ensuring that data are of high

quality. Thus, we discuss not only what is involved in *producing* data but also what is involved in *evaluating* descriptions. Ideally, as we suggest, evaluations would feed back into the production of data, but frequently evaluations are carried out as a post-production task. To this end, we discuss various criteria that are relevant to an evaluation of data. However, because this chapter focuses on concepts and the link between concepts and measures, and does not provide a full discussion of measurement, we emphasize the criterion of validity and conceptualize it more broadly than is customary.

We provide many examples to illustrate our points about methodology. However, one of our recurring examples is democracy. This is a concept that has been the center of attention in much of the methodological literature.<sup>1</sup> Moreover, it is a concept that is central to a broad body of substantive research in political science and other disciplines.

## CONCEPTUALIZATION

Concepts are the building blocks of the social sciences, as they are of all sciences. There is no theory without concepts, there is no description without concepts, and there is no explanation without concepts. Thus, concept formation – conceptualization – has logical priority in research because it is a key input in all subsequent steps, including those concerned with the production of data. Moreover, though quantity and quality are mutually complementary, every quantitative concept presupposes a qualitative concept. Indeed, as Sartori (1970: 1038) put it, because we cannot measure something if we have not specified its meaning, ‘concept formation stands prior to quantification’. Or, more broadly, as Bunge (1995: 3; 2012: 122) argues, ‘concept formation precedes empirical test’ and ‘in concept formation quality precedes quantity’ (see also Lazarsfeld and Barton, 1951: 155–6). Thus, researchers

need to focus on the formation of concepts and to recognize the qualitative foundations of all research.

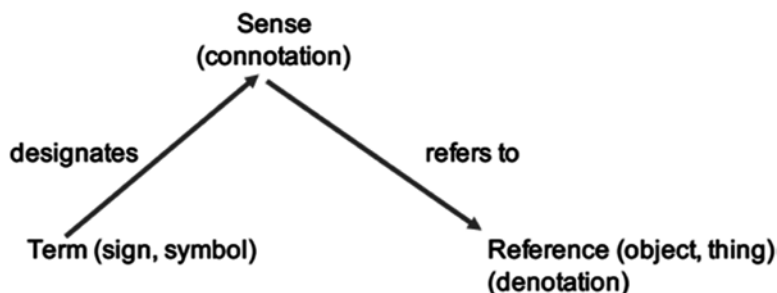

There are no rules on how to form a concept, just as there are no rules that can be followed to create a theory. Concepts are formed through a combination of induction and deduction. As suggested by Adcock and Collier (2001: 531–3), the decisions about a concept that is to be used in the social sciences are frequently made in light of a dialogue with ‘the broader constellation of meanings and understandings associated with a given concept’, or what they label the ‘background concept’. Moreover, the link between conceptualizing and theorizing is very close: as Kaplan (1964: 53) notes, ‘proper concepts are needed to formulate a good theory, but we need a good theory to arrive at the proper concepts’. Concept formation, like theory building, is largely an art.

Nonetheless, the product as opposed to the process of concept formation can surely be assessed. Concepts can be clear or vague. Concepts can be well formed or poorly formed. Concepts can be more or less elaborate and systematized. Indeed, there are various features of concepts that are used to distinguish good from bad concepts. At the very minimum, it is important to be clear about the various parts of a concept and the ways in which the sense or meaning of a concept is organized, which are two matters we address next.

### *Term, Sense and Reference*

A concept consists of three interrelated elements. The first is a *term*. This is a sign that designates the *sense* or connotation of a concept – the part of the concept that is frequently understood as its meaning – and the latter in turn refers to the objects that are included in the *reference* or denotation of a concept (see Figure 19.1).

Most of the discussion about concepts rightly focuses on concepts’ *sense*, which is

**Figure 19.1 The parts of a concept: term, sense and reference**

*Note:* This depiction is an adaptation of what is commonly known as the semantic triangle or the Ogden/Richards triangle (Ogden and Richards, 1923: 11).

given by the conceptual attributes that represent properties of objects and the relationship among conceptual attributes. Indeed, the meaning of a concept can largely be taken to be conveyed by a concept's sense, and debates about concepts focus mainly on this part of a concept. For example, debates about the concept of democracy since the work of Schumpeter (1942) hinge on matters such as what the conceptual attributes of democracy are and what the relationship among conceptual attributes is (Collier and Levitsky, 1997). We discuss this aspect of concepts more fully below. However, first, a few brief comments regarding a concept's term and reference are in order.

First, the role played by the term of a concept might seem rather simple. But Dahl's (1971) effort to introduce the term 'polyarchy', so as to avoid the possible confusion created by the multiple uses given to the term 'democracy', shows that terminological issues are not trivial. Indeed, there are many terms that are given different meaning. Furthermore, understanding how a term is used requires some knowledge of the broader semantic field in which it is embedded. For example, though the term 'regime' has a different meaning in the fields of comparative politics and international relations, the difference is clarified once the term is placed within the semantic field of these two fields of research. Thus, while terminological

matters are not the most important ones, they certainly deserve some attention (Sartori, 2009 [1975]: 61–9; 2009 [1984]: 111–15, 123–5).

Second, the idea of the *reference* of a concept needs to be clarified at the outset. A concept's reference (aka the domain of a concept) is all objects to which a concept refers and is thus related to the unit of analysis of a study. In contrast, a concept's *extension* is those objects which actually have certain properties. It is important to grasp the distinction between reference and extension, and the relationship between them. Though statements about reference rely on theoretical concepts and do not presuppose that of truth, statements about extension rely on empirical concepts and do presuppose that of truth. For example, it is one thing to say that democracy is a series of properties of political communities and another to say country *x* is a democracy. Indeed, the latter is an empirical claim, which could be factually true or false and can only be addressed once data has been collected, and hence is not strictly a conceptual matter (Bunge, 1974a: ch. 2; 1974b: 133–53; 1998a [1967]: 73–80).<sup>2</sup> Thus, we start our discussion here by considering theoretical concepts and purely conceptual operations, before turning to empirical concepts and empirical operations, such as the construction of indicators and data collection.

**Figure 19.2** The structure of a concept: levels and relationships

### ***The Attributes and Structure of a Concept***

Turning to a more detailed discussion of a concept's sense, it is critical to recognize that a concept's sense is conveyed by (i) the conceptual attributes that represent properties of objects and (ii) the relationship among conceptual attributes or, for short, the structure of a concept. For this reason, the meaning of concepts is not fully conveyed by a simple listing of conceptual attributes, a common feature of definitions.

Listing the defining attributes of a concept is useful. It puts the focus on what conceptual attributes should be *included* in a concept. Moreover, inasmuch as a definition also clarifies what conceptual attributes should be *excluded* from a concept (even though they are included by some scholars), such an exercise is critical. For example, one of the ongoing concerns in the discussion about the concept of democracy is how to strike the right balance between expanding the concept of democracy beyond the sphere of elections. This can, for example, be done by adding attributes considered to be part of democracy (e.g. horizontal accountability), and expanding the concept of democracy in such a way that what might be considered extraneous attributes are included in the concept of democracy (e.g. the economic equality of citizens) (Munck, 2016).

However, it is important to note that any such list offers an incomplete sketch of a

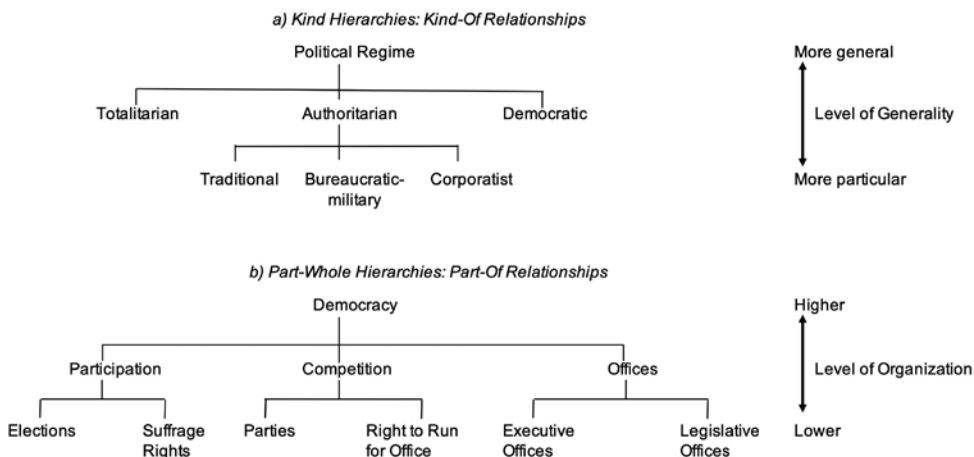

concept. Indeed, inasmuch as more than one conceptual attribute is posited, it is necessary to inquire about the structure of a concept, which is given by the relationships among conceptual attributes at the same level (horizontal relationships) and at different levels (vertical relationships) (see Figure 19.2). That is to say, the meaning of a concept might not be conveyed by each attribute taken individually, in an additive manner, and the structure of a concept could be key to its meaning. Thus, to fully and correctly grasp the meaning of a concept, it is crucial to appreciate that concepts can be – indeed, usually are – *conceptual systems*, which in turn are part of larger conceptual systems or semantic fields.<sup>3</sup>

It is also important to distinguish among different kinds of conceptual systems that connect and systematize multiple concepts that share, at least partially, their sense or their reference.<sup>4</sup> The simplest form is the *typology*, which unifies a series of concepts of different connotation but at the same level and of the same scope by proposing the underlying dimensions of multiple concepts. An example of such conceptual systems is Aristotle's (1995 [c. 330 BC]: Book III, chs 6 and 7) classical typology of political regimes, which relies on the underlying dimensions of the number of persons who exercise power and the ends they seek. Another is Dahl's (1971: 7) modern typology of political regimes, which relies on the underlying

**Figure 19.3 Conceptual systems I: typologies**

Source: Dahl (1971: 7).

**Figure 19.4 Conceptual systems II: two hierarchical structures**

Note: The example of a kind hierarchy draws on Linz (1975); the example of a part-whole hierarchy draws on Schumpeter (1942), Dahl (1971), and Przeworski et al. (2000).

dimensions of contestation and participation (see Figure 19.3).<sup>5</sup>

A different, and more complex, conceptual system is the *taxonomy*, which connects concepts at different levels in a hierarchical structure, in one of two ways. One hierarchical structure, sometimes called a *kind hierarchy*, organizes concepts that partition collections of objects into groups and subgroups, and yields a classic taxonomy. An example of this kind of conceptual system is Juan Linz’s (1975) encompassing and nuanced classification of 20th-century

political regimes (see Figure 19.4, panel a), which are defined in terms of the underlying dimensions of pluralism, ideology, mobilization and leadership. But there is another hierarchical structure, sometimes called a *part-whole hierarchy*, that organizes concepts that decompose wholes into parts and also connects parts to the whole.<sup>6</sup> A classic example of such a hierarchy is the conceptualization of democracy that decomposes a whole – democracy – into parts at various levels of organization (see Figure 19.4, panel b).

## Evaluation

Concepts are not true or false. Nonetheless, not all concepts rest on an equally sound foundation; some have been carefully elaborated and justified, while others are merely stipulated without much in the way of reflection. Without making any claim to exhaustiveness, we propose a set of criteria to assess whether concepts are good or bad.

Most basically, concepts have to be *intelligible*. This means that we should be able to answer the following questions: what is the concept designed by the term or symbol used for? What are the conceptual attributes? What is the structure of a concept, that is, what are the relationships among conceptual attributes? What is the reference of a concept?

Several criteria regarding a concept's term can be highlighted (Sartori, 2009 [1975]: 61–9; 2009 [1984]: 111–15, 123–25, 132–3; Gerring, 1999). Most critical is the criteria of *terminological univocality*, that is, the avoidance of terminological ambiguity introduced through the use of homonyms, terms with multiple meanings, and synonyms, multiple terms with the same meanings. Other criteria concern the *fit* of the term with the terminology used in prior research, and the *familiarity* and *resonance* of the term.<sup>7</sup>

Another criterion is *logical formation*. Inasmuch as any concept consists of more than one conceptual attribute, it is important to ask whether the proposed conceptual system fulfills, for a given domain, two logical requirements. First, they should be mutually exclusive, meaning that no concept or conceptual attribute at the same level overlaps with the meaning of another concept or conceptual attribute; and they should be collectively exhaustive, meaning that no concept or conceptual attribute that is part of a conceptual space is excluded. In addition, inasmuch as any concept consists of more than one conceptual attribute at different levels, whether or not the conceptual attributes

are logically organized by level of generality or organization is a key consideration (Lazarsfeld and Barton, 1951: 156–9).

Yet another key criterion, which deserves some elaboration, is *conceptual validity*, understood here with reference to the sense of the concept and both the conceptual attributes and the structure of a concept.<sup>8</sup> The inclusion and exclusion of conceptual attributes is a key decision in the formation of a concept. The same goes for any decision regarding the relationship among conceptual attributes. And each decision can and should be assessed in terms of the extent to which the decision is theoretically justified.<sup>9</sup>

It bears noting that the assumption underpinning this criterion – that concepts can and should be assessed in light of their theoretical justification – is not universally accepted. On the one hand, many scholars posit that a number of concepts, and especially those that have an obvious normative connotation, are ‘essentially contested’ and that they will always remain ‘open’ in the sense that a research community will never agree on a definitive definition (Gallie, 1956; Gray, 1978). From this relativist perspective, any claim that a certain concept is more theoretically justified than another can be portrayed as arbitrary or subjective. This perspective could even lead to the view that since disputes over the meaning of concepts cannot be resolved, any effort at measurement is futile, in that claims about what is measured cannot be settled.

However, it is not obvious that, for example, democracy, seen as the ‘essentially contested’ concept *par excellence*, merits such a characterization (Bobbio, 1989: ch. 4, 2003: 42; Beetham, 1994: 27; see also Arblaster, 2002: 6–10). Though disagreements about the concept of democracy persist, it is clear that the research by Schumpeter (1942) and Dahl (1971) has led to widespread consensus about the core meaning of democracy in research on democratization (Munck, 2009: 16–23, 2016). The same can be said about other concepts with strong normative

resonance. For example, Waldron (2002) observes that while the institutional or political arrangements required by the rule of law – another concept frequently characterized as essentially contested – are subject to disagreement, there is actually considerable consensus about its basic formal–legal requirements, such as that laws are prospective, open and clear and that there is congruence between official action and declared rule (see also Collier et al., 2006: 228–30; Møller and Skaaning, 2014: ch. 1).

On the other hand, a common epistemology, empiricism, holds that knowledge only concerns observable properties and that empirical concepts but not theoretical ones are acceptable (Bridgman, 1927; Carnap, 1936, 1937). From this perspective, the suggestion that concepts could be assessed in light of theory would be deemed unjustified and all work on theoretical concepts would be no more than a distraction from, and even a hindrance to, the real work of measurement (King et al., 1994: 25, ch. 2, 109–10). However, the distinction between, and mutual irreducibility of, theoretical and empirical concepts is well established (Kaplan, 1964: 54–60; Sartori, 2009 [1975]: 83–4; Laudan, 1977: chs 1 and 2). And the shortcomings of the empiricists' endeavor to reduce the theoretical to the empirical are evident (Bunge, 2012: ch. 13). Indeed, the main concepts in the social sciences are theoretical as opposed to empirical. Key examples are society, economy, class, ideology, politics, state, power, rights, constitutionalism, democracy, rule of law, welfare and peace. Few scholars are willing to remain silent about these concepts.

In short, these two extremes can and should be avoided. *Contra* Gallie, many key concepts have been theoretically developed enough to have some shared meanings, and measurement does not have to wait until all conceptual disputes are resolved. *Contra* empiricists, the banishment of theoretical concepts is simply a self-defeating position that is hard to consistently maintain. Thus,

the validation of concepts by reference to theory is both viable and central.

## MEASUREMENT I: DATA ON INDICATORS

Turning from conceptualization to measurement opens up a whole new series of challenges. Theoretical concepts refer to at least some imperceptible facts. Thus, inasmuch as social scientists seek to describe and explain the world, they must address some complicated empirical operations involved in measurement (see Figure 19.5). First, to bridge theoretical concepts and facts, they must develop *indicators*, which relate observable properties to unobservable ones, and propose how to draw distinctions based on indicators. Second, to produce data, they must engage in *data collection*, which assigns (qualitative or quantitative) values to indicators in light of observables about objects. In other words, they must design and use measuring instruments. Thus, though any attempt to produce data must begin with a clear idea of *what* is to be measured, the distinct issues involved in *how* to measure some theoretical concept –

Figure 19.5 The concept–fact interface

the development of indicators and, relatedly, of measurement scales, and data collection and coding – deserve scrutiny.

### **Indicators**

The general challenge in developing indicators, sometimes called operationalization, is to build a bridge between unobservables and observables, that is, to link theoretical concepts that refer to facts about properties of objects with empirical concepts, an observable property of the same object (Bunge, 1998b [1967]: 192–6).<sup>10</sup>

Due to the nature of indicators, probably the hardest challenge in the design of a measuring instrument relates to what is usually called *content validity* – the extent to which one or more indicators capture the correct and full sense or content of the concept being measured (Adcock and Collier, 2001: 536–40). The goal of measurement is to generate data that can be used to evaluate the truth of claims about facts (e.g. the US is a democracy in 2019). But data will be useful for this purpose only inasmuch as any data collected on some indicators can be linked back to the concept (e.g. the concept of democracy in this example) used in a factual claim. Building such bridges is anything but an easy task, especially when the concept of interest is multidimensional, that is, has many conceptual attributes.

This task is made harder because researchers also have to be concerned about measurement *equivalence*, the extent to which an indicator captures the same sense or content of the concept being measured in different contexts (Przeworski and Teune, 1970: chs 5 and 6; Adcock and Collier, 2001: 534–6; Davidov et al., 2014). Often it is not obvious that the same indicator will have similar meanings in different countries, for different persons and in different time periods. This means, first, that it is often necessary to use several indicators to measure a concept in order to capture different nuances

of the concept and increase the reliability of any measures, and second, that different contexts sometimes call for different indicators to capture the same facts. This can be understood by invoking the distinction between common and system-specific indicators (Przeworski and Teune, 1970: ch. 6). Common indicators work in the same way across different contexts, while system-specific indicators vary across contexts but are functional equivalents, meaning that they are in principle substitutable. For example, actions considered corrupt in one place are considered appropriate behavior elsewhere, so asking similar questions about corruption will not provide equivalent measures. In survey research, questions should preferably have the same meaning for all respondents, but linguistic, cultural and other differences make it difficult to establish measurement equivalence (see also Locke and Thelen, 1995; van Deth, 1998).

At the same time, the search for system-specific indicators can lead to an excessive, even paralyzing, emphasis on the unique and can open the door to relativism. For example, most current global datasets on democracy rely on common indicators and hence could be criticized for not taking into account how different conceptual attributes of democracy should be adapted to different contexts. In addition, some of these datasets have been criticized, and rightly so, for having a Western bias, in that specific Western institutions are treated as universal standards for assessing other countries. However, it is clear that an attempt to factor in ideas from the literature on ‘non-Western democracies’, especially the argument that democracy takes a different form in non-Western societies, amounts to a rejection of any standard to compare countries around the world. What might at first glance seem a rather simple empirical operation – the design of indicators – actually hides many potential pitfalls. Indeed, for these reasons, the development of indicators that offer a basis for testing factual claims has been recognized as an important accomplishment

(Harré, 1981), and the development of broad cross-national measures, such as those used to measure economic activity around the world, are celebrated (Vanoli, 2005).

### **Measurement Scales**

The design of indicators is inextricably linked with another task, namely, the design of the measurement scales used to discriminate among cases. The standard options are well known: there are, most basically, nominal, ordinal, interval and ratio scales. Moreover, the standard way of comparing these scales barely needs mention: the move from nominal toward ratio scales involves a gain in precision. Thus, all else being equal, scales designed to collect data that is more precise and informative are preferable. Or, as is sometimes argued, inasmuch as nominal and ordinal scales are treated as qualitative scales, quantification is a sign of progress.

However, we add a caveat to this conventional wisdom that is suggested by the debate about whether democracy is best seen as a question of either-or or more-or-less (Sartori, 1987; Bollen, 1990; Collier and Adcock, 1999). In this debate, many authors have suggested persuasively that nominal and ordinal scales are sometimes preferable, in that they actually capture better the concept of interest. For example, the common idea of a democratic transition suggests that some changes are actually qualitative in nature and hence that nominal scales are appropriate (Przeworski et al., 2000: 18). Likewise, a common argument in the literature on democratization is that the extension of the right of suffrage evolved one social group at a time, a change well captured by an ordinal scale. Thus, it is important to note that decisions regarding measurement scales are made in the context of specific concerns and concepts, and hence that, as Collier and Adcock (1999: 537) suggest, these decisions should be justified through ‘specific arguments linked to the goals of research’

rather than by reference to the superior information of certain scales when considered in the abstract.<sup>11</sup>

### **Data Collection**

Once a researcher has designed an indicator or a series of indicators, each with their own measurement scale, the distinct task of data collection – the gathering and categorization of relevant information about a phenomenon of interest for a researcher – can begin in earnest. In this regard, we caution against a narrow view of the possible kinds of data and sources of data, and hence a narrow view of the challenges involved in data collection and the problems that might emerge in the course of data collection. Indeed, an overreliance on data from data-rich countries or time periods (e.g. the US in current times) would likely introduce bias into our knowledge of the social world. Moreover, in thinking about data collection, we draw attention to three questions: (1) When and where was it created? (2) Who created it? (3) For what purposes was it created? Answers to these questions provide the background information required to carry out systematic source criticism (*Quellenkritik*), which is the process of evaluating whether information (of all kinds) is more or less valid, reliable or relevant for a particular purpose.

### **Sources of qualitative data**

A key distinction is frequently made between primary sources and secondary sources. Primary sources provide direct or firsthand evidence about events, objects or persons. They include historical and legal documents, eyewitness accounts, interviews, surveys, audio and video recordings, photographs, speeches, diaries, letters, art objects and various kinds of online communications (e.g. emails, tweets, posts, blog entries). Secondary sources provide some kind of interpretation and analysis of events, conditions or experiences. Hence, newspaper articles and reports can be either

primary or secondary sources, depending on whether they provide information about facts or analysis and interpretation.

The ideas associated with systematic source criticism and the distinction between primary and secondary sources have their origin in the academic discipline of history. Historical data presents a number of attractions for social scientists, including more variation on key variables, the ability to investigate how similar causal mechanisms play out in different contexts and the ability to analyze path dependency. However, the more social scientists delve back in time, the more they come to depend on the prior work of trained historians, who have produced the narrative accounts that social scientists use either to code historical datasets or to produce in-depth historical narratives.

This raises an important but often ignored challenge: that social scientists will be prone to solely enlist or overly emphasize ‘works by historians using implicit theories about how events unfold and how people behave very similar to the theory under consideration’ (Lustick, 1996: 607). To mitigate this risk, social scientists first need to recognize that historical work cannot be seen as theoretically neutral. The implicit or explicit theoretical and historiographical perspectives of historians (e.g. the Marxist or Annales schools) color the ways they interpret their findings. Social scientists must therefore build a representative body of historical data from which to draw inferences. This means that they need a deep knowledge about the development of historiography and the debates of historical work in a particular field (Lustick, 1996; Lange, 2013: 141–8).

Different guidelines have been developed to ensure this. Lustick (1996) proposes four strategies:

- *Explain variance in historiography*: Assume a normal distribution among historical works and then identify the consensus.
- *Be true to your school*: Identify a particular historical tradition or school as superior for the pur-

pose at hand and then accept this interpretation, knowing how it differs from other interpretations.

- *Quasi-triangulation*: Limit the readings of history to those interpretations that have a broader support across historical schools.
- *Explicit triage*: Argue why some historical studies are better than others given the task at hand.

Møller and Skaaning (2019: 6) endorse Lustick’s argument that social scientists need to systematically consider differences between historical interpretations, but they criticize the notion that the average or consensus interpretation is less biased. Instead, to avoid selection bias in the sources of data, they suggest that social scientists should factor in the ‘shape of the distribution within historiography’ in three ways:

- *Aim for conceptual consistency*: Prioritize historical interpretations that are based on similar concepts as those being considered by the social scientist.
- *Clarify the vantage point of historical accounts*: Prioritize historical interpretations that are relatively atheoretical or where the thesis conflicts with the thesis that the social scientist is interrogating.
- *Prioritize updated evidence*: Prioritize historical interpretations that are based on newer evidence.

These three criteria are anchored in a simple Bayesian logic and they enable social scientists to heed what has been termed ‘the Ulysses Principle’, that is, to figuratively tie oneself to the mast in order to take precautions against influencing the evidence that is used to examine descriptive or causal propositions (Møller and Skaaning, 2019).

This principle, it bears noting, is not only relevant when dealing with historical sources. Recent methodological debates have emphasized the possibility of going deep more generally by shifting the focus from the macro level of analysis to the micro level, so as to probe mechanisms (Beach and Pedersen, 2016). While there are different ways of doing this, they all force social scientists to deal with qualitative data sources, such as interviews, archives, newspapers, organization records

and reports and participants' observations (see Tilly, 2008; McAdam et al., 2008). This requires not only a close familiarity with the data, but also careful consideration about how to avoid bias in the identification and reading of qualitative sources. If one takes out the historical part of the criteria mentioned above, they are applicable for processing many different kinds of qualitative data.

### *Sources of quantitative data*

Shifting focus to quantitative data, these normally take one of five forms:

- 1 *Hand-coded data*, such as the CIRI Human Rights Database, the Manifesto Project Database, the Uppsala Conflict Data Program, the Freedom House data on Political Rights and Civil Liberties and the Polity IV Project, where researchers or their assistants code events or conditions based on some predefined criteria.
- 2 *Machine-coded data*, such as the Integrated Crisis Early Warning System, the Global Database of Events, Language, and Tone (GDELT), and the Fragile States Index, where researchers develop automated algorithms that can categorize behavior, conditions or opinions.
- 3 *Ordinary survey data*, such as the World Values Survey, the Afrobarometer and various national election studies, where a sample (often representative) of people belonging to a particular group (citizens of a nation, employees in a firm, parliamentarians, members of an organization, etc.) is enlisted to respond to a number of questions about opinions and behavior.
- 4 *Expert survey data*, such as parts of the Varieties of Democracy dataset, the Chapel Hill Expert Survey, the Perceptions of Electoral Integrity dataset and the Quality of Government Survey, where experts are enlisted to answer questions about a certain topic about which they have special competence.
- 5 *Administrative data*, such as election turnout and vote share, roll call votes, number of state employees and government financial and economic statistics, which have been collected by national public agencies and international organizations (e.g. the UN, the World Bank, the IMF and the OECD).

In situations where we are interested in measuring not opinions but the actual condition

of, say, different aspects of democracy or the prevalence of corruption, another distinction has received much attention: namely, the difference between fact-based and judgment-based indicators. Those favoring fact-based (directly observable and verifiable) indicators emphasize that such data are more transparent and replicable and therefore broadly recognizable. They criticize judgement-based and perception-based data for being based on fuzzy and unsubstantiated inferences and personal biases.

Users and producers of judgement-based indicators have responded to this criticism by pointing out that fact-based indicators are often unable to capture all relevant nuances of particular phenomena. The preference for fact-based data rests, according to Schedler (2012: 28), on two conditions, which are often not fulfilled: '(1) transparent empirical phenomena whose observation do not depend on our judgmental faculties and (2) complete public records on those phenomena'. For example, some aspects of democracy, such as freedom of expression, are not easily observable. More generally, '[s]ome empirical phenomena we cannot observe in principle, others we cannot observe in practice' (Schedler, 2012: 28). In a nutshell, the problem is that directly observable empirical information is often incomplete, inconsistent or insufficient.

Different types of evidence can of course be used simultaneously to answer particular research questions. Just as researchers can make use of methods triangulation in order to appraise theoretical expectations, they can also carry out data triangulation and take advantage of the strengths and shortcomings of different kinds of sources of data (Skaaning, 2018). In general, the combination of information from different kinds of data increases our ability to capture related, but distinct, aspects of the variable in question. In addition, relying on multiple indicators can reduce the impact of idiosyncratic measurement errors associated with single indicators and facilitates systematic assessment of how reliable the data are.

There has recently been much talk of new data collection methods, based on increased computer power and a plethora of new information that is accessible online – what has been referred to as ‘big data’. Web scraping of information from, for example, newspapers or Wikipedia or social media (Twitter, Facebook) allows scholars to build large data-sets. One partial novelty here is to treat text – including alterations of text on Wikipedia and the like – as data. These newer sources of data collection are addressed in other chapters of the *Handbook*. Hence, all we note here is that the issues of conceptualization and measurement discussed in this chapter are also relevant for these new data collection enterprises.

### *On coding*

One of the more versatile means of producing systematic data – whether quantitative or qualitative, whether on variables or causal mechanisms, whether for a large-scale or a small-scale project, whether for the current period or times long past – is hand-coding by a single scholar or a team of scholars. Even though this is only one among various means of assigning values to indicators, given its important role in the social sciences we offer some comments about this procedure.

The production of hand-coded data normally proceeds in particular stages. Relevant information is gathered, after which a coder evaluates the evidence on one or more issues and translates it into a score based on more or less explicit and precise standards or coding rules. Despite careful attention to the selection of sources, training of coders and documentation of coding procedures, specific biases can still influence the scores (Bollen and Paxton, 1998, 2000).

The accessibility and selection of sources is a major issue. Evidence has been through a filtering process in which some information passes through and some is filtered out. This process is likely to introduce problems because the filters are selective in non-random ways, meaning that the

information is generally neither complete nor representative.

If the patterns of incomplete data are not random, descriptive and explanatory analyses using the data will be biased. For instance, Casper and Tufis (2003) have demonstrated that some of the most prominent democracy measures are not genuinely interchangeable, even though they are all anchored in Dahl’s (1971) definition of polyarchy and even though they are highly correlated (between .85 and .92). One reason for this could be systematic missingness. For example, relevant information is frequently not available for poor countries and autocracies. Missingness can be evaluated by simple tests of non-random missingness (see e.g. Ríos-Figueroa and Staton, 2012), where one examines whether there are significant differences between the scores for units covered by the data and those units that are not covered on other variables expected to be related to the outcome that is being researched.

Another issue is how the coders or respondents process the evidence. They can introduce random and systematic measurement errors by interpreting the sources differently, either because they base their evaluation on different pieces of (relevant or irrelevant) information, because they weight the same evidence differently or because they have different understandings of the concepts and scales that are used. More generally, various actors in the ‘data supply chain’ respond to different incentives and have variable capabilities that influence – and sometimes consciously manipulate – the production of data (Herrera and Kapur, 2007).

In addition, the practical procedures in the specific coding processes can introduce method effects. For example, scores can be influenced by how many units and questions the coders process, whether and when revisions can be made or whether they code across cases or over time. All of these factors tend to influence the implicit reference points in the minds of coders and thus the scores that are generated through exercises in coding.

On a more general level of abstraction, the reproducibility of measurement procedures is an important aspect of social science. This requires a systematic approach to data collection, precise descriptions of the procedures and transparency of these issues. Ideally, researchers should be able to reproduce or replicate the scores, and then assess the results of independent coding exercises. For example, where multiple, overlapping indicators exist, if the same variable is coded by several coders for the same units, one can assess the extent to which they generate consistent and converging data. In such cases, inter-coder reliability tests are valuable tools to assess whether the assumptions about consensus among coders are met (Gwet, 2014).

One way to do this is to employ Item-Response Theory (IRT) modeling techniques. These use patterns of agreement between the scores from different coders/indicators (and sometimes also other kinds of information, such as coder characteristics) to identify variations in reliability and systematic bias, and use this information to reduce measurement error in connection to latent concepts and to generate systematic estimates of uncertainty.

## **Evaluation**

An evaluation of measuring instruments and the data on indicators produced by using these instruments, much as with concepts, hinges first of all on *intelligibility*. If an independent scholar is not able to comprehend how the data was produced, what decisions were made to produce the data, and what the reasons were for at least the key decisions, the data cannot be properly scrutinized. In other words, without transparency, there is no possibility of replication and no way of assessing reliability and validity.

The demand for transparency has traditionally been directed mostly at quantitative data, but it has recently been pushed by the DA-RT (Data Access and Research Transparency)

initiative within the American Political Science Association with respect to qualitative research as well. One of the tools that has been proposed is data repositories that allow researchers to store qualitative data in a systematic way. This enables scholars to document their evidentiary record and makes it possible for other scholars to acquaint themselves with what is written in the sources that are referred to for evidence. For instance, the use of active citation gives readers a quick way to assess if a particular observation or interpretation does indeed seem to be supported by the work that is referenced (Lupia and Elman, 2014).

There are many other criteria that could be used to assess measuring instruments and data on indicators. As noted, measuring instruments can be more or less *versatile*, that is, they can be better or worse suited to generate data on various concepts in different domains (that is, temporal and spatial units). Data can be more or less *reliable*, that is, yield the same results when repeated measures are carried out independently. Data can have more or less *measurement error*, and identifying the sources of such error and providing estimates of uncertainty is part of best practice.

Importantly, in contrast to the evaluation of concepts, the evaluation of data on indicators can rely on empirical tests, using the data that has been produced and other available data (Cronbach and Meehl, 1955; Campbell and Fiske, 1959; Adcock and Collier, 2001; Seawright and Collier, 2014; McMann et al., 2016). For example, in a test of *convergent-discriminant validity* a researcher examines to what degree a new measure converges with established measures of the same concept and diverges from established measures of different concepts. In turn, in a test of *nomological validity* a researcher examines to what degree a new measure is able to reproduce well-established relationships among variables. Thus, it is important that researchers take advantage of the various empirical tests that can yield information that is relevant to an assessment of data.

However, the value of such tests depends very much on the current state of empirical knowledge. That is, a test of convergent-discriminant validation requires that a researcher can take for granted that the other measures, the standards with which the measure of interest is compared, are valid. In turn, a test of nomological validation requires that a researcher can take for granted that the established relationship is valid. Yet frequently this is not the case, and hence these tests may simply not be relevant. Moreover, the proponents of new measures frequently challenge existing conceptualizations or explanations, making agreement with prior knowledge an improper standard.

Thus, it is critical to stress the centrality of the question of *content validity*, that is, the extent to which one or more indicators capture the correct and full sense or content of the concept being measured (Adcock and Collier, 2001: 536–40). Assessing the validity of data is complex, because it concerns the link between observables and unobservables. Moreover, unlike estimates of convergent-discriminant and nomological validity, it cannot be quantified through an analysis of the data. However, it is important to recognize some key points about content validity. First, the question of content validity is distinctive. Second, it has priority in an evaluation of measurement validity, in the sense that it should be addressed first, during the process of indicator construction, and that it affects the data that are used in tests of convergent-discriminant and nomological validity. Third, it is an important consideration regardless of the kind of data (quantitative or qualitative) that is produced.

## MEASUREMENT II: DATA ON INDICES

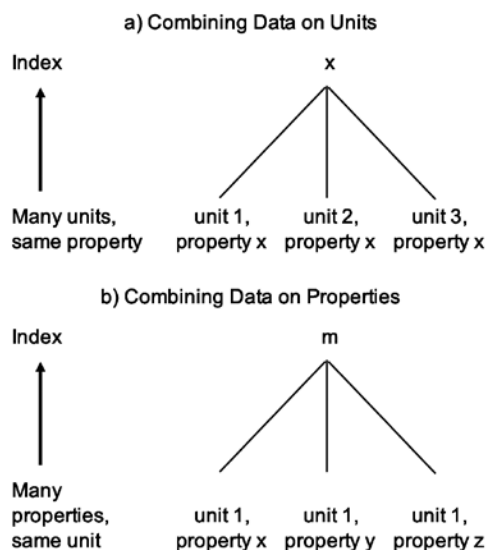

Data analysis for the purpose of description and explanation frequently relies on data on indicators. However, the production of data on indicators frequently raises a new

question: how might these data on indicators be combined? Indeed, there are many reasons why a scholar may want to develop what can generically be called *indices*, which combine data on indicators. The production of indices involves complex considerations, several of which are of a technical nature, and there is a large literature on index formation (e.g. Lazarsfeld, 1958; Lazarsfeld and Menzel, 1961; Blalock, 1982: ch. 7; Bollen and Lennox, 1991; Nardo et al., 2005; Greco et al., 2019). Thus, our discussion is necessarily cursory. Nonetheless, we draw attention to some key distinctions and options that have not always been addressed with clarity in the recent literature, and introduce some considerations that are ignored by the literature on measurement that pays little or no attention to the connection between theoretical concepts and measurement.

At the broadest level, drawing on the distinction between two of the core parts of a concept, its sense and reference (see above), it is possible to distinguish between two kinds of indices: (i) indices that combine data on the same indicator (measuring the same property) in multiple units (e.g. percentage of people in the world earning less than 2 dollars a day), and (ii) indices that combine data on multiple indicators (measuring different properties) in one unit (e.g. how democratic is the US) (see Figure 19.6).<sup>12</sup> In addition, building on these two kinds of indices, megaindices can be, and frequently are, built (e.g. proportion of countries in the world that are democracies, proportions of country dyads in the world that are democratic dyads, etc.). However, the core issues and options concern these two basic situations.

### *Combining Data on Units*

In the social sciences, the lowest level of analysis is the individual, and hence the most fine-grained data that are collected are data on properties of individuals. From this basic starting point, it is possible to combine data

**Figure 19.6 The production of data on indices: two basic situations**

on units all the way up to the highest possible level of analysis, the world system. However, there are two different ways, corresponding to two different social properties, in which data on units can be combined, and the index that is produced is different depending on which option is chosen (Lazarsfeld, 1958: 111–12; Lazarsfeld and Menzel, 1961: 426–8).

When the data on different units (e.g. individuals, firms or states) concerns a property possessed by each unit (e.g. income or life), an index that represents an *aggregate or resultant property* is generated. Examples are GDP, GDP per capita, percent of GDP accounted for by trade, global GDP, number of deaths in war, homicides per 100,000, proportion of the population that supports democracy and percentage of votes won by candidates in an election. In turn, when the data on different units concerns a property a unit has by virtue of a relationship among units (e.g. relative income, capital–labor relations or trading relationship between states), an index that represents a *relational or structural property* is generated. Examples are

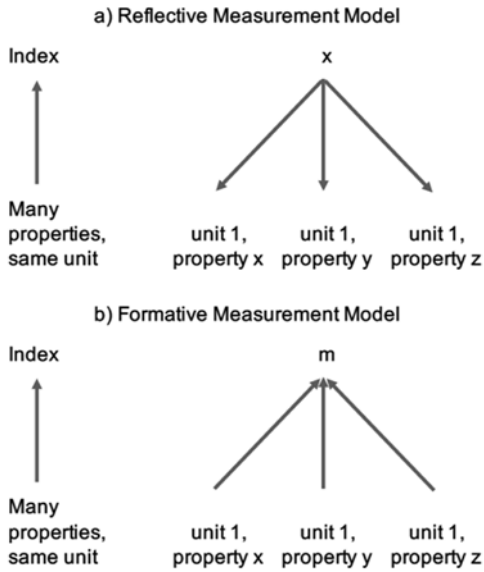

income inequality, polarization of the class structure, conflict levels of industrial relations, judicial independence, state legitimacy, trade dependence between countries and eigenvector centrality.

These are not the only social properties. Indeed, as Lazarsfeld (1958: 112–13; Lazarsfeld and Menzel, 1961: 428–9) pointed out long ago, there is a third kind of social property: *global or emergent properties*. These properties are not based on information about lower level units because they are not possessed by each lower level unit either independently of other units or due to a relationship with other units. Examples of global or emergent properties are crowd behavior, national culture, social cohesion, political stability and the dominant mode of production. The measurement of such social properties does not proceed by combining data on the same property in multiple units.

### **Combining Data on Properties**

A second kind of index is produced by combining data on multiple indicators (measuring different properties) in one unit. To be sure, the production of such indices does not need to be limited to one unit. For example, though some scholars have developed an index of democracy for one country, it is common for scholars to produce indices covering many countries or even the entire world. The increase in the number of units opens some important possibilities, such as tests of dimensionality. But the point is that the focus of such index production is on the question of how data on multiple indicators, each linked with different conceptual attributes, should be combined.

This challenge has been the subject of considerable debate, and different scholars have different views about how such a challenge should be addressed. Nonetheless, in broad strokes, the key choice a researcher faces is whether aggregation, that is, the combination of data on multiple indicators, should be

**Figure 19.7 Combining data on properties: reflective and formative measurement models**

based on what has been called a reflective or a formative aggregation model.<sup>13</sup>

These aggregation models differ both conceptually and substantively. In a *reflective model*, the concept is understood as the common ‘cause’ of the indicators used to measure it. Hence, ‘causation’ runs from the latent concept to the indicators (see Figure 19.7, panel a). Changes in the latent trait (not directly observed) are therefore expected to ‘cause’ a change in the indicator scores, but not vice versa, and that change in the latent variable should simultaneously bring about variation on all indicators. It follows that indicators should have a high positive correlation. This indicates that the multiple indicators and hence conceptual dimensions tap into a single underlying dimension. If so, indicators can be seen as partially interchangeable and dropping one of these indicators would not alter the meaning of the index that is produced. A good example is Teorell’s (2010: 164–5) socioeconomic modernization index, which he constructs, through the use of principal components analysis, by combining information on nine indicators: net

output of the non-agricultural sector as percentage of GDP, gross secondary school enrolment ratio, urban population as percentage of total population, life expectancy at birth, infant mortality rate, the log of GDP per capita, radios per capita, televisions per capita and newspaper circulation per capita. The indicators all load highly on a common latent dimension, which lends support to the index construction.

The assumptions behind a *formative model* are different. A latent concept is construed as the summary of the relevant variation in a set of indicators that are understood as constitutive of a particular concept. In other words, a latent concept is composed of conceptual attributes that are individually important for the meaning of the concept. In this case, ‘causation’ flows from the indicators to the latent concept (see Figure 19.7, panel b). In contrast to reflective models, in formative models the correlation among indicators is considered irrelevant and, since the indicators are understood as defining attributes, excluding one or more of them will fundamentally alter the meaning of the concept that is to be captured. To illustrate, contestation (or competitive elections) and inclusive suffrage are often conceived as the two essential features of representative government (Dahl, 1971; Coppedge et al., 2008). These two conceptual attributes are not necessarily highly correlated with each other. Today, many countries have universal adult suffrage but not much contestation, and historically many countries had a high degree of contestation but highly restrictive voting rights. However, only including indicators that capture either suffrage or contestation would critically alter the core concept that is being measured. Measuring one property cannot substitute for the measurement of another property, and dropping the data on one of the multiple properties would radically alter the meaning of the index that is produced.

### **Evaluation**

The constructors of indices must tackle some distinct choices, beyond those that go into the

production of data of indicators, when they consider whether and how to aggregate data from indicators. In combining data on the same indicator in multiple units, analysts need to be aware of what social property is being measured, and hence whether the appropriate procedure is being used. In turn, in combining data on multiple indicators (measuring different properties) in one (or more) units, they have to be aware at least of the choice between reflective or formative aggregation models. However, as Lazarsfeld (1958: 113) noted, it is by no means self-evident how an analyst should proceed. Indeed, at times it is not even clear whether an analyst faces the challenge of combining data on units or on properties.

Given this uncertainty, the temptation to rely on default options might be strong. But this temptation should be resisted. As with the evaluation of data on indicators, empirical tests, using the data that have been produced and other available data, can be conducted and used to inform the construction of indices. Indeed, various empirical checks can be of help (Bollen and Bauldry, 2011). However, one cannot simply make the data speak for itself. Thus, no matter which of the options is seen as more suitable for a given aggregation task, whatever procedure is used to form an index through the combination of data on indicators needs to be justified theoretically. What this means is that, to ensure what has been called concept-measure consistency (Goertz, 2006: ch. 4), which might be thought of as a counterpart or aspect of the criterion of *content validity* discussed above, what is needed is a theory about how multiple indicators should be combined (Goertz, 2006: 53–65, ch. 5; Munck, 2009: 30–2, 49–51). Indeed, much as with data on indicators, data on indices are valid if they fulfill two criteria: (i) a theoretical concept has been formed in a conscious and careful manner, that is, a theory has been articulated to justify what conceptual attributes are included and excluded, how the included conceptual attributes relate to each other and what the referents of conceptual attributes are;

and (ii) the way in which data on indicators is combined matches the concept that is being measured.

## CONCLUSION

The social sciences, in contrast to disciplines such as logic and mathematics, are factual sciences, given that they refer to facts about the concrete world. Thus, empirics and, more narrowly, measurement, understood as the production of data, are essential parts of social science research. However, empirics should be distinguished from empiricism. Empiricism is a one-sided epistemology that holds that experience is the only source of knowledge and that, in the context of measurement, asserts that theoretical concepts are not different from empirical concepts or that theoretical concepts can be reduced to empirical ones. The history of science reveals the limitations of empiricism. Indeed, a widely recognized indicator of progress is the replacement of classification schemes based on concepts that represent secondary, observable properties with ones based on primary, non-observable properties of things. For example, the conceptualization of chemical elements based on atomic number and electron configuration rather than observable properties such as color or smell, and the classifications in biology based on molecular differences rather than observable morphological traits.

Thus, counter to an empiricist approach to measurement, this chapter places the focus squarely on theoretical concepts and insists on the link between theoretical concepts and measures. Indeed, we have sought to draw attention to various ways in which a clear idea of *what* theoretical concept is to be measured is needed to make decisions regarding *how* to measure that theoretical concept. And to that end, we started by addressing what concepts and conceptual systems are, and then highlighted how both the production of data

on indicators and indices should consider the link between concepts and measures.

We do not seek to convey the message that the link between concepts and data should be the only concern in any measurement project. Other matters are also important. Moreover, not every project on measurement has to be conjoined with a project on conceptualization. There can surely be a division of labor between researchers who seek to form concepts and researchers who produce data. However, for data to be used to ascertain the truth of the kind of factual claims that are routinely made in the social sciences, decisions regarding the production of data *must be guided* by ideas regarding the sense and reference of concepts as well as their structure. Measures that ignore these matters are of limited value and, inasmuch as they are interpreted as measures of theoretical concepts, potentially erroneous.

## Notes

- 1 Collier and Levitsky (1997); Bollen and Paxton (1998, 2000); Collier and Adcock (1999); Munck and Verkuilen (2002); Goertz (2006); Gerring et al. (2019).
- 2 This distinction between reference and extension is frequently overlooked. Indeed, it is not addressed in the influential work on the social sciences by Sartori (1970, 2009 [1984]: 102–6). However, it actually is consistent with Sartori's (2009 [1975]: 84) clarification that 'the rules of transformation along a ladder of abstraction ... apply to observational, not to theoretical, concepts'. That is to say, though the intension and extension of a concept varies inversely (Sartori, 1970: 1040–4; Collier and Mahon, 1993: 846), this statement applies only to empirical concepts and not to theoretical concepts. For more on the distinction between theoretical and empirical concepts, see Kaplan (1964: 54–60).
- 3 Bunge (1998a [1967]: 82–9); Sartori (2009 [1984]: 118–25); Thagard (1992); Collier and Levitsky (2009).
- 4 For useful discussions about concepts and conceptual systems, see Bunge (1998a [1967]: chs 2 and 3), Bailey (1973, 1994), Marradi (1990) and Collier et al. (2012).
- 5 2x2 typologies have been hugely influential in social science, both for descriptive and explanatory purposes. But typological property spaces are often much more complicated, as they can contain more than two dimensions and as each of these dimensions can be divided into more than two classes. For example, one could add the rule of law, the effective power to govern and/or the guiding ideology as separate dimensions to the regime typology in Figure 19.3 if one has good theoretical reason to do so. Or one could subdivide contestation and/or participation into different levels, say low, medium and high. The problem with such operations is that the property space can quickly become too complex to be useful for theorizing and empirical analysis. Thus, the essence of forming a typology is to first identify the dimensions and the classes on each dimension, and then to reduce the property space in order to focus on the most important types (Lazarsfeld and Barton, 1951: 169–80; Elman, 2005; Collier et al., 2012).
- 6 On the distinction between kind and part-whole hierarchical structures, see Thagard (1990, 1992: 7–8, 27–33) and Collier and Levitsky (2009).
- 7 For an exemplary critical analysis of the term 'authoritarianism', as used in the study of political regimes, see Przeworski (2017).
- 8 Though the idea of measurement validity is ubiquitous in the literature on measurement, the distinction between conceptual validity and measurement validity is rarely made; for exceptions, see Jackson and Maraun (1996) and Billiet (2016: 196–200). Yet, inasmuch as the idea that there are theoretical concepts apart from their measures is accepted, as is the case here, this distinction is crucial.
- 9 For exemplary justifications of the concept of democracy, see Dahl (1989) and Saward (1998).
- 10 Inasmuch as some observable property of another object is lawfully related to the observable property of an object under consideration, the observable property of another object could be used as an indicator.
- 11 There is an associated issue that crops up frequently in the measurement of democracy. Scholars have good reasons to want qualitative *and* quantitative distinctions. However, one common practice – the derivation of qualitative distinctions from quantitative distinctions – deserves scrutiny. Indeed, such exercises tend to rely on a rather arbitrary assertion, usually made with little reference to the concept of democracy, that some point on a scale can be treated as the dividing line between democracy and non-democracy. It is preferable to start with qualitative distinctions and then refine these measures by adding quantitative distinctions.
- 12 The problem of combining data also occurs if multiple scores are generated for a single indica-

tor in the same unit (e.g. when multiple coders are used in data based on expert rating) or if data are generated for multiple indicators of the same conceptual property in the same unit (e.g. when a battery of indicators are used to measure some psychological trait). Here we take as our starting point data which can already be treated as data on conceptual properties.

# Measurement Models

Christopher J. Fariss, Michael R. Kenwick  
and Kevin Reuning

## INTRODUCTION

Measurement models in general, and latent variable models in particular, are now common in political science research. This is because political scientists are increasingly focused on improving the measurement of unobservable concepts and understanding the relationships and potential biases between different pieces of observable information and the measurement procedures that link this information to theoretical concepts. Recent methodological and computational advances have led to a flourishing of new latent variable modeling applications. These new tools provide researchers with a means of measuring difficult to observe concepts based on events, ratings or other pieces of observable information that are assumed to be a result of the underlying unobservable latent trait.<sup>1</sup>

Latent variable models are built on the idea that observable variables are manifestations of an underlying conceptual process that is not perfectly observable or knowable

and includes increasingly computationally sophisticated probability models (e.g., Imai et al., 2016; Jackman, 2000, 2001; Martin and Quinn, 2002; Plummer, 2017; Carpenter et al., 2017) and computationally simply additive scales (e.g., Guttman, 1949; van Schuur, 2003). In this chapter, we review the scientific measurement process and the assumptions needed to construct models of unobservable theoretical concepts.

The scientific process of measurement occurs in three iterative stages: *conceptualization* of the sociological or physical system being studied, *operationalization* of the data generating process that approximates the system and *empirical analysis* of the data generated by that system. The relationship between each of these steps is assessed using construct validity tools.<sup>2</sup> Because the measurement process is iterative, it is incumbent on the researcher to (1) acknowledge the starting point of the measurement process and (2) provide an assessment of the quality of the links between these steps. We provide

more details about these recommendations throughout this chapter, although our focus here is on how latent variable models can be used to assess these steps.

Latent variable models allow for the empirical assessment of how the different observed pieces of data relate to one another through their association with the estimated latent trait. Even computationally simple additive scales are models that represent an underlying latent concept. Additive scales require the same process of assessment as more computationally difficult latent variable approaches (van Schuur, 2003). We discuss these additive scaling models as a starting point for thinking about estimating latent variable models more generally, because these models share the same set of assumptions. New computationally sophisticated latent variable models allow the researcher to relax these assumptions in conceptually meaningful ways.

The particular examples of latent variable models that we review in this chapter have been applied across a variety of subfields, encompassing the study of political ideology (Barbera, 2015; Bond and Messing, 2015; Martin and Quinn, 2002; Martin et al. 2005; Caughey and Warshaw, 2015; König et al., 2013; Pan and Xu, 2018; Treier and Hillygus, 2009; Windett et al., 2015), political attitudes, knowledge and preferences (Blaydes and Linzer, 2008; Pérez, 2011; Jessee, 2017; Stegmueller, 2011, 2013), regime institutions (Treier and Jackman, 2008; Pemstein et al., 2010; Kenwick, 2018, Gandhi and Sumner, 2019), UN voting positions (Voeten, 2000), human rights abuse (Schnakenberg and Fariss, 2014; Fariss, 2014, 2019; Fariss et al., 2020), human rights treaty embeddedness (Fariss, 2018b,a), judicial independence (Linzer and Staton, 2016), demographic variables (Anders et al., forthcoming), and institutional transparency (Hollyer et al., 2014). We discuss several latent variable models that are capable of accommodating different forms of conceptual dependencies between units, in particular temporal interdependence in time-series cross-sectional data.

We provide examples that build on insights from a recently published article on temporal dependence and sudden temporal changes in time-series cross-sectional data (Reuning et al., 2019).<sup>3</sup>

After discussing the measurement process and construct validity in more detail and laying out different dynamics of latent variables, we highlight places that we believe are ripe for future research. In particular, we discuss new ways to theoretically include time in latent variable models, ways to scale expert surveys, the use of Multiple-Indicator-Multiple-Causes models and issues with different model fit statistics. Finally, we end with a list of recommendations for the applied researcher using latent variable models.

## THE MEASUREMENT PROCESS

The process of measurement can be broadly characterized as having three steps.<sup>4</sup> The process of measurement allows the researcher to think explicitly about each of these three steps and the relationships between them because it links theories, the *concept*, with operational procedures, the *construct*, which generate observable information, the *data*. We discuss each of these steps here.

In the first step, a researcher generates a systematized definition of a concept in which they are interested. The systematized definition should be specific enough to have intellectual traction, but sufficiently broad so that it can be meaningfully applied to a set of objects across time, space or both (Shadish, 2010). What does this mean in practice? That there is necessarily a trade-off between specificity and generalizability and, when applied, the researcher must clarify the boundary conditions that define the set of objects for which the measurement procedure operates and the set for which it does not. At the extreme, the conceptual process should cover more than one object, but less than all objects. Specifying these boundary conditions is part

of the conceptual step in the measurement process. However, because the measurement process is iterative, the researcher can and should return to this first step in order to make refinements to the systematized definition based on information obtained in the second or third step of the process.

Often in political science, even a well-defined concept cannot be directly observed in the real world. In the second step, the researcher must therefore begin to identify how the latent trait relates to observable information, thereby creating a data generating process from the latent trait to the observed indicators. A researcher interested in democracy might, e.g., identify whether a country holds competitive elections, whether there is a representative legislature with the ability to effectively pass legislation and whether there has been alternation in power among competing political groups. Thus, this second step involves the critical task of designing the data generating procedures used to collect information that relates to the underlying concept of interest for the objects under study.

Once the data generating procedures are defined, the researcher proceeds to the third step, which involves collecting observational information about a set of objects and the categorization or scoring of those objects. This process maps the observed information collected about the objects in the second step back to the concept of interest defined in the first step through a defined categorization or scoring procedure. The definitional rules of the operational procedure should be consistent with the conceptual definition defined in the first step. The creation and use of any operational protocol requires that researchers make decisions about how to weight each piece of information and how they individually or jointly inform the researcher's beliefs about an object's score for the underlying trait.

In sum, the three steps are: (1) define theoretical concept and scope; (2) identify how observational data connects to the theoretical concept by defining the data generating

process; (3) use the operational procedure to categorize or score cases which are the subjects or units of study. Most of our discussion from here focuses on the second and third steps. This procedure highlights the fact that all measurement inherently involves the creation of a measurement model, which is the second step of the measurement process, but with links to both the first and third steps. Like all other models in social science, those used in measurement require careful validation about the relationships between steps.

At the broadest level, measurement validation centers upon what is known as construct validity, which is an assessment of both the theoretical content of the operationalization protocol and the empirical content that is believed to be captured by this construct (e.g., Adcock and Collier, 2001; Jackman, 2008; Shadish, 2010; Shadish et al., 2001). Construct validity encompasses a variety of different ways to evaluate a measure and operationalization.

Two important parts of construct validity are translation validity and measurement validity. Translation validity is an evaluation of the match between the theoretical construct and the proposed data generating procedure, which generates the observed pieces of information. Measurement validity is an evaluation of the fit between the proposed data generating procedure and the actual data obtained from it.

Translation errors occur when the operational protocol does not match the theory of the concept. Measurement errors occur when the fit between representation of the data generating procedure (the measurement model) and the data is poor. As researchers validate their measures along these two related criteria, they may choose to (1) update the types of information to collect, (2) modify the method for linking this information into scores on the latent trait or (3) modify the theoretical concept that the data generating procedure is derived from. The measurement process is an inherently iterative process between each of the three steps outlined above.

Thus, to generate good estimates of a theoretical concept of interest, the research must understand the relationship between each part of the measurement process.

## MEASUREMENT MODELING ASSUMPTIONS

All measurement models, regardless of their complexity, require assumptions about the underlying trait. In this section we provide an overview of these assumptions for some of the measurement models that are most commonly used in the social sciences (additive scales and IRT models). We begin by discussing the assumptions of additive scales, proceed to identify assumptions of latent variable models and finally provide an overview of latent variable model assumptions about dynamics and their relationship to local independence.

Before proceeding, it is useful to provide a brief overview of the notation we will use in the following section. We denote the latent trait as  $\theta$ , which is observed across units indexed with  $i$ , which takes on values of 1, 2, ...,  $N$ , where  $N$  is the total number of units in the sample. We observe  $\theta$  indirectly through observable pieces of information often referred to as 'items' or 'manifest indicators', each of which is indexed using  $k$  with values 1, 2, ...,  $K$ , where  $K$  is the total number of manifest indicators. The realized values of these indicators are  $y$ , with  $Y$  acting as the manifest indicator yet to be observed. This notation lets us refer empirically to both the potential observed realization of data  $Y$  and the actual realization of data  $y$ . Formally, we let  $Y_{ik}$  denote the score of subject  $i$  on item  $k$ , a random variable with realization  $y_{ik} = \{0, 1\}$ . For simplicity, we assume that each indicator is binary. In the next section, we will continue to build towards an additive scale as a latent variable representation of a concept. We also discuss the assumptions underlying this model and the standard unidimensional item

response theory models which we review later in the chapter.

### *Assumptions of Additive Scale Measurement Models*

To make the notation and formalizations presented in this section more clear, we introduce a small deterministic example that illustrates the relationships between the different model parameters and data. As we mentioned above, we let  $k$  take on integer values from 1, 2, 3, which represents three distinct questions of varying ability that we will ask of five hypothetical subjects. These are the items which generate responses (i.e., the item responses) from each subject. We first introduce a new parameter  $\alpha_k$  which represents a feature of the items. In a testing setting,  $\alpha_k$  parameters represent the difficulty of a particular question as it relates to the ability of the test-takers or subjects, which is represented by  $\theta$ . In additive scales it is assumed that if the latent trait for unit  $i$  is greater than  $\alpha_k$  then we will observe  $y_i = 1$ . More generally,  $\alpha_k$  accounts for the variation in how high (or low) a unit has to be on the latent trait to achieve a positive outcome for indicator  $y_k$ . For this example, we are supposing that we know the true values of this parameter in our measurement model. Later on, we will estimate these parameters.

In our example we consider the following latent traits for five units ( $\theta_1 = -2$ ,  $\theta_2 = -1$ ,  $\theta_3 = 0$ ,  $\theta_4 = 1$ ,  $\theta_5 = 2$ ) and three items ( $\alpha_1 = -1.5$ ,  $\alpha_2 = 0$ ,  $\alpha_3 = 1.5$ ), which are all arrayed along the same unidimensional line. The relationship between the five units and the three items are displayed visually in Figure 20.1. The unidimensional line represents values of the unobservable theoretical concept of interest but the substantive meaning of the entities along the line differ because some are subjects and the others are the data generating objects (i.e., the item or test questions).

**Figure 20.1 Latent variables and item parameters**

Note: This plot displays latent traits for 5 units  $\theta_1 = -2, \theta_2 = -1, \theta_3 = 0, \theta_4 = 1, \theta_5 = 2$  and 3 items  $\alpha_1 = 1.5, \alpha_2 = 0, \alpha_3 = 1.5$  all arrayed along the same unidimensional line. The unidimensional line represents values of the unobservable theoretical concept of interest but the substantive meaning of the entities along the line differ because some are subjects and others are the data generating indicators (i.e., the item responses generated by the subjects). The subjects and items are comparable in this space however. In particular, the comparison of the distance between subject and object determines the observed binary item responses for each subject-object pairing.

The relationships displayed visually in Figure 20.1 are unobserved. What we actually observed are binary responses (e.g., the answers to questions generated by subjects or the categorical values created to compare country-year units). Our measurement goal is to create a test or categorization scheme that relates the observed data back to the unobserved latent traits. This is done by assuming a data generating process from the latent trait to the indicators. Here we will use a deterministic function for the relationship between each subject-item pairing, which is displayed

in Equation 1. Later on we will introduce a probability model for accomplishing this task.

$$y_{ik} = \begin{cases} 1 & \text{if } \theta_i > \alpha_k \\ 0 & \text{if } \theta_i \leq \alpha_k \end{cases} \quad (1)$$

Equation 1 represents the data generating function for the binary item responses produced for each subject-item pair. For the illustrative example,

$$y_i^+ = \sum_k^K (y_{ik}) \quad (2)$$

Equation 2 represents the observed additive scale value for each subject  $i$ , which is determined by the value of the logical proposition in equation 1. Table 20.1 presents the additive scale values for  $y_i^+$  based on the pairwise comparisons between the five subjects and the three items. The additive scale is a deterministic, continuous scale, which satisfies the conditions outlined by Guttman (e.g., Guttman, 1949; van Schuur, 2003). In words, the first subject's ability is always less than the value of the item. To reiterate, the values are substantively distinct but are comparable together on the same latent scale.

The additive scale can also be rewritten as a function of just the values of the latent trait and the difficulties. This is the function in Equation 3, where the additive value is found by checking the latent trait's value against the ordered alphas. This emphasizes that in additive scales there is an assumption that all items can be ordered in such a way that

**Table 20.1 Example of additive scale function**

Latent Trait	Items			Additive Scale
$\theta_i$	$\alpha_1 = -1.5$	$\alpha_2 = 0$	$\alpha_3 = 1.5$	$y_i^+$
$\theta_1 = -2$	$\theta_1 \leq \alpha_1 \Rightarrow +0$	$\theta_1 \leq \alpha_2 \Rightarrow +0$	$\theta_1 \leq \alpha_3 \Rightarrow +0$	$y_1^+ = 0$
$\theta_2 = -1$	$\theta_2 > \alpha_1 \Rightarrow +1$	$\theta_2 \leq \alpha_2 \Rightarrow +0$	$\theta_2 \leq \alpha_3 \Rightarrow +0$	$y_2^+ = 1$
$\theta_3 = 0$	$\theta_3 > \alpha_1 \Rightarrow +1$	$\theta_3 \leq \alpha_2 \Rightarrow +0$	$\theta_3 \leq \alpha_3 \Rightarrow +0$	$y_3^+ = 1$
$\theta_4 = 1$	$\theta_4 > \alpha_1 \Rightarrow +1$	$\theta_4 > \alpha_2 \Rightarrow +1$	$\theta_4 \leq \alpha_3 \Rightarrow +0$	$y_4^+ = 2$
$\theta_5 = 2$	$\theta_5 > \alpha_1 \Rightarrow +1$	$\theta_5 > \alpha_2 \Rightarrow +1$	$\theta_5 > \alpha_3 \Rightarrow +1$	$y_5^+ = 3$

Note: The additive scale values are based on the status of the logical propositions for each subject-item comparison.

they are monotonically increasing in difficulty. Once ordered, a researcher can identify where a unit is on the additive scale based on when its indicators switch from 1 to 0.

$$y_i^+ = \begin{cases} 3 & \text{if } \theta_i > \alpha_3 \\ 2 & \text{if } \theta_i > \alpha_2 \quad \text{and } \theta_i \leq \alpha_3 \\ 1 & \text{if } \theta_i > \alpha_1 \quad \text{and } \theta_i \leq \alpha_2 \\ 0 & \text{if } \theta_i \leq \alpha_1 \end{cases} \quad (3)$$

We can visually represent the relationship between the values of the additive scale, the latent trait, and the items in Equation 3. We do this in Figure 20.2.

Up until now, we have assumed a deterministic model between the observed items and the latent trait, which are consistent with the assumptions from Guttman (1949). In later measurement research, Mokken (1971) developed a stochastic version under the assumptions of a unidimensional latent variable, latent monotonicity and local independence. Under these assumptions, the

**Figure 20.2 Example of additive scale function**

*Note:* This plot displays latent traits for 5 units  $\theta_1 = -2$ ,  $\theta_2 = -1$ ,  $\theta_3 = 0$ ,  $\theta_4 = 1$ ,  $\theta_5 = 2$  and 3 items ( $\alpha_1 = 1.5$ ,  $\alpha_2 = 0$ ,  $\alpha_3 = 1.5$ ) all arrayed along the same unidimensional line displayed in Figure 20.1. The additive scale values on the y-axis are based on the status of the logical propositions for each subject-item comparison in Table 20.1.

proportion of ‘correct’ answers by subject  $i$  to item  $k$  is nondecreasing in the sum of all the items. These assumptions also imply that all of the items are positively correlated across all subsets of subjects (Mokken, 1971). Under these assumptions the unweighted sum of the variables increase as  $\theta$  increases. Mokken Scaling Analysis (MSA) is simply a stochastic version of a Guttman scale, in which items measure a single latent construct and can be ordered by difficulty (Guttman, 1949) but are not assumed to be generated without error (van Schuur, 2003).

The assumptions made by Mokken (1971) are common across many latent variable models and so are worth exploring in more depth. The first assumption is that  $\theta$  is a *unidimensional latent variable*, which means that the values of the latent trait reside on a single axis. This assumption can be tested using parameters from the Mokken Scaling Analysis (MSA) model (van Schuur, 2003). If this assumption fails, it means that the latent trait cannot be collapsed into a single dimension but that units can be high in one dimension and low on another.

The second assumption is of *latent monotonicity*, which means that the item step response function is strictly increasing on  $\theta$ ;  $\theta_1 \leq \theta_2 \Rightarrow P(Y_{ik} \geq y_{ik} | \theta_1) \leq P(Y_{ik} \geq y_{ik} | \theta_2)$ . This implies that as a unit increases in the latent variable, the probability of observing a positive indicator also increases.

The third assumption is of *local independence*, which means that the item responses are not deterministically related to each other outside of their relationship to the latent trait. This implies that the probability of the set of each subject’s item responses is

$$P(Y_{i1} = y_{i1}, Y_{i2} = y_{i2}, \dots, Y_{iK} = x_{iK} | \theta_i) = \prod_{k=1}^K P(Y_{ik} = y_{ik} | \theta_i) \quad (\text{van Schuur, 2003}).$$

The only relationship between items is through their relationship with the latent variable. This can be violated in the testing environment when getting one answer correct depends on getting previous answers correct.

To summarize, additive scaling is a data generating procedure that maps the latent trait to an additive index. In order to estimate a stochastic additive scale, researchers must make assumptions about unidimensionality, monotonicity and local independence. As we discuss next, these assumptions are also present in more complicated latent variable models which also allow more variation in how the latent trait relates to the observed indicators.

### Identification Assumptions of Latent Variable Models

We now move to estimate  $\theta$  itself because, up until this point, this parameter has been entirely conceptual. We do this through the Item Response Theory (IRT) framework which allows us to estimate  $\theta$  as well as other parameters in the data generating process. In addition, using this framework we can add an additional layer of complexity of cross-sectional time-series data (i.e., country-year units) instead of the five hypothetical subjects from before.

In principal, IRT models are rooted in the same assumptions as the additive scale above; that is, we assume that  $\theta$  is a *unidimensional latent variable* and that its relationship with its associated items is characterized by *latent monotonicity* and *local independence*.

Under the IRT framework, the latent trait is  $\theta_i$  where the subscript  $i = 1, \dots, N$  indicates multiple units.  $y_{ik}$  is the observed value for item  $k$  for unit  $i$ . For each item  $\alpha_k$  and  $\beta_k$  are also estimated.  $\alpha_k$  continues to act as a ‘difficulty’ parameter, or a threshold that benchmarks how likely an indicator is to be observed relative to the values of the latent trait. In our formulation, this is analogous to an intercept in a traditional logistic regression model.  $\beta_k$  is often referred to as the ‘discrimination’ parameter and is the analogue of a slope coefficient.

The relationship between  $\theta_i$  and our indicator  $y_{ik}$  is:

$$P(y_{ik} = 1) = \Lambda(\alpha_k - \beta_k \theta_i) \quad (4)$$

where  $\Lambda$  is the logistic function. Unlike in the case of the additive scale, this is necessarily probabilistic.<sup>5</sup> The likelihood function encompassing the latent trait, realizations of the manifest indicators and item-specific parameters take the following form:

$$\mathcal{L} = \prod_{i=1}^N \prod_{k=1}^K \Lambda(\alpha_k - \beta_k \theta_i)^{y_{ik}} (1 - \Lambda(\alpha_k - \beta_k \theta_i))^{1-y_{ik}}$$

The model estimates the placement of one unit relative to all the other units based on the values of the observed items. Without additional information such models are not identified, which means that estimation is not possible because multiple sets of values for the parameter estimates will fit the data equally well. There are generally three types of identification problem that most applied researchers will encounter: additive, scale and rotational. In each of these cases the likelihood is invariant across multiple parameter estimates. To prevent this situation, the researcher must make several benign assumptions that provide additional information to the model and prevent invariance.

The issues of scale and additive invariance are often the easiest to solve. In the case of additive invariance,  $\theta + \delta$  and  $\alpha - \delta$  lead to equivalent likelihood for any  $\delta$ . Scale invariance is similar except is a result of multiplication:  $\delta \cdot \theta$  and  $\frac{\theta}{\delta}$  would again produce equivalent likelihoods. This invariance is commonly solved by providing information to  $\theta$  through a standard normal distribution as the prior. This is useful as it leads to estimates of  $\theta$  that are mean 0 with a standard deviation of 1.

Rotational invariance can be more complicated. Rotational invariance is the result of equivalent likelihoods that result when  $\theta$  is multiplied by  $-1$  or ‘flipped’. In the context

of a latent variable for ideology, estimates with negative numbers as conservative and positive numbers as liberal are the same as when negative numbers or liberal and positive numbers are conservative. Put differently, the model has no way of knowing whether to order the units from liberal to conservative, or from conservative to liberal ideologies.<sup>6</sup>

One simple strategy for resolving rotational invariance is to fix the values of the latent trait for two or more units. In the political ideology example, this could be achieved by assigning values of the latent trait for a very liberal and a very conservative individual. An alternative strategy imposes assumptions about the relationship between

the manifest indicators and the latent trait through the discrimination parameters,  $\beta_k$ . For example, Fariss (2014) relies on a series of indicators believed to positively correlate with respect for human rights, and therefore restricts the  $\beta$  parameters to take on positive values. In practice, this can be done through the use of truncated distributions (e.g., half-normal) or strictly positive distributions (e.g., gamma).

As a demonstration of issues of invariance, consider the simple single dimensional model for five units. We plot these five units along a single dimension in Figure 20.3. The first row shows the baseline, placing all five units in order. The second row shows

**Figure 20.3 Identification issues in latent variables**

*Note:* This plot displays latent traits from four idealized models. The top row displays the 5 units scaled so that the mean value is 0. The other rows show the consequence of the values of the latent trait when adding a constant (row 2), multiplying a constant (row 3), and multiplying by  $-1$  (row 4). These models each provide the same values for comparisons of the value of one unit relative to any other or to the mean value of all of the units. Since we do not know the true absolute value of the concept we wish to make inferences about, it is useful to constrain the values of the latent trait to occupy the standard normal density function. By constraining the model in this way, we ensure that we are not mixing and therefore comparing values from the other models represented in this visualization.

a rightward shift of all five units (additive invariance). Since the latent dimension is arbitrary, this move does not matter as long as all units move in a similar way and there are no assumptions made about where the center of the latent space is.

In row 3 we demonstrate the issue of scale invariance. Here, the latent trait has been multiplied by 2, expanding the latent scale. Again, because each unit moves equally the end result is no different from the initial placement in row 1 if there is no constraint placed on the scale of the latent trait. Finally, row 4 shows rotational invariance. The latent traits have been reversed so that  $\theta_1$  moves from 2 to  $-2$ . This is equivalent to the first row if there is no constraint placed on the direction of the scale.

In our running examples, we place normal priors on the latent trait and resolve the issues of location and scale invariance.<sup>7</sup> To resolve rotational invariance, we constrain  $\beta_k$  to be greater than zero, such that increasing values of each manifest indicator are associated with increasing values of the latent trait. Finally, we place weakly informative normal priors on the difficulty parameters. The prior assignments can therefore be expressed as:

$$\begin{aligned}\theta_i &\sim N(0,1) \quad \forall i = 1, \dots, N \\ \beta_k &\sim \text{HN}(0,3) \\ \alpha_k &\sim N(0,3)\end{aligned}$$

where HN is the half-normal distribution, with support on  $[0, \infty)$ .

### **Local Independence and Assumptions about Dynamics**

The model described above can be expanded to include units over multiple time periods. In the above equations, this is accommodated by replacing  $\theta_i$  with  $\theta_{it}$  where  $t$  indexes time periods from 1, ...,  $T$ . There is no requirement that all units must be observed over all time periods.

This does lead to some methodological questions. Latent variable models, including simple additive and cumulative scales, are built on the assumption that each observed variable for a unit is generated independently of the other observed pieces of information about that unit. This is the assumption of *local independence*. For the type of cross-sectional time-series data that we consider in this chapter, the assumption of local independence means that any two observed variables are *only* related because of the fact that they are each an observable outcome of the same latent variable.

There are three relevant local independence assumptions: (1) local independence of different indicators within the same country-year; (2) local independence of indicators across countries within years; and (3) local independence of indicators across years within countries. Priors are a useful and common means of addressing potential violations of the lattermost type of local independence violations. Applied researchers in international relations are likely to encounter problems where they are attempting to estimate a measure of multiple units observed over time. The dependencies within a unit across time can be modeled as part of the prior on the latent variable. In this section we discuss three broad approaches in the field. Two of these are relatively common, while the last has been recently introduced. In each case we discuss the assumptions that the model makes, the benefits of it and the costs.

#### **Static model**

The three modeling strategies we present are differentiated by the prior information assigned to the latent variable. We start here with the simplest model, the static model. The static model places a standard normal prior on all units for all time periods:

##### *Static model prior*

$$\theta_{it} \sim N(0,1) \quad \forall i = 1, \dots, N \quad \forall t = 1, \dots, T$$

The standard normal prior, as discussed above, prevents additive and scale invariance. Estimates for the latent trait for each unit in

each time period are differentiated exclusively by the values of the indicators for that unit at that time period. This model treats each unit-time period as independent, which is a bold assumption to make in most applied research. In addition, this limits the information that is being used to estimate the latent trait and so is likely to increase credible intervals. In the case where the indicator variables contain sufficient information on the latent trait, this modeling strategy may not be problematic. Unfortunately, this is seldom the case when using social science data, where indicators are often coarse or missing. As a result, these indicators often do not contain sufficient information to differentiate between theoretically distinct units. The benefit to this approach is that it does not force any atheoretical ‘memory’ on the latent trait allowing sudden changes in the latent trait across time-periods.

### *Standard dynamic model*

To address temporal non-independence in the data, many researchers have used a dynamic prior for the latent trait, where the latent trait for unit  $i$  in time  $t$  is related directly to the latent trait for unit  $i$  at time  $t - 1$  (Martin and Quinn, 2002; Schnakenberg and Fariss, 2014; Fariss, 2014; Caughey and Warshaw, 2015; Kōnig et al., 2013). The choice of a ‘random walk’ prior on the latent variable is particularly common.

The random walk approach begins with the use of a standard normal prior on the latent trait in the first observation period for every unit. Then for each subsequent time period, the prior is normally distributed with mean  $\theta_{i(t-1)}$ , and a standard deviation  $\sigma$  which is either assigned by the researcher or, more commonly, estimated from the data.<sup>8</sup> Here, we assign a weakly informative prior to  $\sigma$  by using a half-normal distribution with standard deviation of 3 and mean 0.

#### *Standard dynamic model priors*

$$\begin{aligned} \theta_{i1} &\sim N(0,1) \quad \forall i = 1, \dots, N \\ \theta_{it} &\sim N(\theta_{i(t-1)}, \sigma) \quad \forall i = 1, \dots, N \quad \forall t = 2, \dots, T \\ \sigma &\sim \text{HN}(0,3) \end{aligned}$$

This strategy trades the assumption that observations are independent with the assumption that the latent trait will be correlated over time and will follow a random walk. As a result, estimates from dynamic models typically have less uncertainty because more information is used to estimate each latent variable. This also induces smoothing over time because changes between time periods are constrained. When researchers have theoretical reasons to expect that the latent trait is relatively slow-moving over time, both modeling features can be desirable. If, however, the latent trait is subject to rapid fluctuations or state changes between time periods, this temporal smoothing can produce biased estimates. The modeling strategy we introduce below is designed to address this problem while still accounting for temporal dynamics.

### *Robust dynamic modeling*

We recently proposed an alternative strategy that drew on the robust modeling literature to implement a robust version of the dynamic modeling (Reuning et al., 2019). In the Bayesian framework, robust models alternate normal distributions with the Student’s  $t$ -distribution to account for outliers (Gelman et al., 2014; Lange and Sinsheimer, 1993; Lange et al., 1989; Geweke, 1993; Fonseca et al., 2008). In the context of dynamic latent variables, potential outliers are the ‘shocks’ where values of the true latent variable change suddenly within a unit’s time series.

The robust dynamic model continues to use a standard normal distribution for the first observation in a unit’s time series.<sup>9</sup> In subsequent years, the prior follows a Student’s  $t$ -distribution with four degrees of freedom. Setting the degrees of freedom to a relatively low value increases the density of the tails of the distribution, which allows ‘extreme values’ to be estimated from time period to time period. Thus, the model smooths estimates across time during periods of stability, but also allows for rapid changes in the latent

trait during periods of volatility. It is possible to estimate the degrees of freedom, but this can lead to identification problems, which we explore in more detail in the appendix to Reuning et al. (2019). Setting a low degree of freedom of 4 has been recommended in other contexts (Gelman et al., 2014) and so we believe that it will be useful in most latent variable cases.

#### *Robust dynamic model priors*

$$\begin{aligned}\theta_{i1} &\sim N(0,1) \quad \forall i = 1, \dots, N \\ \theta_{it} &\sim T_3(\theta_{i(t-1)}, \sigma) \quad \forall i = 1, \dots, N \quad \forall t = 2, \dots, T \\ \sigma &\sim \text{HN}(0,3)\end{aligned}$$

## **EXTENSIONS OF LATENT VARIABLE MODELS AND SUGGESTIONS FOR FUTURE RESEARCH**

In this final section, we highlight different fruitful paths for research using latent variable models. We discuss new ways that theory has informed particular modeling strategies and how this can provide new insights. We then present Multi-Rater/Aldrich-McKelvey Scaling models, which allow researchers to use latent variable models to reduce the impact of rater preferences when trying to develop uniform scales from expert surveys. We go on to introduce Multiple-Indicator Multiple-Causes models. These models are relatively common in psychology but are rarely used in published political science research, even though they provide a principled way to test what drives change in a latent variable. We then discuss problems with different model fit statistics. We close with a set of best practices useful for guiding future research.

### ***The Seriousness with Which One Must Take Time***

The modeling structures outlined above identify only a few ways in which researchers

may care to model temporal dynamics. In practice, researchers are beginning to identify a variety of new strategies to address different forms of temporal non-independence. At times, for example, researchers have reason to suspect that the relationship between a manifest indicator and the latent trait may change over time. Kenwick (2018), for example, is interested in civilian control of regime institutions and argues that the strength of this control increases over time, with civilian control expected to be higher in a state where civilians have ruled for several decades than in one that had previously experienced a military take-over. He therefore structures the prior distribution on the latent trait for civilian regimes as a random walk with drift, allowing the values of the latent trait to systematically increase (or decrease) over time. Fariss (2014) faces a different type of temporal non-independence in the study of human rights violations, and argues that the standards with which human rights reports are written has changed over time. To accommodate these potential biases, Fariss (2018b) allows the item discrimination parameters linking standards based indicators to latent trait to vary over time to mitigate temporal biases.

In each case, the specific modeling structure used to generate estimates of the latent trait was informed by prior theory and the results are empirically validated against competing models. These examples demonstrate how the choice of modeling structure can fundamentally alter the estimates of the latent trait itself, and the theoretical inferences one draws from the measurement analysis. These insights are often non-trivial and must be treated with the same care with which other forms of hypothesis testing are conducted. Nevertheless, these examples demonstrate how the proliferation of dynamic variable modeling techniques offers fertile new testing grounds for the theoretical evaluation of concepts of interest.

### ***Models of Other Unit Dependences: Multi-Rater/Aldrich–McKelvey Scaling***

Latent variable approaches can also be useful in the context of expert and non-expert survey when there is concern over how individuals will respond to survey items. This question was first approached in research on surveys of voters in the United States (Aldrich and McKelvey, 1977; Hare et al., 2015), but has also recently been used in the context of expert surveys to quantify country level attributes (Marquardt and Pemstein, 2018). The benefits of these approaches, which we will refer to here as multi-rater IRT, is that in using them, researchers can place answers from survey participants that might view underlying concepts on different scales onto a single scale.

As an example, take the work of Marquardt and Pemstein (2018), in which the authors use a multi-rater model to place expert surveys about democratic practices within a country on a single scale. They start with a survey of experts, asking them to rate several countries on a variety of democratic attributes. The problem with using these ratings directly is that different experts might have different opinions about how democratic a country must be to be considered the most democratic, and may also vary in their general understanding of the question. This is a form of *differential item functioning* where the relationship between an item (a response to a particular survey question) and the latent trait varies.

To account for differential item functioning the  $\beta$  (discrimination) and  $\alpha$  (difficulty) parameters are estimated for each survey participant but held constant across the countries that they rated. For example, if  $Y_{ic}$  is expert  $i$ 's response to a question on country  $c$  then it would be estimated as a function of  $\alpha_i + \beta_i \theta_c$ .

This technique is fruitful not only in the context of expert surveys but also for non-expert surveys where there are varying perceptions. Hare et al. (2015) use this to

identify ideological placement of US senators from a survey of voters. The multi-rater method accounts for the fact that more liberal voters are likely to see the same senator as being more conservative than a moderate voter.

Nevertheless, in order for measures to be made comparable, there has to be a degree of overlap in the units that survey participants rate. This returns to the problem of bridging discussed above. Without overlap, the latent estimates will not be comparable across units. Overlap allows us to identify the degree of differential item functioning and so provide estimates of latent variables that are comparable when there is significant differential item functioning.

### ***Adding Even More Structure: MIMIC Models***

The final extension we consider is less focused on particular latent models and more on the use of estimates from the latent models. Latent models produce estimates of the latent traits that include error. The error needs to be a part of any future models that use the latent variable. When the latent variable estimates are used as an independent variable, estimation that incorporates error can be achieved relatively easily. All that is necessary is to take  $N$  draws from the posterior of the latent variable, estimate  $N$  models that use the latent variable as an IV and then combine those estimates using the same process that is used to combine multiple imputations.<sup>10</sup>

Estimating models where the latent variable is the dependent variable requires more care, but there are methods that are commonly used outside of political science that can accomplish this goal. Multiple-Indicator Multiple-Causes (MIMIC) models were developed starting in the 1970s to allow researchers to use multiple measures of a trait when estimating the impacts of exogenous variables on that trait (Jöreskog

and Goldberger, 1975; Muthén, 1989). The MIMIC model approach is commonly employed in psychology (Krishnakumar and Nagar, 2008) and was more recently introduced to political science in the context of political psychology (Pérez, 2011).

In brief, MIMIC models include covariates for the latent variable that is being estimated. These covariates are included in the initial estimation process and so capture the error that is inherent in measuring a latent variable. Covariates are included by modeling  $\theta$  directly as a function of the covariates instead of just setting a simple prior on it.<sup>11</sup> In addition to providing better estimates of the covariates on the underlying latent trait, MIMIC models can be modified to identify differential item functioning that is correlated with one of the covariates (Pérez, 2011).

One caveat for MIMIC models is that we are unaware of anyone who has connected the MIMIC approach to the dynamic latent variable approaches discussed here. Both approaches involve modifying the modeling of the latent variable (either through an informative prior or a regression setup) and so connecting the two will require additional work.

### **Assessing Model Fit: WAIC for Hierarchical and IRT Models**

WAIC (the Watanabe–Akaike or widely applicable information criterion) is currently one of the more preferred model diagnostics for Bayesian models (e.g., Gelman et al., 2014). However, several open research questions remain under-explored when using WAIC with hierarchical or IRT models.

WAIC is an approximation of leave-one-out validation, but approximating leave-one-out validation leads to a problem in IRT data over what ought to be ‘left out’ when validating models. That is, should individual items be left out for all unit-time periods, for units from a panel or for all unit-years? Or should all the items be left out for one of these unit

structures? Newly published research extends WAIC to cases in which items are clustered within an observation (Furr, 2017) as well as other work incorporating time dynamics (Li et al., 2016). Another recent area of work is diagnostics, and best practices for WAIC and other models (Vehtari et al., 2017).

When there is concern over the validity of WAIC statistics, it is useful to also estimate a K-fold cross validation. This of course also requires removing a set of data and estimating the model. We suggest that researchers randomly sample indicators to remove so that each unit-time is still in the model. This allows estimates of latent traits for each unit-time and those estimates can be used to calculate a held-out log-likelihood.

We suggest that while this area of research continues, researchers should provide multiple checks of model fit. Posterior predictive checks are another very powerful way to test how well an IRT model fits data (Gelman and Hill, 2007). Overall, fit statistics, posterior predictive checks and visual analysis of the temporal patterns of well-known cases allow for the evaluation of competing models without relying on a single statistical tool.

### **Best Practices for Applied Measurement Research**

Finally, as researchers use these methodologies, we propose a few useful suggestions on how to best approach modeling latent variables. It is our intention that these suggestions are consistent with the statistical modeling choices made when selecting the component parts of latent variable models, and that these choices will be made with reference to the two main types of construct validity also discussed. Recall that the process of measurement occurs in three iterative stages: *conceptualization* of the sociological or physical system being studied; *operationalization* of the data generating process that approximates the system; and *empirical analysis* of the data. The specific terms we use for each

of these three stages is *concept, construct, data*. Construct validity is an overarching term for assessing the relationship between one or more of the entities represented in each of these steps.<sup>12</sup>

- **Validate by letting the theoretical concept drive the measurement specification:** We have referred to this type of validation as translation validity and it is concerned with the link between the theoretical concept and the operationalized construct. It is not possible to consider a measure of an unobserved concept without referencing a theoretical concept. For a construct to be valid, it needs to translate the theoretical concept into an operational procedure that will generate data consistent with the theory. Thus, the first step for any research on latent variables is to outline the assumed relationships between the data generating process and the concept to be measured. Will the data generating process produce indicators that reflect the underlying concept of interest? Are the proposed items manifest of the underlying concept? Are the proposed items substitutes for each other? How are proposed items measured over time?
- **Validate by assessing the assumptions of the measurement model as they relate to theoretical concept of interest.** This is also a suggestion about translation validity. How does the specification of the measurement model translate the theoretical concept into the operational procedure that generates the observed data? Every measurement model has underlying assumptions and it is important that any empirical patterns are the result of the underlying data and not of the assumptions. In the case of latent measurement models, researchers must pay close attention to any parameters that are set without reference to theory of their concept of interest.
- **Validate the fit of the measurement model as it relates to the observed data.** How does the model of the data generating process, the latent variable, fit the observed data? This is an assessment of measurement validity. Measurement validity is an evaluation of the fit between the proposed data generating procedure and the actual data obtained from it. WAIC (the Watanabe–Akaike or widely applicable information criterion) and other statistical tools are useful ways to test model fit,

but researchers should not just select a model based on a single statistical tool. One useful way to test competing models is to focus on divergent estimates and use *a priori* knowledge about the world to validate which one is the best.

There is no guarantee that any single modeling strategy will be equally well-suited for use with all data types or for estimating all types of latent concepts. The assumptions of the measurement model will influence the conclusions researchers draw about the underlying theoretical concept of interest, as well as the empirical linkages between these concepts and other political phenomena.

## CONCLUSION

The assessment of theories about political institutions and behaviors often requires measuring concepts that are not directly observable. Thus, for science to proceed, measurement is essential, because without a clearly articulated link between the empirical content of a study and the theoretical structure that gives rise to that content, it is not possible to make claims about the relationship between data and the world. Yet, despite the necessity for valid measurement, research in the social sciences still often tends to ignore the construct validity of most measures and usually takes existing data, especially experimental data, for granted or at least as good enough. Thus, one of the critical steps in evaluating theoretical concepts is the development, formalization and validation of measurement models. This is because there is no model-free way to measure unobservable or difficult to observe concepts. And many of the concepts of interest to the political science community are often by definition difficult to observe. As we have discussed in this chapter, construct validity – and measurement models in general, and latent variable models in particular – are tools which are useful for systematically evaluating the

relationship between concepts, operational procedures (e.g., the data generating process) and data.

## Notes

- 1 For the purposes of this chapter, we focus exclusively on unidimensional measurement models that are explicitly created in an effort to link observed data to an unobservable concept.
- 2 The development of the concept of construct validity has occurred over many decades. Primary contributors include: Campbell and Fiske (1959); Campbell (1960); Campbell and Ross (1968); Cook and Campbell (1979); Shadish (2010); Shadish et al. (2001). However, the conceptual meaning of the terms used in these article have evolved over time. As Jackman (2008) notes, 'there are several species of measurement validity. But at least in the context of latent variables, the term "construct validity" has lost much of the specificity it once had, and today is an umbrella term of sorts' (122). We use the term construct validity in this way and point out specific subtypes where appropriate. We note further that different fields and subfields use the various construct validity terms in different ways, which has led to some confusion when translating across terms. Adcock and Collier (2001) review this issue in brief, but like them, we leave a full accounting for the agreement and disagreement of overlapping validity concepts to future work.
- 3 Reuning et al. (2018) provide a complete and detailed set of replication files that demonstrate how to use these particular latent variable models using both applied examples and a set of simulation-based models: <https://doi.org/10.7910/DVN/SSLCHF>.
- 4 We build on ideas covered in Adcock and Collier (2001) and elsewhere (e.g., Jackman, 2008; Shadish, 2010; Shadish et al., 2001).
- 5 The additive scale can be seen as a result of rewriting this to  $\beta_k (\theta - \alpha_k)$  and fixing  $\beta = \infty$ . This creates the step function that can be seen in Figure 20.2.
- 6 As the number of dimensions for the latent variable increases there is an increasing number of invariant rotations. For one dimension there are only two equivalent estimates; with two dimensions that number increases to eight (e.g., Jackman, 2001).
- 7 In the following section we will continue to leverage the normal prior for identification constraints, but we will introduce modifications to accommodate temporal dynamics.
- 8 The  $\sigma$  parameter is sometimes referred to as the innovation parameter.
- 9 In practice, one can also substitute a Student's t-distribution with a very high degree of freedom (e.g., 1,000), which closely approximates the normal distribution.
- 10 Mislevy (1991), Bolck et al. (2004) and Schnakenberg and Fariss (2014) each provide arguments and detailed suggestions on how to incorporate the uncertainty from latent variable estimate using the multiple imputation equation formula from Rubin (1987).
- 11 For more detailed discussion of estimations of MIMIC models see Fahrmeir and Raach (2007).
- 12 Two important parts of construct validity are translation validity and measurement validity. Translation validity is an evaluation of the match between the theoretical construct and the proposed data generating procedure which generates the observed pieces of information. Measurement validity is an evaluation of the fit between the proposed data generating procedure and the actual data obtained from it (Fariss and Dancy, 2017).

# Measuring Attitudes – Multilevel Modeling with Post-Stratification (MrP)\*

Lucas Leemann and Fabio Wasserfallen

## INTRODUCTION

Reliable information on public opinion is, for the empirical analysis of many political science questions, a *conditio sine qua non* – not only for the whole sub-field of political behavior, but also for researchers interested in, for example, the congruence of public opinion with the legislator or government action (and how that is shaped by institutions). The basic methodological challenge for research on public opinion is to make valid inferences from a collected survey sample to the larger (underlying) population. Also, there may be several (sub-)populations of interests if we want to compare, for example, public opinion across the US states with national polling data that only includes a small number of respondents for certain states. We will present and discuss in this chapter multilevel regression and post-stratification, so-called MrP, which has made a seminal contribution to the estimation of

public opinion for subnational units, and also advances public opinion research in several other respects.

Often, we collect national polls, but may be interested in the estimation (and comparison) of public opinion on lower constituency levels (such as states or congressional districts in the US, Bundesländer or Wahlkreise in Germany and cantons and municipalities in Switzerland). The problem is that the sub-samples of respondents in the poll for some units – particularly the smaller ones – are too small. Small samples will increase the estimates' mean squared error – these estimates remain unbiased but their variance is large in small samples. In addition (and related to) this small-n problem, samples are often not representative for the larger population. The usual fixes for these caveats have been that researchers pool data from several surveys (to increase the sample) and that they use raking or post-stratification for calibration, which, in

effect, induces the structure of the underlying population on the sample (Miller and Stokes, 1963; Erikson et al., 1993; Zhang, 2000). The more recent literature has established MrP as a superior solution to these methodological problems, with several studies testing, validating and extending the method (Gelman and Little, 1997; Lax and Phillips, 2009b; Warshaw and Rodden, 2012; Leemann and Wasserfallen, 2017).

MrP is powerful because it combines the multilevel modeling of the survey data with post-stratification, using information on the population structures for which we aim to derive estimates. In short, researchers using MrP (a) organize the data in fine-grained ideal types, (b) make predictions for each ideal type using (national) survey data and (c) use post-stratification for the estimation of public opinion of the (subnational) constituencies of interest. This approach provides more precise estimates in case researchers face the small-*n* problem discussed above and/or work with skewed samples. Equally (or even more) important is that MrP provides a flexible and general framework that has opened avenues for constant improvements, fruitful combinations with other methods and sophisticated applications that are nicely tailored to specific data and research design challenges.

In the next section we present the basics of MrP and discuss technical issues, methodological limitations and extensions of the method. In essence, MrP is a stepwise framework that is conducive to flexible adaptations. Many different substantive political science puzzles have been empirically addressed with different versions of MrP. The contributions to various political science literatures in that respect are quite impressive, considering that MrP is still a young method. Among others, MrP has contributed to the literatures on political behavior, American politics, federalism, comparative politics and institutions. More specifically, several MrP studies generated important

insights into the study of partisanship, ideology, the responsiveness of institutions to public opinion, congruence of elite and voter preferences and polarization (e.g., Lax and Phillips, 2012; Tausanovitch and Warshaw, 2013; Leemann and Wasserfallen, 2016; McCarty et al., 2019). The impressive track record of MrP and its broad scope of substantive applications (also beyond political science, e.g., in sociology) may be considered to be the greatest contribution of the still rather young method. In that sense, MrP is much more than the successor of raking or post-stratification – with substantial potential for future research.

As far as methodological advances are concerned, Ghitza and Gelman (2013) elaborated a method for the analysis of deeply interacted subgroups; Leemann and Wasserfallen (2017) developed a MrP approach that relaxes the data requirement and increases the prediction precision; and Kousser et al. (2018) and Tausanovitch and Warshaw (2013) combine MrP with joint scaling and IRT. These are just a few examples of some recent methodological improvements that are, in all these cases, sophisticated answers to specific research design challenges. In addition to making academic contributions, MrP is also widely applied in the real world. This comes as no surprise, given that political actors are eager to get precise estimates of public opinion in election and referendum campaigns (Hanretty et al., 2016a). In addition, MrP's logic of ideal types lends itself straightforwardly to the analysis of public opinion in specific subgroups, which is of importance for political actors that want to develop campaigning efforts targeting specific subgroups of the population. A further attractive feature of MrP is that it allows leveraging of large datasets, also from samples with unequal participation (Wang et al., 2015; Downes et al., 2018). In the digital age, such data become the norm.

In this chapter we illustrate the basics of MrP with a running example, before we

discuss several technical issues, extensions and advances of the method. Moreover, we provide a broad overview of MrP, as it is applied in several (sub-)fields of the political science literature, by also discussing some (selected) substantive insights that we could gain thanks to several sophisticated studies. The broad spectrum of MrP applications is quite impressive and shows that MrP is, next to its methodological appeal, an approach that has great potential to further contribute important insights to various puzzles of political science. Finally, we elaborate on the challenges and limitations of MrP and speculate on future developments.

## MULTILEVEL REGRESSION WITH POST-STRATIFICATION (MRP)

Raking and post-stratification are two ways to generate weights for each individual observation. The idea of both methods is to rely on some stratifying variables (e.g., education, gender, age) to generate weights such that the weighted sample has the same marginal or joint distribution (with respect to these variables) as the target population.

Let's take a step back and look at the estimates of the outcome variable rather than how to generate weights for the observation. In both raking and post-stratification, we generate weights for each individual observation. Another way to think about this is that we organize the data in ideal types. If we were to post-stratify by education (six levels), gender (two levels) and age (four categories), we would think of the population as consisting of 48 different ideal types. Each individual in the sample can be assigned to a specific ideal type that is defined by the individual's education, gender and age. To generate weights, we can look at the magnitude of the share of respondents that belong to a specific ideal type and how large that share should be in the target population. The

weight is chosen such that the weighted share in the sample is equal to the actual share in the target population.

For raking or post-stratification, one just takes the mean of the outcome variable among all people belonging to the same ideal type. That estimate is then the best guess for the outcome variable for people of that ideal type. If the outcome variable is the support for a specific politician, the estimate will be between 0 and 1 and be interpreted as the share of people of that ideal type that support a specific politician.

What multilevel regression with post-stratification (MrP) does is different in the way we determine the estimate of the outcome variable for a specific ideal type. Rather than using this estimate for the ideal type's average support, MrP relies on a model to estimate the support among all survey respondents (Gelman and Little, 1997; Park et al., 2004). Based on this model, we can generate different predictions for different ideal types. This is the main technical difference from simpler methods, such as raking or post-stratification. As we show later, relying on a model rather than just a simple mean opens up many doors for analysis.

### *An Example: Voting on a Minaret Ban in Switzerland*

An example will help to illustrate MrP and its extensions discussed later. The example here is an (in)famous vote in Switzerland in 2009, when a slight majority of the Swiss population supported an initiative to ban the future construction of minarets. Surveys in advance of the vote indicated that it would be rejected but to the surprise of many it was accepted. The example here will rely on a dataset from a post-vote CATI carried out by universities in cooperation with a private company.

We start the illustration with a fairly simple MrP analysis which only includes

individual-level variables (education, gender, age). We thus think of the sample and also the population of consisting of 48 different ideal types.<sup>1</sup> At the core of MrP is a multi-level (or hierarchical) response model with the variable of interest as the outcome (in this example a yes or no vote for the minaret ban). It can be modeled as a probit or a logit – we opt for the probit. Education, gender and age are added to the model as random effects such that each education group has its own draw from a common normal distribution as well as the groups for gender and age. In addition, we add a random effect for the subnational units (here, cantons) to the model. If attitudes vary regionally (beyond variation due to different demographics), we account for this in the subnational (here, cantonal) random effects. There are 26 cantons in Switzerland and this leads to 1248 (26 × 48) different ideal types.

$$\begin{aligned}
 Pr(y_i = 1) &= \Phi\left(\beta_0 + \alpha_{k[i]}^{education} + \alpha_{j[i]}^{gender} + \alpha_{m[i]}^{age} + \alpha_{n[i]}^{canton}\right) \\
 \alpha_k^{education} &\sim N(0, \sigma_{education}^2), \text{ for } k = 1, \dots, 6 \\
 \alpha_j^{gender} &\sim N(0, \sigma_{gender}^2), \text{ for } j = 1, 2 \\
 \alpha_m^{age} &\sim N(0, \sigma_{age}^2), \text{ for } m = 1, \dots, 4 \\
 \alpha_n^{canton} &\sim N(0, \sigma_{canton}^2), \text{ for } n = 1, \dots, 26
 \end{aligned} \tag{1}$$

This model yields estimates for the parameter  $\hat{\beta}_0$  as well as for the realizations of the random effects (e.g., for the first education group it is  $\hat{\alpha}_{k=1}^{education}$ ). This allows us to create a prediction for any of the 48 ideal types by adding the respective random effect realization of that ideal type. For any ideal type, we can add the constant to the four chosen random effect realizations and have an ideal type's score on the latent variable. After transforming that – via the cumulative standard normal distribution – into a probability, we derive an estimate of the share of a specific ideal type that is expected to support the minaret ban. This is markedly

different from what one does when relying on raking or post-stratification, where we would have just taken the average response (among all respondents of that ideal type). In this example, there are actually less observations than ideal types, but since the predictions are model-based this does not pose a problem.

The second step of MrP is post-stratification. We generate an average support for each ideal type and then weigh this by the relative share of a type in the target population ( $N_{ng}$  denotes the number of people of type  $g$  living in subnational unit  $n$ ). This is only possible with precise information on the structure of the target population. Often used variables such as age, education, gender and (in the US) race are known due to the census. Here, we need to know exactly how many people of a specific age group, education level and gender live in a specific subnational unit. This allows us to determine the average support in a subnational unit by weighing the support per ideal type (denoted as  $g$ ) by the share of that type in the unit:

$$\hat{\pi}_n = \frac{\sum_{g \in n} \hat{\pi}_{ng} N_{ng}}{N_n} \tag{2}$$

The running example here is the vote on the minaret ban in Switzerland in 2009. The raw data of the exit poll suggests that a majority of 51.5% of the electorate was against the ban. In other surveys leading up to the vote, an even larger majority seemed to oppose the ban. It was a great surprise to many observers when, on the day of the vote, the official results were announced: 57.5% of voters supported the ban. This triggered a larger debate about the values of public opinion polling in Switzerland. Would MrP have helped here? Yes, the simple MrP model described above provides an estimate of 58.0%, which is very close to the true value.

### Using MrP to Generate Subnational Preference Estimates

As mentioned above, MrP has received a lot of scholarly attention mostly due to its ability to generate credible estimates of subnational preferences (Lax and Phillips, 2009a,b). So far, we have only used MrP to correct for the unequal make-up of the sample’s structure (non-response bias). In a next step, we will use additional context-level variables to generate subnational estimates. We can add context-level explanatory variables by redefining the distribution of the cantonal random effect to be  $\alpha_n^{canton} \sim N(\beta X_n, \sigma_{canton}^2)$  whereas  $X$  is a matrix with a leading column of 1’s. Context-level variables were not included in the original MrP paper (Gelman and Little, 1997), but from Park et al. (2004) onwards many published MrP models include context-level variables.

Warshaw and Rodden (2012) show – looking at US data – that using context-level variables improves the district-level estimates. Since the estimated support for an ideal type is based on a model prediction rather than a simple sample average, one can easily include additional information into the model. With

US data, the most common variable used is the presidential vote share in the preceding election, but other frequently used variables are median income, share of veterans or share of evangelical Protestants and Mormons.

In the example here, we can also add a context-level variable. We are looking for a variable that only varies across cantons and that is likely correlated with the collective part of the voting decision. Variables picking up on political culture or more structural variables such as unemployment or income levels could be used as well. But since Swiss voters vote frequently on issues, we can actually use a past vote on a related issue. In 2008, an initiative wanted to change the constitution – to de facto reverse a ruling by the highest court – to make it easier for municipalities to vote on naturalization cases. The issue at hand and the likely motivating factors as well as the partisan vote recommendations were similar to those in the minaret ban vote. We include the share of people voting in favor of that initiative (which was eventually rejected) to the response model.

Figure 21.1 shows the estimates based on the raw data and two different MrP models. The estimates based on the raw data take the

Figure 21.1 Cantonal estimates and true approval rate

**Figure 21.2 Cantonal estimates and uncertainty**

average response per canton. The MrP without any context-level variable is what was defined in Equation 1, and the third model includes the vote share in the earlier vote. The disaggregation estimates do not perform well due to the low sample size per canton. This is in line with prior research (Lax and Phillips, 2009b; Warshaw and Rodden, 2012; Leemann and Wasserfallen, 2017). In addition, we see that the MrP estimates based on a model with no context-level variable yields estimates biased toward the sample mean (here 48.5%). We discuss this below in more detail. Finally, adding a context-level predictor increases prediction accuracy and the estimates based on MrP with a context-level variable are neatly clustered around the 45 degree line.

### ***Some Technical Remarks***

Why is it that MrP performs so much better than raw data in the estimation of sub-national public opinion? Part of the answer is that the model is estimated on all observations in the sample, while the disaggregation

results only rely on responses from a specific canton. The key is in the multilevel model used here that allows for partial pooling. When estimating the realizations of the random effects, for example, for the four age groups, all observations are used. When then generating predictions (e.g., for a young well-educated woman in the canton of Zurich), the model also benefits from men in other cantons in different education groups.

Partial pooling comes into the model by incorporating random effects. Random effects can be thought of as a weighted average between a global estimate and a local estimate, whereas the specific weights are based on the entire variation and the local variation (see Gelman and Hill, 2007: 253–4 for a more thorough discussion). Hence, the multilevel model allows for a more efficient use of the data.

A consequence of partial pooling is that the cantonal random effects can be biased toward 0 and this leads in the predictions to a bias toward the sample mean. The sample mean within a unit is less influential on that unit's random effect realization if there are few observations within the unit (Gelman and

Hill, 2007: 253). As a consequence, the partial pooling will be stronger for smaller units with fewer respondents (Buttice and Highton, 2013: 5). This can be nicely seen in Figure 21.2, where the estimates of MrP without a context-level variable are too steep and show little variation across cantons.

Once we add context-level variables the subnational estimates vary much more, since they enter the model as a regular variable and we estimate a fixed coefficient.<sup>2</sup> Almost all MrP applications now rely on a multilevel model with context-level variables and it is good practice to include them.

Finally, it is also worth considering that MrP is partly based on post-stratification. And post-stratification will perform best when there is little variation within a cell (here: specific combination of gender, age, education and canton) but large variation across cells. That is the case for any procedure that relies on strata, cells or ideal types. MrP will perform better the more homogeneous preferences are within an ideal type and the more variation there is among different ideal types.

One issue we have not yet touched upon is uncertainty. We presented the estimates as point estimates and did not discuss any strategy to generate the appropriate confidence intervals. Since the estimates are based on model predictions, we can easily generate the uncertainty estimates by relying on simulation (Herron, 1999; Gelman and Hill, 2007). This approach works whether one relies on `stan` or `lme4` to estimate the response model. We can illustrate how certain or uncertain we are by displaying the 95% confidence interval for the minaret vote.

Most confidence intervals have a width of about 12 percentage points and 24 of the 26 cantons had an actual result that was in line with the MrP estimate, that is, the official outcome was within the confidence interval.

This section described the standard MrP model and used an example to illustrate that MrP can help with two different – but frequent – challenges encountered when

working with survey data. On the one hand, MrP can deal well with data sets that suffer from non-response bias as it is found in many standard surveys used by academics. On the other, it enables researchers to generate subnational estimates that are by far superior to disaggregation.

Finally, a last point that has not yet received a lot of attention is how to select context-level variables. In the running example here it is easy to come up with a related but older ballot vote and to use those results as the context-level variable. But what do we do if we want to estimate support or opposition to a new EU treaty in a country that does not hold regular ballot votes on issues? It is worth stressing that the selection of context-level variables is important for two reasons. First, those are the only variables that enter the model as ‘fixed effect’ (in the hierarchical meaning and not meant to describe the within-estimator). Since MrP engages in prediction we should worry about overfitting (James et al., 2013). Second, it has been shown that using optimal context-level variables can greatly increase the prediction precision of MrP (Warshaw and Rodden, 2012). While authors discuss the variables included in the model, there is often no systematic justification provided for the specific choice.<sup>3</sup> We return to this issue below.

### ***Methodological Limitations and Extensions of MrP***

MrP has proven to be a valuable method in the political science toolbox, but it also comes with limitations and downsides. For one, MrP may work well to estimate district-level preferences when we have at least some responses in every district. However, MrP will not work to one’s satisfaction at increasing degrees of granularity – at some point, the identified small areas are too small and one will have hardly any respondents in the sample.

But beside this general limitation there are also more specific points. Buttice and

Highton (2013) published a paper that shows that the performance of MrP can vary and that there is no guarantee that MrP estimates are precise. They argue that MrP performs well for cultural political attitudes in the US but that this does not extend to all areas. The strength of this paper is that they work through various aspects that are important.

One relevant aspect to assess whether MrP can do well or not is the intra-class correlation (ICC). The ICC accounts for how strongly opinions vary across states and how strongly they vary within states. Buttice and Highton (2013) argue that MrP performs most strongly when almost all variance is on the context level (for them, the state level). In addition, they underline the value of having context-level variables in the multilevel model.

Another point made by Buttice and Highton (2013) is that researchers cannot rely on a canonical response model when analyzing different issues. More practically expressed, the hierarchical response model should be differently specified when researchers analyze public opinion on cultural issues (e.g., same sex marriage) or economic questions (e.g., tax levels). This echoes the point made by Warshaw and Rodden (2012), who advise including variables that are strong predictors of variation across units in the response model. The question of how to choose optimal context-level variables remains difficult. As we discuss later, machine learning applications of MrP promise improvements in that respect.

Some of the discussed shortcomings have already been addressed in the literature. First, the problem of *too many* subnational units was encountered early on by researchers working on German elections, where there are 299 districts. This is the problem that Selb and Munzert (2011) tackled: they wanted to estimate constituency-level estimates for 299 German Wahlkreise. Technically, nothing is wrong and one can estimate an MrP model. Realizations of the context-level random effect are 0 for those units that have no

respondent in the sample. But this approach might be inefficient as it does not exploit all information we have. While we may not have any respondents from a specific unit, we might have respondents from neighboring units, and could exploit that.

Another problem in such a situation is that we may not have socio-economic data broken down by unit, as electoral districts need not perfectly overlap with administrative boundaries, which are usually the standard units of census data. Hence, it is not immediately clear how one would carry out the post-stratification step. The major contribution in Selb and Munzert (2011) is to formulate a model where the unit-level random effect is spatially autocorrelated – this then allows us to exploit that we know which respondents live closer or further away from a specific district. They show how information can be added in such a model and also how this can be used within an MrP model (given that one does have administrative data on the electoral districts to be able to post-stratify). They replicate the empirical example of Park et al. (2004), which only has 50 units, and show that by adding a spatially autocorrelated random effect the estimates do not improve by very much. With a well-specified MrP model there is not that much unexplained variation that is spatially correlated and can be absorbed. But that just shows that it is not always necessary to rely on their extension – nevertheless, when facing too many districts, Selb and Munzert (2011) have shown a reliable and feasible procedure to produce estimates.

A second extension relates to the ability of the researcher to build a strong response model. While Buttice and Highton (2013) and Warshaw and Rodden (2012) advocate improving model quality by selecting better context-level variables, there is also another complementary strategy. It is also possible to add additional individual-level variables that will greatly improve the estimates. Variables such as party affiliation and income might be powerful predictors but are not part of the

census. If a variable is not part of the census, we cannot get the joint distribution, and hence it is not possible to post-stratify by such additional variables. This is unfortunate since one usually relies on less strong models due to the data constraints following in the post-stratification step. This was the motivating problem that Leemann and Wasserfallen (2017) address.

The first part of their argument is that the need for the full joint distribution stems from the binary part of the response model. When generating predicted probabilities, the impact of the realization of, e.g., the gender random effect will vary depending on where an ideal type's score on the latent variable is. Simply put, if the response model was a linearly additive model (as with, e.g., OLS) there would be no problem. But since we rely on binary models, we are confined to using a joint distribution. The second part is that they show how one can generate a synthetic joint distribution whereby one assumes independence between gender/education/age and, e.g., party ID (simple synthetic) or learns about the correlational structure from the survey data itself (adjusted synthetic). Following their approach allows reliance on powerful predictors on the individual level as long as one can find marginal distributions for those variables at the subnational level. This leads to multilevel regression with synthetic post-stratification (MrsP). For the authors, MrsP is MrP's better half. They show in simulations and replications that MrsP can outperform MrP and reduce the estimation error by as much as MrP does over disaggregation.

## THE USE OF MrP IN THE LITERATURE

The chapter has so far presented the underlying methodology of MrP by illustrating the method with a running example and has discussed several methodological limitations and extensions of MrP. What has become clear from this discussion is that MrP

provides a more precise and sophisticated method for subnational unit estimation as compared to disaggregation or raking. In addition, the discussion has shown that MrP builds on a distinct methodological structure, which provides the ground for ongoing and future innovations, adaptations and combinations of MrP with other methods. Accordingly, MrP is not simply the more precise successor of disaggregation or raking. Rather, the advances of MrP allow for the study of a new set of substantively interesting political science research questions.

It is noteworthy that the development of the method is not (exclusively) out-sourced to specialized method journals, but has also been advanced by substantive political science research. This combination of methodological development and substantive advances of various sub-field literatures is one of the most exciting features of the recent MrP literature. In the following, we discuss the state-of-the-art literature by focusing on three themes: testing and validation in different contexts, combinations of MrP with other methods and the broad substantive applications of MrP.

Multiple articles using MrP provide a rigorous methodological testing of the method. The previous section already discussed important methodological limitations and extensions of MrP in that respect. Given that MrP is still a relatively young method, the analyses of both the estimation precision and the scope conditions under which it performs well are critical for its establishment as 'gold standard' (Selb and Munzert, 2011: 456). An important factor for the quick establishment of MrP is that several substantive articles using MrP test and validate the precision of MrP in various different settings and contexts before they apply the method. Situated in the scholarship on American politics, Enns and Koch (2013), for example, estimate state public opinion on the level of US states and validate their application of MrP with specialized polls that were conducted for a subset of six states.

Going one level deeper, Warshaw and Rodden (2012) made a seminal contribution in popularizing MrP by showing how the method can be applied for the estimation of public opinion on congressional and state legislative districts in the United States. Among others, they validate the method by comparing MrP estimates with results of same sex marriage referendums in Arizona, California, Michigan, Ohio and Wisconsin. Also, other cross-validation methods have been applied, such as randomly splitting data from the whole sample (using only part of the sample for predictions). However, the validation with voting data is particularly stringent, as it uses the real world as a benchmark (as the example illustrated in the previous section does). Leemann and Wasserfallen (2016) make a similar test of their Swiss MrP models by comparing cantonal MrP estimates with results of 186 direct democratic votes, whereas Tausanovitch and Warshaw (2013) use, as real-world comparison, 2008 presidential vote shares.

Besides showing that MrP outperforms other approaches, several of these studies also advance MrP in some respect, often by combining it with other methods. For example, Enns and Koch (2013) estimate state-level policy preferences from 1956 to 2010, extending the use of MrP to the analysis of long time series. Also, Pacheco (2011, 2012) estimates time-series data for her analysis of change in US state public opinion, using imputation techniques to improve the estimates. A classic question of MrP studies is the study of congruence between public opinion and the views of their political representatives, and between public opinion and policy outcomes. The MrP literature has been careful to make sure that the opinions of voters and representatives are measured on the same scale. To that end, Kousser et al. (2018) combine MrP with joint scaling; Tausanovitch and Warshaw (2013) scale survey items with IRT; and Leemann and Wasserfallen (2016) field their own survey, accounting for the joint scaling in the design of the questionnaire.

The availability of precise time-series public opinion data and consistent estimates of elite and voter opinions on the same issues produced important empirical insights for the literatures on public opinion, representation and democratic performance.

The previous section discussed the pertinent challenges of the specification of the hierarchical response model as well as the methodological contributions by Selb and Munzert (2011) and Leemann and Wasserfallen (2017). More generally speaking, the literature on the limitations and extensions of MrP highlights that researchers ought to be familiar with the basics of MrP. They should develop an application of the method that is carefully tailored to their research design by taking into account all available data sources for their units of analysis. In that respect, also the work by Ghitzza and Gelman (2013) makes an important contribution by reducing model-dependency with the analysis of deeply interacted subgroups, which are subsets of the population that are defined by multiple demographic and geographic characteristics.

This line of research is of interest for political scientists that are interested in very specific subgroups of the population. Also, for political actors that are seeking information on turnout and vote choice – preferably on a very specific level in terms of voter characteristics that allow for targeted campaigning efforts. Accordingly, it does not come as a surprise that MrP has become a standard tool in the field of campaigning and forecasting. A further powerful feature is that MrP can leverage large data sources that nowadays can be collected through online surveys. We name just a few examples here (from a long list): Hanretty et al. (2016a) present a forecast model for the 2015 British general election, and, among many others, CBS (in the US), YouGov (in the UK) and LeeWas (in Switzerland) conduct regular surveys using MrP. A further, rather general, attractive feature of MrP is that it can be applied to the analysis of large datasets collected online, including from samples

with unequal participation (Wang et al., 2015; Downes et al., 2018).

In the digital age, large datasets that are not random samples of the target population have become the norm. MrP has been successfully used in the analysis of such non-random samples, even in a case in which Xbox players were used to predict the 2012 presidential election in the US (Wang et al., 2015).<sup>4</sup> While MrP has received some attention for its seeming ability to work well with non-probability polls, there is no secret magic entailed in the use of a regression model and a post-stratification procedure. When non-probability samples can yield valuable insights and when they cannot, will likely be a question that will attract much more research, particularly from polling companies that have an economic interests in further developing such approaches. For now, we refer to Ansolabehere and Rivers (2013) for a useful overview and discussion of the necessary assumptions.

Coming back to the use of MrP in the political science literature, it has been applied to a broad spectrum of substantive research. Among others, MrP has advanced literatures on partisanship, ideology, the responsiveness of institutions to public opinion, congruence of elite and voter preferences and polarization. For example, Kestel et al. (2010) analyze how public opinion matters for senate vote confirming supreme court nominees, McCarty et al. (2019) analyze how polarization differs between voters and legislators, while a series of studies investigates the congruence between public opinion, representatives and policy outcomes – typically as a function of different institutional and electoral arrangements (Kousser et al., 2018; Lax and Phillips, 2012; Tausanovitch and Warsaw, 2013; Leemann and Wasserfallen, 2016). For a still rather young method, MrP has an impressive track record in providing substantive empirical insights to various (sub-)disciplines of political science. This may be its greatest success (and promise for the future).

Beyond political science, MrP has also been used, for example, in sociology. Claassen and Traunmüller (2017) use MrP as a tool for the analysis of hard to measure populations (not as a method for estimating public opinion). More specifically, they estimate the demographic structures of Hindus, Muslims and Jews in Great Britain using survey data. Since there is good census data for these religious minorities in Great Britain, they can validate the accuracy of their estimates. Thus, methodological advances and extensions of MrP (that are motivated by substantive research) are not restricted to the political science literature.

## CONCLUSION

MrP has, in a rather short time, established itself as the standard method for the estimation of public opinion for subnational units (and other subgroups of populations and samples). MrP provides a distinct and flexible framework in three steps, with the specification of the hierarchical response model, the prediction for ideal types and the post-stratification step. This general methodological structure allows for tailored applications, combinations with other methods and innovative extensions. In this chapter, we presented all steps of MrP with a running example, before discussing in greater detail technical issues, methodological limitations and extensions.

We have also discussed multiple advances of MrP and expect much more to come. As discussed, the selection of optimal context-level variables for the response model is critical, yet not straightforward. With the increasing use of machine learning approaches in political science (see e.g., Montgomery and Olivella, 2018), there are promising ideas and projects that are likely to provide further useful solutions for the challenge of selecting the response model in MrP applications. Machine learning is

an umbrella term for a lot of methodologies that improve model-specification and prediction accuracy with a disciplined approach. Several working papers combine classifiers with post-stratification and aim to bring the promise of statistical learning to MrP (Goplerud et al., 2018; Ornstein, 2017; Broniecki et al., 2018). The combination of MrP with other methods has already shown it to be very productive, and semi-automated procedures will likely help further improve MrP for certain applications.

However, most important for the continuing success story of MrP will be that methodological innovations are not an end in itself. Rather, future advances of MrP have to provide solutions for technical problems that are motivated by substantive research puzzles and are powerful enough to solve them. To the extent that this will continue to shape the development and applications of MrP, the importance of MrP for the political science literature will continue to grow. As the discussion of the broad substantive applications of MrP in the literature has shown, its track record in that respect is already quite impressive.

## Notes

- \* A complete replication file with an illustrative example can be found here: [https://github.com/lleemann/MrP\\_chapter](https://github.com/lleemann/MrP_chapter).
- 1 Gender has two categories, education has six categories (mandatory schooling or no response, apprenticeship, university-entrance diploma (Matura) and teachers college, additional job training, advanced training, university degree including universities of applied sciences), and age has four categories (18–34, 35–49, 50–64, 75–).
- 2 Fixed refers here to a coefficient that is estimated as a specific value, unlike random effects, where we estimate the variance part. This is not what is often referred to as within-estimator. See Gelman and Hill (2007: 245–6) for a more detailed discussion.
- 3 There is one exception: Leemann and Wasserfallen (2016) touch on this issue in the appen-

dix and show that they try to pick context-level variables based on AIC and BIC measures of the estimated models.

- 4 See also the work of Hanretty et al. (2016a,b) on UK YouGov samples for various elections and votes.

# Web Data Collection: Potentials and Challenges

Dominic Nyhuis

## INTRODUCTION

The universal adoption of the world wide web has brought about tremendous opportunities for the social sciences. Scores of data on every conceivable subject are often just one click away, making this the golden age of data. Indeed, one might reasonably argue that the main challenge in empirical social research has shifted from the collection of data to drawing value from the vast datasets. These changes are exemplified by the establishment of entirely new research fields, often summarized with the shorthand of computational social science (Alvarez, 2016; Behnke et al., 2018), and new professions such as the fabled data scientist – part statistician, part computer scientist, part social scientist.

One important aspect of these changes is the development of new methods for analyzing large datasets (see, e.g., Chapters 28–30 on text analysis and 55–56 on machine learning in this *Handbook*). In this chapter, we will

take a step back and consider an element of the research process in the era of big data that is less frequently talked about, but equally important – the question of how to assemble web data in the first place. The value of these skills hardly needs elaboration. If researchers know how to automatically collect data from the web, they are able to amass enormous datasets with little human input and little to no cost, putting even junior researchers with no research budget in a position to make valuable research contributions. What is more, while this skill set is highly sought after both inside and outside of academia, it is still surprisingly rare, such that mastering the art of web data collection allows scholars to push the boundaries of their particular field.

To be sure, even though web data collection is much less costly than, say, survey research, it can be a fairly cumbersome exercise nonetheless. Consider the workload in an ordinary survey research project. Survey research requires great care in preparing the

questionnaire and effort in surveying the respondents. Once the field work is done, however, the researcher can typically expect to hold a fairly clean spreadsheet of responses to proceed with the analysis. By contrast, in many web data collection projects, most time and effort is needed when the data collection in a strict sense is already completed. Data cleaning (e.g., checking for duplicate entries and correcting errors of various kinds) has become an integral part of the data collection exercise. This and other challenges related to web data collection are important considerations when deciding upon the best data collection strategy.

To elaborate the potentials and challenges of web data collection, we begin the remainder of this chapter with some technical backgrounds. Specifically, in the next section, we elaborate the basic ideas about gathering data from application programming interfaces (APIs) and how to scrape data from websites. We should caution readers that while the techniques are simple enough, there are quite a few fundamentals to cover before these methods can be pulled together for a practical application. The aim of this introduction is to provide you with a sense of the fundamental ideas in web data collection, not to equip you with the necessary tools to apply these ideas in practice. After reading this introduction, you should understand the basic building blocks of websites and web interactions, which suffices to achieve the majority of use cases in web data collection. (The final section points to some further readings to apply the techniques in practice.)

The third section discusses some current challenges in web data collection, where we distinguish between technical and conceptual challenges and try to highlight some potential remedies. The fourth section introduces a practical political science application that operates with web data. The aim here is not to discuss the substantive findings, but rather to highlight how the authors employ the tools we describe to make a valuable contribution to the political science literature.

## THE FUNDAMENTALS OF WEB DATA COLLECTION

### *Application Programming Interfaces (APIs)*

We can distinguish between two main strategies for web data collection: collecting data by scraping websites and gathering data from application programming interfaces (APIs). By web scraping, we mean accessing a website and extracting those pieces of information from the page that we are interested in. The relevant information is typically embedded in a larger context that we do not care about. Therefore, the greatest challenge in web scraping often lies in discarding the irrelevant parts. This step is mostly done away with when we collect data from programming interfaces. Such interfaces are explicitly set up by the providers of web services to streamline, among other things, the exchange of information. Simply put, web services define a set of valid operations and data that can be retrieved from these access points.<sup>1</sup>

The main difference between data collection via web scraping and programming interfaces is the format in which we receive the data. When we access an ordinary online resource, we receive an HTML document from the server, which contains a lot of superfluous information. APIs, by contrast, provide the sought-after information in much more useful data formats that can easily be converted into conventional data matrices.

Let's consider a practical example to highlight the difference between web scraping and APIs, but also to show how both strategies exhibit clear similarities. We employ the Wikipedia API which allows us to access various pieces of information from the service.<sup>2</sup> In this case, we access the daily page views for the Mannheim entry with the following query:

```
https://en.wikipedia.org/w/api.php?action=query&
titles=Mannheim&prop=pageviews&pvipdays=7&
format=xml
```

This small example can teach us a lot about the art of gathering data from the web. Consider first the structure of the query. It looks very similar to ordinary URLs. The specific query consists of four components that you will encounter all over the web. The query begins by defining a scheme, which describes the protocol that is used to exchange messages between the user and the server, in this case the HTTPS scheme. HTTP and HTTPS are the most common protocols in web interactions and while we will spare you the technical details, they prescribe the structure of the messages that are exchanged between the user and the server. The response from the server will often contain some requested file, for example, an HTML document, a JPEG image, a PDF file or, in the present case, an XML file.

After the scheme, we specify the domain where the resource is located, in this case ‘en.wikipedia.org’. Effectively, we are looking to retrieve information from the Wikipedia server. Next, we define the path to the specific resource on the server. Here, the individual elements of the path are comparable to nested folders on your computer, such that ‘api.php’ resides within the ‘w’ folder. The last component of the URL contains the specific query, which is preceded by a question mark. The elements of the query consist of key–value pairs where the individual keys (‘action’, ‘titles’, etc.) define the parameters. Our choices are specified in the values that are linked to the keys with equality signs. The key–value pairs are separated from one another with ampersands. A summary of the four most common components of URLs are presented in Table 22.1 with examples.<sup>3</sup>

Note that while the components are identical, the keys for the search queries differ between the three examples. This is what we mean when we say that each web service defines a set of valid operations. Indeed, while both Twitter and Google Scholar place the query string in a ‘q’ key, this is a mere convention and they could just as easily have named the query parameter something else.

**Table 22.1 Common components of URLs**

<i>Component</i>	<i>Example</i>
Scheme	https:// https:// https://
Domain	en.wikipedia.org/ twitter.com/ scholar.google.com/
Path	w/api.php search scholar
Query	?action=query&titles=Mannheim&prop=pageviews&pviptime=7&format=xml ?q=metoo&src=typd ?hl=en&q=anthony+downs

Note further that we typically do not use every possible parameter, but only the ones that we need to formulate our query, while other parameters might operate as defaults in the background or they might even be appended by the server as needed. For example, our results do not change when we drop the ‘src’ parameter from the Twitter URL.

An overview of the possible parameters for the Wikipedia API can be accessed at ‘https://en.wikipedia.org/w/api.php’. Along with defining the set of valid parameters, the web services also limit the possible parameter values. For instance, the ‘format’ parameter in the initial example is likely to only have a small set of possible values. Finally, note that not all of the four basic building blocks need to be present for constructing a valid URL. For example, ‘https://stackoverflow.com/’ describes a perfectly valid resource location that only consists of the scheme and the domain, and which will retrieve the main HTML document of the Stackoverflow site.

After inspecting the basic components of URLs, let’s return to the query we made to the Wikipedia API to collect the daily page views for the Mannheim Wikipedia page. The five key–value pairs of the request are listed in Table 22.2. The five elements are quite descriptive and we can easily infer the function of each. The ‘action’ parameter specifies that we are looking to make a query to extract

**Table 22.2 Parameters of the Wikipedia query**

Key	Value
action	query
titles	Mannheim
prop	pageviews
pvipdays	7
format	xml

some kind of information. The ‘titles’ parameter defines the specific page. The ‘prop’ parameter defines the type of information we are looking for, the daily page views. The parameter ‘pvipdays’ specifies the range for the request, in this case the last seven days. Finally, the ‘format’ parameter defines the format of the response, in this case an XML-formatted document, which we will discuss in a second.

If you type in the full URL from the beginning of this section into your browser, you should receive a response that looks similar to the one that we have displayed in Figure 22.1. Before we take the response apart, let’s stick with the URL for just a moment longer. One common solution to many problems in web data collection is the systematic manipulation of the URL to access not just one page

but all pages of interest. For instance, if we were interested in the daily page views of not just one but a set of Wikipedia articles, we could simply replace the value ‘Mannheim’ in the ‘titles’ parameter with other values, e.g., ‘Konstanz’, to retrieve the page views of that page, and so on (for examples see Kämpf et al., 2015; Roll et al., 2016).

APIs typically provide a variety of information. If we dig deeper into the documentation of the Wikipedia API, we find that there are a number of possible values for the ‘prop’ parameter, associated with the ‘query’ value of the ‘action’ parameter.<sup>4</sup> For instance, many Wikipedia pages are geolocated and we can retrieve this information using the ‘coordinates’ value for the ‘prop’ parameter. Dropping the ‘pvipdays’ parameter, which we only needed to specify the time frame for the ‘pageviews’ value in the ‘prop’ parameter in the previous version of the URL, we can construct the following request:

<https://en.wikipedia.org/w/api.php?action=query&titles=Mannheim&prop=coordinates&format=xml>

Pasting this query into the browser, results in a response from the server containing the

```

▼<api batchcomplete="">
  ▼<query>
    ▼<pages>
      ▼<page _idx="99627" pageid="99627" ns="0" title="Mannheim">
        ▼<pageviews>
          <pvip date="2018-11-03" xml:space="preserve">562</pvip>
          <pvip date="2018-11-04" xml:space="preserve">593</pvip>
          <pvip date="2018-11-05" xml:space="preserve">617</pvip>
          <pvip date="2018-11-06" xml:space="preserve">528</pvip>
          <pvip date="2018-11-07" xml:space="preserve">546</pvip>
          <pvip date="2018-11-08" xml:space="preserve">517</pvip>
          <pvip date="2018-11-09" xml:space="preserve">546</pvip>
        </pageviews>
      </page>
    </pages>
  </query>
</api>

```

**Figure 22.1 Response from the Wikipedia API (Mannheim page views between November 3 and November 9, 2018)**

        </coordinates>
      </page>
    </pages>
  </query>
</api>

```

**Figure 22.2** Response from the Wikipedia API (Mannheim coordinates)

XML document in Figure 22.2. The document is quite similar to the document in Figure 22.1. The only changes are in the center of the document, which now contains the latitude and longitude values associated with the Mannheim Wikipedia page.<sup>5</sup> Having familiarized ourselves with the idea of manipulating URLs to gather all the information we need, let's return to the XML document in Figure 22.1, which can teach us even more about the basics of web data collection.

The XML format is quite similar to the HTML format, hence we can learn many of the properties of the latter document type from studying the former. Additionally, many of the same tools are used to extract information from XML and HTML documents. XML documents are nothing more than plain text documents that are structured in a particular way. The structuring elements are called tags. Such tags are enclosed by a '<' and a '>' sign. Typically, an opening tag is mirrored by a closing tag, which is indicated by a '/' character. Together, an opening and a closing tag form a node in a document. This sounds much more complicated than it is. Consider as an example the '<query>' tag in Figure 22.1, which is matched by the '</query>' tag further down in the document.

One important characteristic of XML-like documents is their hierarchical structure. In a well-formatted document, an outer node encapsulates one or more inner nodes. For instance, the '<query>' node encapsulates the '<pages>' node, which encapsulates further nodes still. Nodes in an XML document

and in an HTML document in particular can also encapsulate content. In the example in Figure 22.1, the daily page view figures are included in the document between the opening and the closing '<pvip>' tags. Compare this to the output in Figure 22.2, where all the sought-after information is embedded in the document structure. Lastly, the opening tags frequently have additional parameters and values associated with them, the so-called attributes and attribute values. For instance, the '<pvip>' tag in Figure 22.1 contains the attribute 'date' with the seven date values for the Mannheim page views.

As we have pointed out, an XML document is nothing more than a structured text document. Therefore, you could easily download the document to your hard drive and open and manipulate it with a basic text editor. The version of the document in Figure 22.1, i.e., the version with the indentation, is nothing more than an interpretation of the document by the browser that is intended to improve the readability of the document. The indentation reflects the hierarchical document structure where more indented nodes reside at lower levels. Incidentally, the interpretation of the document by the browser is why the document might look slightly different for you if you have been following along with the example, as each browser may render the document slightly differently.

We began the discussion in this section by suggesting that one of the advantages of data collection via APIs over web scraping is the

fact that the data comes in much more useful data formats that can easily be converted into conventional data matrices. While neither the document in Figure 22.1 nor that in Figure 22.2 look particularly simple at first glance, they are in fact quite bare bones data formats from which the relevant pieces of information can easily be extracted. We will not elaborate how to do this here, as the actual extraction would require some minor coding and we want to remain at a more principled level in this introductory section. Suffice it to say that CSS selectors and XPath expressions are two syntaxes which have been specifically designed for the purpose of extracting information from XML-type documents. Both make use of the hierarchical structure of XML documents and their various components (tags, attributes) to extract the relevant pieces of information. (See the final section for suggestions on how to implement these ideas in practice.)

Moving from the practical back to the principle, one additional benefit of APIs over web scraping is that the provider of the information clearly encourages the data collection and often explicitly spells out the terms of usage in the API documentation, putting our collection efforts on more secure ethical and legal footing. Finally, APIs may occasionally even enable us to access data that we could not access otherwise. In sum, the clear benefits of collecting data via APIs over web scraping suggests that whenever we embark on a new data collection project, we should ascertain whether the information can be acquired through an API.

These advantages notwithstanding, there are several downsides of gathering data from programming interfaces. On a technical level, APIs are somewhat idiosyncratic, as each provider gets to define a set of valid inputs and operations with which we must familiarize ourselves before interacting with the interface. Therefore, when a user wants to collect data from a programming interface, this typically means having to engage with the documentation of the API. The need

to adapt our tools to the specific case is of course equally true when scraping data from a website, but in this case the data provider cannot place any arbitrary restrictions on our arsenal. Related to this point is the possibility that providers change the functionality of their interfaces over time, potentially breaking the code you wrote to interact with an API. At least this point is no different for web scraping, where changes in the source code of a website can easily break your code.

In addition to these rather technical challenges, greater concerns typically stem from the restrictions that providers frequently place on their interfaces. From the point of view of the providers, restrictions are perfectly reasonable, as the simplicity of querying APIs is both a blessing and a curse for them. The ease of requesting huge amounts of data in very high frequency can cause an enormous burden on the servers and certainly invites disruptive behavior by malicious users. Providers employ a number of tactics to combat such behavior that all tend to be detrimental to our collection efforts. First, many APIs require users to register their application and to provide their authentication credentials as part of their query. This is more of a hassle than a limitation which allows providers to track how often users access their services, and who they are, in order to identify bad behavior.

More problematic are the limitations which are frequently placed on the data that can be queried from the services. Consider the Wikipedia API once more for a practical example. Say we were interested in the page views for a set of pages in the last year. We could change the 'pviptdays' parameter in the initial URL to the value '365' to gather the page views for a whole year:

```
https://en.wikipedia.org/w/api.php?action=query&
titles=Mannheim&prop=pageviews&pviptdays=365
&format=xml
```

At the time of writing, when we paste this URL into the browser, we receive data for the past 60 days along with a warning message that users may not access page views for a

longer time period. Another restriction that we typically face is a cap on the number of requests we can make in a given time period or the volume of data that can be queried. Yet another restriction could be set with regard to the data that can be queried in the first place. At the time of writing, the free-of-charge version of the Twitter API not only restricts backward searches to seven days, but also restricts users to searches in a database containing only a sample of the tweets which were published in this time frame. In light of these limitations, organizations – be they civil society actors or private organizations – have occasionally set up parallel services that collect the data as it becomes available, to redistribute the data with a different set of restrictions. Naturally, the ability of these services to provide the data is highly dependent on the terms of usage, and in many cases these supplementary services come with a price tag.

We want to close this discussion by pointing out that a great many APIs have been set up to provide easy access to data of all sorts. We encourage users to take a moment and check out some services. Familiarize yourselves with the documentation to see whether you can make sense of the API properties and identify the similarities to the components that we have discussed so far. One excellent starting point is the site *ProgrammableWeb*,<sup>6</sup> which has categorized thousands of application programming interfaces. Maybe you can even come up an interesting research project when you see what type of data is available.

One final benefit of using APIs for web data collection should not be left unmentioned. So far, we have accessed APIs directly with our browser. We could also access these sites using a scripting language such as Python or R and extract whatever piece of information we are interested in with few lines of code. For many of the most popular APIs, specific modules have been written in these languages that mimic the functionality of the programming interfaces by assigning the API operations to specific functions of these modules. This is to say that if a module has been programmed for

an API, we do not have to engage with the API documentation, but can simply use the functionality of the module to extract whatever data we are looking for, such that the module turns our request into a valid query and sends it to the API to retrieve the data.

## **Web Scraping**

In the previous section, we have accessed APIs to retrieve data in the XML format. In web scraping, we typically access documents in the HTML format, the most common document format on the web. The basics of HTML are not all that different from XML, so you will be able to recognize many of the features that we have outlined in the previous section. We should point out right away that modern HTML documents are characterized by a number of features that go well beyond this basic model. We will only introduce the basic ideas in this section, point to some complications in the following section and refer you to the further readings in the final section on how to deal with these complications in real-world applications. We want to emphasize, however, that despite these complications, the majority of use cases can still be accomplished with the tools that we outline in this section.

Like XML, HTML documents are hierarchically structured with the same basic features as XML, i.e., HTML documents are composed of nodes, tags and attributes. The main difference between XML and HTML is that HTML tags have a pre-defined meaning which is the same for every web page you will ever visit. By contrast, the tags and attributes in the XML documents we considered in Figures 22.1 and 22.2, e.g., ‘<query>’, ‘<pages>’, were defined by the curators of the Wikipedia API to best structure the data that is output by this specific API.

For HTML documents, there is only a limited set of tags with a predefined meaning and the tags have attributes associated with them that further specify the nodes. This limitation

enables the interpretation of an HTML document by the browser, since there is no ambiguity regarding the purpose of a particular tag in the overall document structure. Put differently, when you open an HTML document in your browser, you are, in fact, accessing a plain text document that looks quite similar to Figures 22.1 and 22.2 and the browser simply provides you with an interpreted version of the source code.

A lot follows from these considerations for the purpose of scraping data from the web. First, the great variability of the web is really only a superficial matter. Underlying this variety are always the same structuring elements, which allow browsers to make sense of the documents. Let's elaborate this with two examples. Only a handful of tags are used to embed a table in HTML source code. The entire table is always nested inside a '<table>' node, table rows are always indicated by a '<tr>' node, and so on. This means that in order to extract tabular information from a web page, it suffices to identify the relevant '<table>' node and to extract all the information encapsulated by the node. Indeed, due to the simplicity of identifying these types of structures within HTML code, numerous convenience functions have been written for the purpose of converting tabular information in HTML source code to

conventional data matrices. Another example is the '<li>' node, which inevitably encapsulates a list. Again, if the sought-after information comes in the form of a list, it is quite simple to identify and extract the relevant elements from the HTML source code using the querying syntaxes we mentioned in the previous section – CSS selectors and XPath expressions.

Let's consider a practical example. Many studies have relied on hyperlinks in websites for inferences about networks between issues or organizations (cf. Ackland and O'Neil, 2011; McNutt and Pal, 2011). The network datasets in these studies are often impressive but the underlying technical ideas are perfectly straightforward. For the purpose of a mock example, we consider the Mannheim Wikipedia entry. An excerpt from the site is provided in Figure 22.3. Our aim is to extract all hyperlinks to other Wikipedia articles from the source code of the site to build a network of pages with Mannheim at the center of the network. In a real-world case study, we might go on to extract all links from the resulting pages and repeat the process to build a comprehensive network or we might repeat the process for all German cities over a certain population threshold and build a network for each city to analyze whether and where these networks overlap.

## Mannheim

From Wikipedia, the free encyclopedia

Coordinates: 49°29′20″N 8°28′9″E﻿ / ﻿

*This article is about the city in Germany. For other uses, see Mannheim (disambiguation).*

**Mannheim** (German pronunciation: [ˈmanhɛm] ⓘ (ⓘ listen); Palatine German: *Monnem* or *Mannem*) is a city in the southwestern part of Germany, the third-largest in the German state of Baden-Württemberg after Stuttgart and Karlsruhe with a 2015 population of approximately 305,000 inhabitants. The city is at the centre of the larger densely populated Rhine-Neckar Metropolitan Region which has a population of 2,400,000<sup>[3]</sup> and is Germany's eighth-largest metropolitan region.

Mannheim is located at the confluence of the Rhine and the Neckar in the northwestern corner of Baden-Württemberg. The Rhine separates Mannheim from the city of Ludwigshafen, just to the west of it in Rhineland-Palatinate, and the border of Baden-Württemberg with Hesse is just to the north. Mannheim is downstream along the Neckar from the city of Heidelberg.

Mannheim is unusual among German cities in that its streets and avenues are laid out in a grid pattern, leading to its nickname "die Quadratestadt" ("The City of Squares"). The eighteenth century Mannheim Palace, former home of the Prince-elector of the Palatinate, now houses the University of Mannheim.

```

**Figure 22.4** Source code of the Mannheim Wikipedia page (excerpt, November 13, 2018)

To implement this idea in a practical web scraping application, we would typically begin by inspecting the source code of the page. All common web browsers allow you to right-click on a site and select the option of displaying the source code. Alternatively, you could download the source code to your hard drive and open the document in a text editor to check the underlying document structure. If we were to actually implement this use case, we would download the source code to our hard drive and then operate on it with a scripting language of our choice. A small portion of the page's source code, containing the second paragraph of the page in Figure 22.3, is displayed in Figure 22.4.

Once again, the indentation of the document is not part of the source code but an interpretation of the document by the browser that is intended to help human readers make sense of the document. We can clearly see the similarities between this document and the XML document we examined in the previous section. The document is hierarchically structured with opening and closing tags that encapsulate additional nodes and pieces of content. Inspecting the document a little closer, we find that the whole paragraph is enclosed by a '<p>' node. '<p>' nodes always wrap around paragraphs in HTML documents. If we were to extract all the '<p>' nodes from the document, we would get rid of much of the unwanted information, such that we would be left with almost only the content we might be looking for if our goal was to run a text analysis on the page.

As our interest only lies in extracting the internal links on the Wikipedia domain, we find that the links are – always – embedded in an '<a>' node. Specifically, the opening and closing '<a>' tags encapsulate the text that is displayed as the link to users in the interpreted version of the HTML document. Consider the first link, which reads:

```
<a href="/wiki/Rhine" title="Rhine">Rhine</a>
```

Going back to the interpreted version of the document in Figure 22.3, you will find that the first link in the second paragraph displays the encapsulated content between the two '<a>' tags: 'Rhine'. The interesting piece of information for our mock example is not the name of the link, however, but the value of the 'href' attribute in the opening tag: '/wiki/Rhine'. This sequence of characters describes the path for the Wikipedia entry on the Rhine river.

At this point we have all the technical pieces assembled to construct a link network of arbitrary size starting with the Mannheim page at its center. In the first step, we would simply write a query to extract all the '<a>' nodes and specifically the value of the 'href' attribute associated with the '<a>' nodes. From this list, we would discard all the links to resources that do not reside on the Wikipedia domain. For instance, at the time of writing, the first link to an external domain is 'https://www.mannheim.de/'. Note that external links do not complicate this discussion in any way. These links are still embedded in an '<a>' node and the link target

is still associated with the ‘href’ attribute. In this particular case, the link looks as follows.

```
<a rel="nofollow" class="external text"
xhref="https://www.mannheim.de/">www.
mannheim.de</a>
```

We note that additional attributes are associated with the ‘<a>’ node that we do not want to discuss here, but we find the ‘href’ attribute easy enough. We would shorten the remaining list of internal links – either links that specify a path on the Wikipedia domain or links that provide a full URL on the target domain – by discarding links that do not link to HTML pages, but to images or the like.

The next step in our mock research project is just as simple. We would take the URL for the Mannheim page – ‘https://en.wikipedia.org/wiki/Mannheim’ – and discard the path component from the URL ‘/wiki/Mannheim’ to replace it one by one with the new links, such as the one we identified above to construct new URLs: ‘https://en.wikipedia.org/wiki/Rhine’; then we would download the source code of the new page and start over. At this point, it is just a matter of repeating these few steps as often as we care to, to build a hyperlink network of arbitrary size.

We hope that this example has given you some intuition of how even simple web scraping tools allow us to build sizeable datasets by automating the collection tasks. Automating the tasks is greatly simplified by the fact that websites are all composed of the same building blocks. Let’s close this section with some final remarks on web scraping in practice. First, and related to the mock example we just discussed, it is not uncommon that we build our web scraping applications on the basis of an index page of one kind or another to collect a set of links to additional sites. For example, when gathering data from an online news source, we might start the data collection on an index page which contains links to a set of articles. We would first extract the links and open the individual pages in a second step to extract the content of the news articles. To be sure, the links on

such index pages may not link to HTML documents at all, but rather to PDF files or similar, which we could download with the same tools in order to extract the information from them in a second step.

As a rule of thumb, it is useful to distinguish between the collection and the extraction steps in web data collection. In practice, we are often interested in extracting data from thousands of HTML documents. Since we are bound to make mistakes in the extraction step, it is helpful to first store all the target pages on your hard drive and then attempt to extract the relevant information from the target pages. This way, we create as little traffic on the server as possible, which we should always strive for in web scraping. The additional upside of distinguishing between the collection and the extraction step is that you have a local copy of the target material, which might be valuable to ensure the replicability of your work when the data on the server changes. Before moving on, we encourage you to take a look at the source code of a couple of websites. You should already be able to recognize bits and pieces and to make sense of the overall structure of the page.

## CURRENT CHALLENGES IN WEB DATA COLLECTION

While the basic tools outlined in the previous section are not difficult to put into practice, there are a number of challenges that we currently face in our efforts to automatically collect data from the web. This section serves to elaborate some of these challenges and, where possible, hint at some solutions. To structure the discussion, we distinguish between technical and conceptual challenges.

### *Technical Challenges*

We have outlined the basic building blocks of conventional websites and how they help us

in collecting data from the web. We now have to backpedal a little and concede that these elaborations have been truer in the online world of the early 2000s than in today's web. Modern web architectures increasingly move away from this basic model and continue to add elements that make the task of the web scraper a little more challenging. Foremost among these challenges is the incorporation of non-static elements into websites. Think for instance about websites that continuously load content as you scroll through them. For a practical example, do an image search on Google and continue to scroll to the bottom of the page. You will notice that the site grows longer as you continue to scroll down to offer you additional images associated with your search term. This architecture is designed to keep you from having to push a button for additional images, ensuring a smoother browsing experience. At the same time, the designers have wisely decided that it makes little sense to load all possible pictures from the start, as this would mean loading a bunch of images without any sense of how many the user actually wants to see.

What happens is that a script is running in the background that appends the source code and loads additional pictures from the server only when it becomes necessary. The problem for web scrapers is that when we download the source code of a page, we typically only get the initial version of the source code, since we do not run the embedded scripts. One solution when faced with dynamic web pages is to mimic the user behavior with tools that allow for automating the browser in order to extract the information you are looking for.

Continuing with the example, this might mean accessing the Google image search for a particular search term in any browser with a scripting language and then running a function that continuously scrolls to the bottom of the page in order to load additional images. While this might sound technically elaborate, the tools are fairly straightforward to use. Originally developed for testing web applications, we can make use of these tools

to automate our browsers with the aim of collecting data. Nevertheless, despite these somewhat unfortunate trends in modern web development, most websites are still sufficiently static that we can achieve most of our goals in web data collection with the traditional tools.

A second technical challenge is that a website-centric view of the web is increasingly outdated. Many of the most popular services on today's web are exclusively built for the mobile screen, creating additional hurdles for the data collection. In the worst of cases, if these services do not provide access to their data via an API, this might mean having to emulate a mobile screen on your computer to run the app and access the data from there. Again, this is more of a developing challenge and, at least for now, most services still provide an accompanying website.

One final challenge is the sheer size of the data that occasionally results from our collection efforts. Especially when we engage with social media platforms where our research questions sometimes require that we continuously collect data, we might have to learn more complex tools specifically designed to cope with the data stream. One possible solution to the problem of too extensive data could be to think about how and whether to sample the data. Monroe (2013) rightly points out that for many applications, sampling is not a viable option. Indeed, even in our mock example, we probably need the full set of articles to understand the network of Wikipedia pages. That being said, collecting the full set of documents should not be the default just because we can. Before embarking on a new data collection project, researchers should think about what data they need to answer their research question. Think, for example, about traditional analyses of political communication, where scholars have gained valuable insights just by looking at a small subset of articles written about a particular subject (e.g., Eberl et al., 2017; de Vreese et al., 2006). These same considerations should guide our collection efforts when we engage with data from the web.

## ***Conceptual Challenges***

Beyond these more technical challenges, there are also conceptual concerns that need to be kept in mind when collecting data from the web. The first among these are issues related to data quality and data generation mechanisms. By collecting data from the web, we can typically sidestep the problem of data sparsity quite easily. At the same time, we need to be particularly mindful about how the data came to be on the web in the first place. Such concerns are quite apparent when we try to infer public opinion from utterances on social media. Not only are social media users far from a representative sample of the general public (Mellon and Prosser, 2017), the propensity to voice an opinion in such a public forum likely distorts the sample even further, begging the question of what we can learn about the public from social media.

Although we have seen some elegant efforts in recent years to estimate public opinion from immensely unrepresentative samples (Buttice and Highton, 2013; Wang et al., 2015), such models require a baseline of sociodemographic information to which we typically do not have access when we engage with social media posts. Lacking a baseline of socio-demographic information for weighting the posts, we have to take them at face value and hope for the best when trying to make inferences about public opinion.

A particularly telling example in this regard is the work by Tumasjan and colleagues (2011) who forecast the 2009 German federal election using social media data. Their results have been criticized for disregarding the Pirate party as the then newcomer in the German party system (Jungherr et al., 2012). Jungherr and colleagues suggest that when incorporating the Pirate party into the dataset, the forecast would have seen the Pirate party win the election, which did not even manage to cross the 5% exclusion threshold. The results by Jungherr and colleagues suggest that the Pirate party had a particularly web-savvy and outspoken group of supporters,

creating substantial biases in the dataset. To be sure, this is not to say that research on social media is not worthwhile, but it is important to keep the data generation mechanisms in mind when engaging with such data. For instance, the countless studies on elite usage of social media are much less problematic, as we can describe the population of interest and how the sample differs from the population (e.g., Ernst et al., 2017; Jackson and Lilleker, 2011; Vergeer and Hermans, 2013).

One final challenge relates less to the individual collection efforts and more to the aggregate consequences of relying on data from the web for social research. There is a considerable gap between the social science research agenda and the availability of web data, where some areas are characterized by excessive data availability while data in other areas is no less sparse today than before the advent of the web. Along with this disparity comes the concern that if we let our research focus be guided by data availability, we might disregard important research questions.

There is both a narrow and a broad variant of this concern. In the narrow version, we frequently engage with data just because it is available – not because it provides the best information for the point we are trying to make. Possibly the most well-known version of this phenomenon is the research focus on Twitter over competing social media platforms, most notably Facebook. This is not due to a collective perception among scholars that Twitter is the most important social media platform – it simply reflects the fact that Twitter provides easier access to its data. Clearly, we cannot learn all we might want to learn about public usage of social media platforms from Twitter, both because the user base differs drastically between the platforms and because platform design governs user behavior.

In a broad version of this concern, there is good reason to wonder whether data availability governs the very scope of certain research programs, such that some topics might be a little excessively researched while our efforts could be better spent in areas where data is

less easily accessible. The importance of social media for modern societies notwithstanding, one might wonder, for example, whether the ease of gathering data from social media platforms has left researchers asking too often whether social media might be an interesting road to go down. To be sure, the standards for choosing research questions are no different when engaging with web data than in other areas, so we want to close this discussion with the simple suggestion that it is important to take particular care to make the case for the theoretical and societal relevance of our research questions (e.g., Lehnert et al., 2007) and to avoid the temptation to have our research efforts be guided by what data we can easily access.

## AN APPLIED RESEARCH EXAMPLE

Despite the technical and conceptual challenges briefly sketched above, scholars have, of course, put web data to good use in numerous exciting applications. In this section we want to highlight one example from the literature in greater detail. Our emphasis here will be on the question of how we might replicate the study and not so much on the results. For this discussion, we have picked the study by Lucas and colleagues (2015). In their work, the authors provide two applications of the Structural Topic Model (cf. Roberts et al., 2014), a model for the quantitative analysis of text. Quantitative text analysis frequently goes hand in hand with web data collection, as data from the web often takes the shape of more or less structured text (cf. Grimmer and Stewart, 2013; Wilkerson and Casas, 2017). The aim of the model is to assign topical categories to a collection of texts where the researcher does not pre-structure the results much beyond specifying the number of topics to be estimated. We will not discuss the specifics of the model any further, as we are only interested in how the researchers have collected and processed the data for their application.

Lucas and colleagues provide two applications. In the first application, they classify a set of teachings by Muslim clerics. We will focus on the second application, where the authors analyze a sample of Chinese and Arabic social media posts that deal with the revelations of the NSA surveillance programs by Edward Snowden. Lucas and colleagues aim to assess how users in China and in the Arab world have reacted to this story and whether the two discourses were systematically different.

The authors begin by assembling data from Twitter, for the Arab-speaking social media posts, and from Sina Weibo, as the Chinese equivalent, containing mentions of Snowden in the period between June 1 and June 30, 2013. Lucas et al. collect their data from a third-party data provider, Crimson Hexagon, not least since the APIs for both platforms are quite restrictive in terms of how far back users can collect data. Nevertheless, in principle the same data could be collected from the companies directly, as they provide access to their data via programming interfaces. We encourage you to check out the API documentations for Twitter<sup>7</sup> and Sina Weibo.<sup>8</sup> Both require the creation of an account to start collecting data, but otherwise it is fairly straightforward to gather data from these platforms and to replicate the analysis by Lucas et al. for a topic of choice.

To run the analysis, the authors convert the texts into one language in order to run a single, comprehensive model on all social media posts. They choose to convert the texts into English, for which they make use of the Google translation algorithm. They send their queries to the Google server using the `translateR` add-on in R, but it is simple enough to write out the request by hand without having to rely on this module. We have provided a valid query to the Google translation API and we can easily identify the URL components we have introduced above:

```
https://www.googleapis.com/language/translate/v2?key=userkey&q=web%20data%20collection%20is%20surprisingly%20simple&source=en&target=fr
```

The URL contains a scheme ('https'), a domain ('www.googleapis.com'), a path ('language/translate/v2') and the specific query with four elements: 'key', 'q', 'source' and 'target'. 'q' contains the specific sentence to be translated. The only new element here is the fact that the space characters in the query are replaced with the sequence '%20', as spaces are invalid characters in URLs. The query reads: 'web data collection is surprisingly simple'. The 'source' parameter tells the server what language the query is written in (English); 'target' is the language to be converted into (French). The only element that is not a true representation of the actual query is the value of the 'key' parameter. Similar to the two previous APIs, Google requires that users register with the service before using it. Registering is quite straightforward and we encourage readers to create an account to replicate the example.<sup>9</sup> When you replace the 'userkey' value in the 'key' parameter with your own private key and paste the URL into your browser, you will get Figure 22.5 as the response.

My French is not quite what it used to be, but as far as I can tell the sentence expresses the same sentiment as the input sentence. From here, it is simply a matter of running all messages through the translation service and running the quantitative text analysis in a second step. The example highlights once more that interacting with application programming interfaces is absolutely straightforward and provides quite simple access to data, or in this case to services that operate on data. The great simplicity and power of automated web data collection stems from the fact that once

you have figured out how to run an operation once, it is simple enough to generalize the operation to run it many times to build large datasets with few lines of code.

## WEB DATA COLLECTION IN PRACTICE

To conclude this chapter, we would like to provide readers with some guidance as to where they can find help for a practical web data collection application. While there are dedicated programs and platforms built around specific APIs, we discourage the use of such black box solutions for the purpose of web data collection. Instead, it is useful to learn a programming language to be able to adapt the tools to a variety of scenarios.

We recommend the use of the R programming language for several reasons. First, R has made tremendous strides in recent years in the area of web data collection and a number of packages have been published that allow you to accomplish a variety of tasks in web data collection. Additionally, a number of packages have been written in R to interact with APIs, such that you can access these services from within R. The benefit of R for social scientists in particular is that the language has become enormously popular in the area of statistical computing, such that a number of readers might already be familiar with the language, allowing you to collect the data without having to learn an entirely new language. Finally, the strength of R in the area of data analysis and data visualization

```
{
  "data": {
    "translations": [
      {
        "translatedText": "la collecte de données Web est étonnamment simple"
      }
    ]
  }
}
```

**Figure 22.5** Response from the *Google Translate* server to the query

enables running the whole analysis from start to finish in the same environment.

Even though the benefits of web data collection should be evident to most scholars with an interest in quantitative research and even though the underlying technology has not dramatically changed for many years, there are surprisingly few comprehensive treatments of the subject. One book-length discussion of the ideas introduced in this chapter is provided by Munzert and colleagues (2014). Using the R language, the volume provides an applied introduction to web data collection, while also addressing many of the more complex problems not addressed in this chapter, such as interacting with forms, providing authentication credentials, or dealing with dynamic websites.

A second, and similar, volume is the work by Nolan and Temple Lang (2014). The book differs from the work by Munzert and colleagues in that it is a little less applied and possibly less useful for beginners. At the same time, the book provides assistance even in edge cases that may not be covered by Munzert et al. (2014). As pointed out, however, the great majority of data collection scenarios can be accomplished with the most basic tools, making the interaction with the more fringe tools a somewhat excessive exercise for most ordinary users. It should be pointed out that both volumes have suffered a little from the more recent developments in the area of web data collection, as some of the current core packages in R were not available at the time of the books' writing and are therefore not addressed in either volume. Nevertheless, as the underlying principles for web data collection have not changed, it is still worthwhile to check out how the general ideas sketched out above are implemented in practice.

Finally, while we recommend the use of R for web data collection, R is far from the only language that can be used for the task of gathering data from the web. A second and frequently used scripting language is Python, which also provides a number

of well-developed packages in the area of quantitative text analysis, which is often of interest for analyzing data from the web. An excellent introduction on how to collect data from the web using Python is provided by Mitchell (2015).

## Notes

- 1 Application programming interfaces have many applications beyond providing access to data. We restrict our discussion to those cases that are most relevant for social scientists interested in web data collection.
- 2 Later in this section, we highlight a resource that provides an overview of existing APIs.
- 3 The second example searches tweets containing the phrase 'metoo': <https://twitter.com/search?q=metoo&src=typd>. The third example searches for entries on Google Scholar for 'anthony downs': <https://scholar.google.com/scholar?hl=en&q=anthony+downs>. Note that the empty space in the search query in the latter example is replaced by a '+' sign, as empty spaces are not valid in URLs. As we are only interested in highlighting the similarities between different URLs, we refrain from discussing the parameters of the additional examples. We encourage you to check out some examples of URLs in the real world to see whether you are able to identify the components.
- 4 <https://en.wikipedia.org/w/api.php?action=help&modules=query>
- 5 Incidentally, we note that the output contains the parameter 'globe' with the parameter value 'earth', so apparently Wikipedia is ready to go for the human colonization of Mars.

# How to Use Social Media Data for Political Science Research

Pablo Barberá and Zachary C. Steinert-Threlkeld

Citizens across the globe spend an increasing proportion of their daily lives on social media websites, such as Twitter, Facebook or Instagram. Their activities on the sites generate granular, time-stamped footprints of human behavior and personal interactions, sometimes with longitude and latitude coordinates. A sizable proportion of these digital traces have to do with politics – social media is an increasingly popular source of political news, as well as a forum for political debates on which virtually every political candidate running for office is now present.

The data generated from these interactions is in many cases freely available for research purposes and provides a depth and breadth that was unimaginable even one decade ago. Its high degree of spatial and temporal granularity allows the study of behavior at low levels of aggregation but also at a more macro scale and from a comparative perspective. The fact that human behavior is observed

unobtrusively also facilitates collecting data at a larger scale and reduces certain types of biases. This set of advantages makes social media data a new and exciting source of information to study key questions about political and social behavior.

At the same time, the volume and heterogeneity of this new type of data present unprecedented methodological challenges. Several sources of bias can limit the generalizability of our findings. Often it is difficult to connect online interactions with offline behavior. Unlike data created by governments or collected by researchers, the data-generating process is not always known. For example, we don't know if the platform was running a randomized experiment at the time of data collection or whether content was being blocked by the internet provider. And, of course, many scholars have raised concerns about the ethics of collecting data from individuals without, in some cases, obtaining their informed consent.

In this chapter, we provide a fair assessment of these advantages and limitations in the use of social media as data generators for research in the social sciences, with a particular emphasis on the study of political behavior. We illustrate these strengths and weaknesses with examples from two types of studies: those where social media is being used merely as a source of data, and those where the focus is on how social media is transforming different political phenomena. The first group includes research that uses social media to measure public opinion, the ideology of citizens and elites, the structure of social networks, government censorship, conflict dynamics and elite rhetoric, and where social media sites are used as a new space to conduct affordable field experiments. The second set of studies deals with questions such as how social media platforms contribute to the success of collective action events, how they are transforming election campaigns and whether their usage is contributing to greater political polarization and the spread of misinformation.

Throughout the chapter, we consider ‘social media data’ as any type of information obtained from websites whose value primarily comes through user interactions. The best-known examples include Facebook, Instagram, Twitter and Sina Weibo, all of which provide infrastructure to facilitate users sharing, and commenting on, content. The content can be user generated, such as status updates or photos from personal devices, or created by a third party, such as a newspaper, and shared by users. Excluded from this definition are sites such as reddit and YouTube, whose primary purpose is to surface content from elsewhere and comment on it. Despite that stipulation, the issues described throughout this chapter apply almost equally to these social media-like websites.

To further explore the opportunities and limitations of social media data, we also provide an in-depth description of an applied example that uses Twitter data to study the dynamics of protest movements in Egypt and Bahrain in 2011.

## ADVANTAGES OF SOCIAL MEDIA DATA

Perhaps the most important advantage of social media compared to traditional sources of data in the social sciences, such as surveys or government records, is the ability to unobtrusively collect information about a large sample of individuals with only minimal costs. Being able to observe subjects in a real-world environment where they are engaging in ordinary interactions reduces the likelihood that individuals change their behavior in response to knowing they’re part of a social science research project, which minimizes Hawthorne and social desirability biases.<sup>1</sup> Although the set of APIs available for academic research has shrunk in recent years (Freelon, 2018), large amounts of such data are still freely available at a minimal cost, which facilitates comparative and longitudinal analysis of any phenomenon.

This new ability to collect information about human behavior at scale is revolutionizing the state of the art across many fields. One such example is the study of social networks. This literature had traditionally relied on either small-scale networks, such as those related to high-school classrooms (Moreno, 1934) or social groups (Zachary, 1977), or on partial views of a network reconstructed through survey responses to questions about social ties, such as in the study of communication networks (Huckfeldt et al., 2004; Mutz, 2002). Large-scale network datasets from social media sites have offered new evidence to answer some of the key standing questions within this field (see e.g. Bakshy et al., 2015; Ugander et al., 2011; Lerman et al., 2012).

A second notable advantage of social media data is that its homogeneity in format and content facilitates systematic comparisons for different types of actors, across multiple countries, and over time. This homogeneity applies to multiple dimensions: constraints on text length; the use of similar language and textual marks (e.g. hashtags); the ability

of different types of actors to interact directly (e.g. via shares or retweets), among other many platform affordances and features. This strength of social media data is already leading to important breakthroughs in the analysis of political mobilization (Anastasopoulos and Williams, 2017; Freelon et al., 2016) and agenda-setting dynamics (Barberá et al., 2019), as well as in the comparative study of political polarization (Bright, 2018) and censorship (Hobbs and Roberts, 2018).

Third, social media data offers unparalleled temporal and spatial granularity. It allows researchers to observe longitudinal trends to identify events and also to study geographic patterns. This advantage can be especially relevant in autocracies or conflict areas, since it would be difficult or impossible to gather real-time data in such situations. Social media data have proven particularly useful for understanding the dynamics of Syria's protests and subsequent civil war (O'Callaghan et al., 2014; Freelon et al., 2015; Kostyuk and Zhukov, 2017); the same is true for Ukraine (Gruzd and Tsyganova, 2015; Zhukov, 2015; Wilson, 2017; Driscoll and Steinert-Threlkeld, 2020). In the last section of this chapter we offer an additional example that focuses on protests in Egypt and Bahrain leading to the Arab Spring. For technical discussions of using temporal data to detect events, see the computer science literature on event detection (Sakaki et al., 2010; Cadena et al., 2015; Alsaedi et al., 2017) or work by Golder and Macy (2011) on the relationship between diurnal and seasonal mood patterns. For the possibility of social media data for the generation of political event data, see Zhang and Pan (2019) and Steinert-Threlkeld (2019).

Fourth, despite obvious concerns about the representativeness of samples obtained from social media (a point to which we return next), for some groups of actors virtually the entire population is present on social networking platforms. For example, more than 85% of world leaders have active Twitter or Facebook accounts (Barberá and Zeitzoff,

2017) and virtually all members of the US Congress also maintain profiles on these sites (Pew Research Center, 2017), making it possible to make externally valid inferences about their communication strategies and rhetoric with data obtained from these accounts.

As we consider samples of ordinary citizens, it is worth emphasizing that representativeness of social media users is only a concern if the behavior under study is thought to vary according to variables by which users on social media differ from the population from which they are drawn. For example, Malik et al. (2015) find that a 1% increase in the population size of a census block group correlates with 5.7% fewer geolocated Twitter users. As a result, using Twitter to understand behaviors correlated with living in rural areas, such as sentiments toward a trade war or support for political candidates, is likely to underestimate those behaviors in the population.<sup>2</sup> Similarly for studying older or poorer Americans.

On the other hand, many behaviors should be less sensitive to non-representative samples. For example, factors affecting information contagion – weak and strong ties, the influence of media and celebrities, etc. – probably do not vary by age, location or race. During the Arab Spring, users of social media were certainly not representative of their populations (Ghannam, 2011; Breuer, 2012); the vast majority of protesters in Tahrir Square, for example, learned about the protests from satellite television or face-to-face communication (Wilson et al., 2012). It is not clear, however, why patterns of information diffusion found on Twitter at this time (Brym et al., 2014; Borge-Holthoefer et al., 2015; Steinert-Threlkeld, 2017b) should be assumed to be distinct from information spreading outside of social media. Other outcomes, such as diurnal patterns of behavior or user to user interactions, for example, should also not vary on observables.<sup>3</sup>

The fifth advantage of social media data, that many well-known offline behaviors also

occur online, supports the claim – representativeness issues matter, but probably not as much as feared – of the previous paragraph. Social media users’ ideology is recoverable from the structure of their social network and maps onto offline estimates of ideology (Barberá, 2015; Bond and Messing, 2015). Dunbar’s Number (Dunbar et al., 2015), attitudinal homophily (Bliss et al., 2012), diurnal activity (Golder and Macy, 2011) and geographic constraints (Takhteyev et al., 2012) occur offline and online, and Facebook users’ scores on the Big Five personality traits (extraversion, neuroticism, conscientiousness, agreeableness and openness to experience) are recoverable from their behavior on the site (Gosling et al., 2011). Twitter users also exhibit homophily with respect to age, gender and political affiliation (Zamal et al., 2012), and homophily of likes on Facebook permits similar behavioral and personality inference (Kosinski et al., 2013a). The preponderance of evidence suggests it is reasonable to expect that many, perhaps most, behaviors studied using social media are analogues to what would be observed offline, if it were possible to observe these behaviors at scale offline. It is rarely possible, of course, to observe these behaviors at scale offline.

## LIMITATIONS OF SOCIAL MEDIA DATA

A fair assessment of how social media data can be used in social science research requires also a discussion of its key limitations, as well as potential ways to address them. Probably the most important challenge to overcome, as we discussed in the previous section, is that social media users are not a representative sample of the population in any given country. As a result, an analysis of social media data without any type of adjustment may reveal patterns that are not generalizable. Despite this valid concern, it is worth making two points. First, samples that are not

representative can still be scientifically relevant. For example, we may treat the sample of users posting about politics on Twitter as a set of ‘opinion leaders’ that can be more influential than other ordinary citizens. Second, there are actually different types of sampling bias, and it is important to quantify them. We could have sampling bias whenever sociodemographic characteristics are correlated with *both* our outcome variables and the propensity to be present on social media. But there may also be self-selection *within* samples of social media users, particularly when samples are collected at the tweet level, based on whether it mentions or not a set of keywords. For example, if our sample includes tweets mentioning names of parties or political candidates, it will oversample individuals with extreme political identities, because they tend to tweet about politics more frequently (Barberá and Rivero, 2015).<sup>4</sup>

One potential solution to this set of problems would be to apply similar weighting methods as in survey research, where low response rates can lead to similar concerns about sampling bias. However, we are limited by what Golder and Macy (2014: 141) call the ‘privacy paradox’: ‘[social media] data are at once too revealing in terms of privacy protection, yet also not revealing enough in terms of providing the demographic background information needed by social scientists.’

A different type of sampling issues that is also worth mentioning is those due to black-box proprietary sampling algorithms used by social media companies. For example, Morstatter et al. (2013) showed that the Twitter API does not return a truly random sample if we are collecting from the ‘spritzer’ and not sampling using keywords.<sup>5</sup> Why this difference occurs, however, is unclear from existing work, as Twitter populates the spritzer based on a tweet’s millisecond timestamp (Pfeffer and Mayer, 2018). More work is needed, however, to determine how sensitive this result is to studying particular

topics or times, as well as to whether the observed differences are relevant enough to be significant.

A different type of challenge lies in the ability to connect online and offline behavior. The fact that we observe a pattern in an online setting does not mean that it would necessarily replicate in an offline setting. This could be due to affordances of the platforms – e.g. the fact that anonymity is easier in online settings makes vitriol and incivility more likely to occur in interpersonal communications – or to the types of ties that people develop on social media. However, as discussed in the previous section, there is increasing evidence that this is not the case. For example, two recent studies demonstrate that the structure of networks and the nature of social ties are similar in social media and offline networks (Bisbee and Larson, 2017; Jones et al., 2013).

An additional difficulty of conducting network analysis using social media data, especially Twitter, is defining what an *edge* is. Connections form more easily on social media than offline, so it is common to infer edge strength via other behavior. On Facebook, appearing together in a photograph or tagging someone in a status is commonly used to define ‘true’ friends. On Twitter, researchers will infer an edge if a user retweets or mentions another user; for topic modeling, edges usually come from the co-occurrence of hashtags. For Twitter, retweet and user mentions are preferred because they can be easily extracted from the streaming API, whereas finding an account’s followers requires more work and is severely hindered by rate limits which Twitter imposes on how frequently a researcher can request data. A shortcoming of this approach is that it usually creates cross-section data, removing any temporal information about a network. Steinert-Threlkeld (2017a) introduces a method that works within the Twitter rate limits to measure an account’s influence as it changes every day. This approach requires more engineering than relying on retweets

and user mentions delivered via the REST API, but it permits longitudinal observation.

A third limitation of social media data is replicability, for three reasons. First, sharing raw data is difficult. Twitter, the most common social media platform studied, only allows an individual to share 50,000 tweets per day ‘via non-automated means’; this quantity is not large.<sup>6</sup> For studies with millions of tweets, sharing tweets therefore requires either moderate amounts of programming to build a front-end to the dataset to ensure replicators do not receive more than 50,000 tweets per day or a human in the loop for however many days are required to share the entire dataset. Neither option is easy, and both detract from research productivity.<sup>7</sup> The best method for sharing a full dataset is therefore to share the identification number of each tweet, as Twitter has no cap on that quantity *when used for academic research*.<sup>8</sup> For Python and R scripts to download tweets using their ID numbers, see Steinert-Threlkeld (2018).

Sharing tweet IDs invokes the second reason, which is programmer skill. Because downloading tweets requires connecting to Twitter’s application programming interface (API), and the returned data is made available in a format (JSON) with which many researchers may not be familiar, replication requires programming skills that many replicators may not possess. A new R package, *rehydratoR*, simplifies this process. It takes a list of tweet IDs and saves the results to .csv files, in addition to accounting for Twitter rate limits (Coakley et al., 2019).

The third reason is ‘post rot’. If a user deletes a tweet or account, that tweet (and all tweets from that account) is not later recoverable. A tweet included in a study may therefore not be available to a later replicator. While the rate of tweet or user rot is not known, as far as we are aware, anecdotal reports suggest it is about  $\frac{1}{10}$  of tweets after one year. Whether or not this rot changes a replicator’s inference is not known, although there is some evidence that rot does not occur randomly (Timoneda, 2018). Even if the

overall findings may not change, point estimates probably will.

If replicators start with the aggregated data that authors use for their analysis, then these three reasons are obviated. Restrictions from institutional review boards also often require that authors do not share tweet IDs because it would allow other researchers to identify the subjects in the study. In that case, sharing aggregated data is the only approach to replication. This outcome is especially the case in experiments on social media (Munger, 2017; Siegel and Badaan, 2018).

Ethical concerns are, of course, important beyond the discussion about replicability. A controversial recent study that experimentally manipulated the content of Facebook users' news feed to explore whether emotions are contagious (Kramer et al., 2014) opened a debate about what the notion of informed concern means in an environment in which companies constantly manipulate features of their product using experimental methods. Even observational studies with publicly available data can raise ethical concerns because individuals may not have the expectation that their data is being analyzed for research. Even if data is de-anonymized, often it is possible to re-identify personal data (Zimmer, 2010). It is important to note, however, that this problem is present in any other study that uses individual-level data, including those that use survey data. Some recent work in the area of differential privacy (Dwork, 2008) offers exciting new possibilities to strike a balance between data access and privacy.

The fifth limitation is norms of users and companies. On user norms, the primary difference between Facebook and Twitter, and one that is not often appreciated, is that users on Twitter maintain a norm of public production while most users on Facebook opt for privacy. A small minority of Twitter users maintain protected profiles, making their data as inaccessible as the vast majority of Facebook users' data. Companies also maintain their own norms around how much

data to expose via their APIs, so the kind of research possible is at the whim of companies' API policies. For example, Facebook and Instagram used to provide much more user and graph information via their APIs, but they have become much more restrictive in response to recent controversies about data protection. Twitter has made it more difficult to obtain a developer account, the first step to collecting data, though changes to its API have otherwise been positive.

## USING SOCIAL MEDIA TO MEASURE POLITICAL BEHAVIOR

To illustrate the strengths and limitations of the use of social media data in the social sciences, we now offer an overview of recent research within this subfield. Some of the earliest work that took advantage of the opportunities offered by this new source of data was focused on measuring public opinion. Initial claims that lauded the potential of tweets to predict election results (Tumasjan et al., 2010) were soon rebuked by more systematic analysis demonstrating that those predictions were in many instances no better than random guesses (Gayo Avello et al., 2011). With some notable exceptions, such as the work of Ceron et al. (2014), the probability that we will be replacing public opinion surveys with metrics based on social media still seems unlikely (Klašnja et al., 2016). However, there is clear value in social media as a *complement* to survey data, both as an early indicator of changes in public opinion and as a possible signal on unpolled topics or areas (Beauchamp, 2017).

Even if aggregate-level opinion is hard to measure, there is plenty of evidence that social media can reveal a lot of information about citizens' characteristics and behavior. Kosinski et al. (2013b) and Youyou et al. (2015) found that Facebook likes are highly predictive of private traits such as party preference, age, gender, sexual orientation,

alcohol use, psychological traits, etc. It was this type of analysis that Cambridge Analytica allegedly used to target voters with personalized ads through social media, although there is no evidence regarding its effectiveness. Regarding the political domain more specifically, Barberá (2015) and Bond and Messing (2015) demonstrated that the political accounts that each citizen likes on Facebook or follows on Twitter offer enough data to estimate political ideology on a continuous scale (liberal to conservative) with high accuracy. Other recent work (Radford and Sinclair, 2016) suggests that the text of social media messages could also be used to estimate political preferences.

Since most autocratic governments around the world try to exercise some type of control over social media sites, we can also use data from these sources to better understand digital repression strategies. For example, King et al. (2013, 2014) found that it is possible to 'reverse engineer' online censorship using a sophisticated system that scrapes social media in real-time and then checks what has been deleted and why. Their analysis revealed that the Chinese government prioritizes deleting content that could lead to collective action but that criticism of the government is allowed. Another way in which governments can exercise digital repression is through trolls or bots that flood a platform with pro-regime information or with topics to distract from a politically sensitive issue. By muddying the waters, this tactic allows the government to silence dissidents' attempts at political coordination while maintaining plausible deniability that censorship has occurred (Little, 2015; King et al., 2017; Keller et al., 2017). These tactics also make it difficult for researchers to separate true beliefs from pro-government noise. One potential solution is to identify bots using bot detection methods (Ferrara et al., 2016), although this becomes more difficult if we consider trolls, which are accounts controlled by humans.

In the same way that press releases or campaign speeches are often used to examine

elite rhetoric (see e.g. Grimmer et al., 2012), tweets and Facebook posts by politicians can also be a useful source of data to understand political communication. The series of reports on congressional rhetoric released by the Pew Research Center are a good example. There is also a growing body of comparative work on topics such as campaign strategies or populism (Theocharis et al., 2016; Nulty et al., 2016; Stier et al., 2017), including for instance politicians' attempts to overwhelm social media with false messages (a technique also known as *astroturfing*) so that challengers' support appears smaller than it may actually be (Munger et al., 2018). It is also possible to recover politicians' ideology from the images they share on Facebook, which may be especially useful for estimating policy positions of challengers who do not have a voting record or sizable donations Xi et al., 2020.

At a more aggregate level, social media can reveal conflict dynamics with detail unavailable via other approaches. For example, students of repression and dissent generally code repression as a binary or categorical variable. Advances in computer vision techniques can be applied to thousands of protest photos to generate a continuous measure of state and protester violence Steinert-Threlkeld et al., 2020. These techniques can also generate estimates of the race and gender of participants, as well as the number of participants (Sobolev et al., 2020). Though social media tend to have some sort of location bias, it is reasonable to expect that this bias is less than in newspapers because of the lower barriers to entry and unlimited publication space (Steinert-Threlkeld, 2019). Social media data can also reveal daily changes in interstate conflict dynamics (Zeitsoff, 2011; Zeitsoff et al., 2015; Zeitsoff, 2018) and civil wars (Zhukov, 2015; Driscoll and Steinert-Threlkeld, 2020) as well as document more protests in China than newspapers have, by an order of magnitude (Zhang and Pan, 2019). It also has been used to study Black Lives Matter protests in the United States (Anastasopoulos and Williams, 2017; Chen et al., 2017).

Finally, social media can also be a space to conduct affordable field experiments. In a pioneering article, Munger (2017) developed a way to deploy experiments on Twitter using bots to convey treatments. His study discovered that, when users who use racist slurs are exposed to a bot that criticizes their actions, they change their behavior, but only when the ‘punishment’ is coming from someone similar to them. Compared to field experiments deployed in an offline environment, administering treatments has a much lower cost, although it requires an effort in terms of hardware and programming skills. Building a bot to administer a treatment is more challenging than passively collecting data from an API endpoint. Despite this limitation, this approach represents a promising blueprint for future experimental studies with high external validity (Siegel and Badaan, 2018; Coppock et al., 2016).

### **UNDERSTANDING HOW SOCIAL MEDIA AFFECTS POLITICAL BEHAVIOR**

An important part of the ongoing research that uses social media data focuses not necessarily on using these sites as a source of information about behavior, but instead on their potential as a transformative political force whose effects we are only starting to understand. There’s perhaps no better example of this type of work than the efforts to understand how digital technologies were a catalyst in the recent wave of protests around the world, starting with the Arab Spring. Some of the earlier optimism about the democratizing power of social media (see e.g. Valenzuela, 2013) was followed by a wave of skepticism. Authors such as Gladwell (2010) and Morozov (2012) warned against the rise of ‘slacktivism’ fueled by social media sites, which facilitate engagement in protests but also disincentivize commitment and the type of dedicated and trained

activism that can turn revolutionary fever into action. However, recent empirical research in political science has demonstrated that it is precisely the ability of social media to bring in peripheral individuals without resources or deep engagement that can lead to the success of collective action event (Barberá et al., 2015a; Steinert-Threlkeld, 2017b).

This evolving narrative about the impact of technology on protest mirrors the public discussion about how social media has been used in political campaigns. Barack Obama’s election campaigns are widely acknowledged to have brought the data revolution to politics (Kreiss, 2012). An important part of his success lay in understanding the native digital audience and deploying an extensive data collection and analysis platform. In contrast, Mitt Romney’s campaign famously required 22 people to approve every single tweet from the candidate’s account (Kreiss, 2016). But the optimism about how digital technologies can empower grassroots movements was put to the test after Donald Trump’s election in 2016, and the alleged use by his campaign of micro-targeted ads that were tailored to voters’ preferences. Although there is still a significant lack of research about whether targeted advertising on social media can be effective at mobilizing or persuading voters, the existing work generally finds null or very small effects, giving us reasons to be skeptical (Broockman and Green, 2014; Eckles et al., 2018; Kalla and Broockman, 2018; Bond et al., 2012).

Another key research question in this field has been whether news consumption and political conversations through social media may be one of the factors explaining the recent rise in political polarization and extremism around the world. A common argument in the literature is that social networking sites make it easier for citizens to isolate themselves into communities of like-minded individuals, where political agreement is the norm and individuals can avoid being exposed to any opinion that may

challenge their ideological views (Sunstein, 2018). This process could be exacerbated by ranking algorithms that filter out any content that users may dislike (Pariser, 2011). These concerns are not new – Putnam (2000) already expressed concerns about cyberbalkanization nearly two decades ago – but they have re-emerged and are often identified as an additional factor explaining the recent rise in political polarization. Despite these concerns, empirical evidence that this process is happening is scarce: individuals are exposed to more diverse views on social media than in offline settings (Bakshy et al., 2015; Barnidge, 2017; Fletcher and Nielsen, 2018), cross-ideological interactions are frequent even in relation to highly contentious topics (Barberá et al., 2015b), and the increase in polarization in the US has been largest among those who are least likely to be active on social media (Boxell et al., 2017).

Finally, perhaps the most timely topic that has received the broadest media attention is the extent to which social media contributes to the spread of misinformation. Contrary to the conventional wisdom that exposure to false news during the 2016 presidential election was nearly universal, a growing consensus is emerging in the literature that points to important asymmetries in the extent to which this type of information is shared and consumed. Conservative, older citizens are more likely to consume misinformation on social media (Guess et al., 2019) and exposure appears to be concentrated on a small minority of users. Whether or not being exposed to false news can actually affect attitudes and behavior is unclear, and evidence is mixed (Jamieson, 2018; Allcott and Gentzkow, 2017).

### **CASE STUDY: ANALYZING THE DYNAMICS OF PROTEST MOVEMENTS USING TWITTER DATA**

In this last section, we demonstrate the ability of social media as a data generator through a

case study of activists and government accounts from Egypt and Bahrain in early 2011, during the Arab Spring. An analysis of data collected from Twitter explores the question of whether activists can activate offline protest through their online activity on social media.

The phrase ‘Arab Spring’ refers to the large-scale protests that occurred throughout the Middle East and North Africa from December 2010 through the end of 2011. On December 17, 2010, Mohamed Bouazizi self-immolated to protest the seizure of his fruit cart. His action inspired local protests that became national, and the national protests spread to other countries once President Ben Ali fled to Saudi Arabia on January 14, 2011. Hosni Mubarak would abdicate on February 14, and almost every country in the region experienced some form of protest.

Though there is much evidence that the protests were spontaneous (Wilson et al., 2012; Steinert-Threlkeld, 2017b), activists played important roles at various points. Before the protests, they held workshops about peaceful resistance, showed movies about protest or that were critical of a regime, and taught participants how to create political graffiti. These activities demonstrated to others that there exists discontent with a regime, and did so in such a way that others knew that others knew there is discontent. Generating political coordination has the same effect as advertising: the more people know about a product (the protest), the more likely are people to buy it (join the protest) (Chwe, 1998). For example, Egyptian activists deliberately discussed (advertised) the January 25 protests in taxi cabs because they knew the drivers would spread the information to their passengers (Lim, 2012). However, there is still little systematic research on the extent to which activists contributed to the spread of protest – that is the research question we try to address here.

The Arab Spring presents an ideal case to demonstrate the strengths of social media

data. Because the involved countries were – and largely still are – repressive, identifying networks of activists, gaining their trust and administering surveys was (is) a resource-intensive process. For example, even after Hosni Mubarak abdicated, individuals in Tahrir Square were afraid to respond to Western researchers' surveys (Tufekci and Wilson, 2012). Any work coming from that process would be difficult to compare to other situations because the researcher would have invested so much time in gathering data for a particular set of actors in one country. Even within a particular country, it would be difficult to study many movements at once.

Once a researcher has established him or herself in a repressive country, administering surveys presents additional challenges. Respondents are often suspicious of foreigners conducting research or do not want to be seen associating with them. Local enumerators may be hired, adding time and expense to the data gathering process. If an unforeseen event occurs, such as a protest, the researcher is unlikely to be able to pivot to study it. Even if the researcher can study this unexpected event, she or he will be hard pressed to gather many observations per day, not to mention many observations across many locales per day. Survey work is hard, especially in places where it is infrequently conducted.

For the reasons provided earlier in this chapter, social media data ameliorates many of these concerns. To demonstrate how they do so, we analyze 19 activists across four social movements in Egypt and Bahrain, and examine whether their social media behavior led to an increase in offline protest.

In Egypt, we focus on the April 6 movement, which started in early 2008 as a Facebook page rallying support for striking textile workers at a government enterprise in Mahalla al-Kubra, a city of 535,000 inhabitants located 70 miles north of Cairo. Large-scale strikes and protests focused on working conditions and pay had occurred since 2006, sparking a periodic series of worker actions throughout Egypt over the next two years

(Beinin, 2009). The most important event was a large strike that was called for April 6, 2008, which the government reacted to by preemptively arresting activists and closing off public spaces nationwide (Gunning and Baron, 2013: 59–61). The movement persisted at a subdued level of activity – not for lack of trying – for the next three years and would become a central actor in the 2011 mobilization.

The second social movement in Egypt is the anti-sexual harassment movement. Egyptian public spaces have long been dangerous for women (Amar, 2011). As protests increased in Egypt throughout the first decade of the new millennium, so did reports of sexual assault at these events; in many cases, these assaults were linked to civilians hired by the Interior Ministry for that purpose (Langohr, 2013). In response to these events, an assortment of civil society organizations emerged, most notably the Nadeem Center, the Egyptian Center for Women's Rights and the Nazra for Feminist Studies.

We also study the two main organizations in support of human rights in Bahrain, the Bahrain Center for Human Rights (BCHR) and Bahrain Human Rights Society (BHRS), which were founded in 2002 and were still active at the time of the 2011 protests.

To study these movements, we rely on data that contains a complete history of the 19 most important activists within these movements on Twitter. The data was purchased from Sifter, a third-party reseller, and spans the period from January 11, 2011 through April 5, 2011. This time period was selected because it encompasses the time leading to each country's main protest period, the time during the main protest period (January 25–February 11 in Egypt; February 14–March 17 in Bahrain) and the time after the protests.<sup>9</sup> Sifter returned 58,376 tweets; each includes metadata on the number of followers of the account, the number of people the account follows and a character string describing the device from which the tweet was created. Table 23.1 details these data.<sup>10</sup>

**Table 23.1 Descriptive statistics from Sifter data**

Note: Accounts are sorted alphabetically within each movement. Columns from Twitter.com through Nokia refer to the percent of tweets from each source; for example, 84% of @mrmeit's tweets are through Twitter's website. Columns Retweets through Hashtag refer to the percentage of each account's tweets which are a retweet, contain a user mention or contain at least one hashtag.

Did the activities on Twitter by these key leaders have any effect on subsequent protest events in these two countries? Contrary to the conventional wisdom that highly visible activists were a determinant in the spread of protest across these two countries, here we show that there is little evidence supporting that assertion. Table 23.2 presents regression where we test that hypothesis through a multivariate regression on the number of protests with a range of variables related to the social media activity of leaders before those protests took place. The data on protests was extracted from the Integrated Conflict Early

Warning System (ICEWS) (Boschee et al., 2015).<sup>11</sup> To measure activists' social media behavior, we use a set of different variables that include the percentage of tweets from activists, the percentage of tweets that are activist retweets, the percentage of tweets that are activists mentioning others, the percentage of tweets with hashtags that are from activists and the percentage of tweets with links from activists.<sup>12</sup>

Our first model in Table 23.2 shows that none of the variables related with activists' behavior on Twitter predicts subsequent protest. And in fact, *Activist Coordination Tweet*  $\%_{i,t-1}$ , the

**Table 23.2 Main results**

	DV: $Protest_{i,t}$	
	(1)	(2)
Activist Tweet $\%_{i,t-1}$	2.58 (6.98)	1.72 (7.47)
Activist Retweet $\%_{i,t-1}$	5.65 (5.35)	6.26 (5.54)
Activist Mention $\%_{i,t-1}$	-2.23 (7.32)	-1.15 (8.08)
Activist Hashtag $\%_{i,t-1}$	-1.22 (1.13)	-1.27 (1.14)
Activist Link $\%_{i,t-1}$	9.75 (11.80)	11.19 (12.18)
Protest $_{i,t-1}$	0.01 (0.01)	0.01 (0.01)

\*p < .1; \*\*p < .05; \*\*\*p < .01

Note: All activist variables except for Activist Hashtag  $\%_{i,t-1}$  use the total tweets from country, as the denominator. Activist Hashtag  $\%_{i,t-1}$  uses the total tweets with hashtags from country.

percentage of tweets coordinating protests that are from activists, negatively correlates with protest.<sup>13</sup> The second model in Table 23.2 uses a different measure of activist coordination but is otherwise identical to the first. Here, *Activist Coordination*<sub>*i,t-1*</sub> is the interaction of *Non-Activist Coordination*<sub>*i,t-1*</sub> and *Activist Hashtag* %<sub>*i,t-1*</sub>. *Non-Activist Coordination*<sub>*i,t-1*</sub> is the Gini coefficient for hashtags per country-day; if a large percentage of those hashtags are produced by activists, then hashtag coordination comes from activists. This measure is not statistically significant, while *Activist Coordination Tweet*

%<sub>*i,t-1*</sub> remains so. Note that in both models *Non-Activist Coordination*<sub>*i,t-1*</sub> is significant with a p-value less than .01.

Activists in both countries frequently use mobile devices for communication, but they also used desktop computers. One may argue that our results in the previous set of regression models are null because they do not focus specifically on calls for actions from whenever the activists are actually in the streets engaging in political protest. To address this concern, we take advantage of a key piece of metadata that comes with tweets, the ‘tweet\_source’ field. This field is

**Table 23.3 Robustness checks – tweets from phones**

\*p <.1; \*\*p <.05; \*\*\*p <.01

a string created by Twitter to reflect the provenance of a tweet. We find that our results do not change when we analyze specifically the proportion of tweets originated on a mobile device. Although the percentage of an activist's tweets that are from a mobile phone does positively correlate with subsequent protest and has a p-value between .05 and .10, the result does not hold when that value is interacted with the percentage of tweets that are about coordination. This result makes sense, as a tweet does not say whether or not it comes from a mobile device, so a tweet from a mobile device does not provide a signal to others that the author has mobilized.

## CONCLUSION

The aim of this chapter was to offer a broad overview of how social media data is currently being used in social science research, as well as a detailed account of the main strengths and weaknesses of this source of information about political and social behavior. Overall, our assessment shows the immense and still largely untapped potential of social media as data generators. This means we are still at an early stage in the development of standards and best practices in the different literatures that increasingly rely on this type of data, but also that we should expect to see the results of much exciting new research being published over the next few years.

One particular challenge that we didn't discuss at length is the extent to which research that uses social media data can yield findings that can be generalizable across domains and over time, as opposed to idiosyncratic to the particular site whose data is being used. It is certainly the case that some of the websites we study did not even exist 10 years ago, which begs the question of whether they will still exist 10 years from now. We have plenty of examples of successful sites that eventually disappeared, such as MySpace or

Friendster. However, our view is that even if Facebook or Twitter eventually disappear, findings derived from research on these sites will survive and remain valid. Contrary to the common view that characterizes social media interactions as not occurring in the 'real world', behavior on these sites indeed mirrors offline behavior, and thus it can help reveal the mechanisms that drive human behavior, not only on these platforms, but in people's lives more generally.

## Notes

- 1 Of course, the fact that behavior on social media takes place in public may introduce other types of social desirability bias.
- 2 Observing a group over time obviates the numerator problem.
- 3 'On observables' is, of course, a major qualification.
- 4 Keyword self-selection can be mitigated by connecting to the streaming API and downloading a 1% sample of tweets in real time. A downside of this approach is that events or keywords that are not very popular are less likely to appear in the stream since it is a sample.
- 5 Morstatter et al. (2013) show divergence in trends in (1) the number of tweets, (2) topics, and (3) some network features in tweets related to Syria from 12.14.2011 to 01.10.2012. Overall, it is clear that a random sample collected from streaming API may not be a perfectly representative sample of all of Twitter.
- 6 Our discussion here focuses on Twitter, as the main social media platform offering easy access to public data for research purposes. Although similar data used to be available for Instagram and Facebook, recent changes to their platform policies mean that their APIs are essentially no longer available for research purposes (Freelon, 2018).
- 7 An alternative would be to develop a framework that can produce synthetic data with similar properties as the full dataset while ensuring privacy (Raab et al., 2016), but to our knowledge this approach has not been developed for social media datasets yet.
- 8 If the ID numbers are distributed for non-academic purposes, no more than 1.5 million per 30 day period can be shared.
- 9 The end of the main protest period in Egypt is defined as Mubarak's resignation. In Bahrain, protests ended following a major assault on the Pearl Roundabout, the main protest site in Manama;

this assault occurred three days after Gulf Cooperation Council forces, led by Saudi Arabia, marched into Bahrain, and the Pearl Roundabout was dismantled on March 18. Protesters would not again succeed in occupying the circle.

- 10 For additional information about data formats and code to collect and analyze Twitter data, see the materials available in Steinert-Threlkeld (2018).
- 11 ICEWS is a Department of Defense project, led by Lockheed Martin and Michael Ward, that reads newspapers and extracts events. It represents a substantial modification and extension of Philip Schrodt's Kansas Events Data System (KEDS) and Textual Analysis by Augmented Replacement Instructions (TABARI) (Schrodt et al., 1994; Gerner et al., 2002). ICEWS reads thousands of news sources, including non-English ones, and applies a heavily modified version of TABARI, leading to much lower rates of false positives than other machine-coded events data.
- 12 Note that *Activist Hashtag*  $\%_{i,t-1}$  is calculated slightly differently from *Activist Tweet*  $\%_{i,t-1}$ , *Activist Retweet*  $\%_{i,t-1}$ , *Activist Mention*  $\%_{i,t-1}$ , and *Activist Link*  $\%_{i,t-1}$ . *Activist Hashtag*  $\%_{i,t-1}$  is calculated as the percentage of all tweets with hashtags that are tweets from activists, but the other four take the total number of tweets from the activists' country on that day as the denominator. The variables are modeled differently to reflect the information consumption process on Twitter. When one sees a tweet on Twitter, it is presented as part of a sequence of reverse chronological tweets. If one views tweets containing a hashtag, however, all tweets in the subsequent reverse chronological sequence contain that hashtag. The determinant of the length of the latter sequence is therefore all tweets containing that hashtag while the length of all tweets one sees is better approximated by all tweets on that day.
- 13 These coordination tweets are those determined by a supervised topic model. For more details, see Steinert-Threlkeld (2017b).

# Spatial Data

David Darmofal and Christopher Eddy

Political scientists analyze spatial data. We may think of our units of analysis primarily as block groups, zip codes, states, countries or dyads, but all of these data are also spatial data. Indeed, all political science data are spatial data (Darmofal, 2015) since all political behaviors, processes and events take place at spatial locations. But because we think of our units primarily in non-spatial terms, we often miss the implications that decades of geographic research provides for our analyses.

Spatial data present both opportunities and challenges for political scientists. Areal units such as those above are often geocoded so that we know the precise spatial locations of their boundaries and their centroids. Such geocoding allows us to define their neighbors and conduct spatial analyses. This is important because our spatial units often exhibit spatial dependence – similarities or dissimilarities in measures of interest that are related to our units' spatial locations. As a result, we typically need to model our areal units using

spatial models such as spatial lag or spatial error models. Such spatial modeling can shed new insights that are not possible when we conceive of our data in non-spatial terms.

The spatial nature of our data should also lead us to think about our units themselves and what they are capturing. It should also lead us to think about how our choice of units affects our substantive results. Many of the units of analysis that we employ in political science are arbitrary areal units created for governmental administrative purposes rather than because they capture contexts of substantive interest for social and political phenomena. Block groups, census tracts and zip codes are examples of such administrative units. Even when our units do carry a substantive meaning, such as countries, they might not be the appropriate level of analysis – either substate or regional units might make more sense for a particular analysis. Either way, we have a levels of analysis question, a problem well known to political scientists (see, e.g., Singer, 1961; Ray, 2001).

But because political scientists don't primarily think of our data as spatial data, we don't necessarily think of the levels of analysis problem in spatial terms and, as a consequence, we miss the spatial insights that geographers have been considering for decades.

In short, we need to be sensitive to how our results depend upon our choice of spatial units and what these units are actually capturing as contextual units. These issues, reflected in two related concerns – the modifiable areal unit problem (MAUP) and the uncertain geographic context problem (UGCoP) – are the focus of our chapter. In highlighting these issues, we hope to encourage political scientists and geographers toward greater dialogue with each other.

The modifiable areal unit problem – the fact that our substantive results are dependent upon how we divide a spatial plane into spatial units – is well known outside of political science. Openshaw and Taylor's (1979) classic analysis of the subject in 'A Million or So Correlation Coefficients: Three Experiments on the Modifiable Areal Unit Problem' has been cited more than 1,400 times across a variety of disciplines, ranging from geography to demography to sociology.<sup>1</sup> Its influence in political science, however, has been much more limited. A Google Scholar analysis of publications in three of the leading general journals in the discipline (the *American Political Science Review*, the *American Journal of Political Science* and *The Journal of Politics*) finds very few references to this subject that is so central to research in other disciplines. In fact, this Google Scholar search found that *no articles* in the discipline's flagship journal, the *American Political Science Review*, have included the term 'modifiable areal unit problem'. The story is not much better in the other two journals. Only three *American Journal of Political Science* articles have included the term, all since 2007.<sup>2</sup> Only three *Journal of Politics* articles have used the term, all since 2012.<sup>3</sup>

Is the story any more positive when we move away from general journals and look

at the leading subfield journals? Three fields in the discipline that frequently employ areal units are public administration, comparative politics and international relations. A Google Scholar search finds zero uses of the term 'modifiable areal unit problem' in three leading public administration journals (*Public Administration Review*, the *Journal of Public Administration Research and Theory* and the *Journal of Policy Analysis and Management*). In comparative politics, there is only one article in *World Politics*<sup>4</sup> that uses the term, two articles in *Comparative Political Studies*<sup>5</sup> and zero articles in *Comparative Politics*. In international relations, there are zero uses of the term in articles in *International Organization* and *International Studies Quarterly*, and only two articles that use the term in the *Journal of Conflict Resolution*.<sup>6</sup>

The uncertain geographic context problem (UGCoP) is a more recent concern in the geographic literature, identified by Mei-Po Kwan in a highly influential 2012 article in the *Annals of the Association of American Geographers*, 'The Uncertain Geographic Context Problem'. Kwan defines UGCoP as

the problem that findings about the effects of area-based attributes could be affected by how contextual units or neighborhoods are geographically delineated and the extent to which these areal units deviate from the 'true causally relevant' geographic context (the precise spatial configuration of which is unknown in most studies to date; Diez-Roux and Mair, 2010: 134). (p. 959)

In other words, where MAUP recognizes that results can differ depending upon how the spatial plane is partitioned, UGCoP emphasizes the importance of identifying the theoretically appropriate context for understanding particular behaviors, processes and events. It is the substantive complement to the methodological MAUP concern.

Kwan's UGCoP article has been cited more than 440 times in the six years since its publication. However, UGCoP is absent from the political science journals discussed above. None of our leading general journals has published an article that includes the

term ‘uncertain geographic context problem’. None of the top subfield journals discussed above has published such an article either.

In short, two prominent concerns in geography and other disciplines – ones highly relevant for and related to longstanding concerns in political science – have not been utilized much within the discipline of political science. We believe that political scientists can benefit significantly from a greater familiarity with and use of these concepts. After highlighting how the research on contextual influences and racial attitudes can be strengthened by a more careful consideration of the underlying spatial and geographical context, we turn to discuss both UGCoP and MAUP in greater detail.

## CONTEXT IN POLITICAL RESEARCH

Scholars of political science have long been curious about the influence of contextual factors on political behaviors and how such factors may affect the formation of political, policy and racial attitudes. *Context* has been used to explain voting behavior, electoral participation and a growing variety of political and policy positions. According to Books and Prysby (1988: 215), the goals of contextual analysis are at least two-fold: ‘to uncover the extent of contextual effects and to unravel the mechanisms by which these effects occur’. While early research in this vein was typically narrow, focusing primarily on one specific relationship, researchers began focusing more explicitly on the role of context over time. Despite a steady supply of research seeking to understand context in relation to political behavior and public opinion, contextually based inquiries continue to face a variety of analytical and methodological challenges.

A prominent debate within the contextual theory literature apropos the role of context on racial attitudes underscores well the importance of recognizing both the theoretical concerns of UGCoP and the methodological

challenges highlighted by MAUP. By reviewing the evolution of literature surrounding a well-known contextually based theory, the racial threat hypothesis (Key, 1949), the following section illustrates how our ability to understand and accurately capture measures of context can be enhanced by a careful consideration of the geographic literature on context. Today, nearly all studies of racial context and individual behavior include at least a passing reference to Key’s *Southern Politics in State and Nation* (1949). In his book, Key offers a contextual hypothesis of perceived racial threat, suggesting that as the perceived size of a local minority population increases, so too will perceived feelings of racial threat among the predominant population. Ultimately, this is argued to increase levels of racial animosity and boost support for racially hostile policies among members of a predominant group. Indeed, studies lending support to the racial threat hypothesis are in no short supply.<sup>7</sup>

While Key focuses solely on the South, subsequent studies sought to extend the applicability of the racial threat hypothesis to northern urban centers (Katznelson, 1982), urban electoral politics (Browning and Marshall, 1986; Browning et al., 1984) and states more generally (Huckfeldt and Kohfeld, 1989). To be sure, the literature on the racial threat hypothesis has been far from conclusive. Some studies have concluded with null findings, while others have uncovered relationships between minority population size and majority attitudes that are the *opposite* of what Key’s theory would predict (Voss and Miller, 2001).

The ‘predominant explanation’ to these contradictory results, according to Newman (2013: 376), ‘is the countervailing predictions of intergroup threat and contact theory’. In contrast to the racial threat hypothesis, contact theory (Allport, 1954) assumes that intergroup interactions have the potential to positively influence political attitudes and behavior.<sup>8</sup> Whereas the racial threat hypothesis predicts a negative relationship between

rising minority populations and the racial attitudes of a predominant group in a given geographic unit, contact theory predicts larger out-group populations to be positively related to racial attitudes. The underlying theoretical assumption is that intergroup social interaction reduces or corrects negative stereotypes, such as those often portrayed in the mass media. Like the racial threat hypothesis, there is a healthy supply of research supporting the idea that racial contact, under certain conditions, can produce positive attitudes toward out-group members.<sup>9</sup>

Others have suggested that inconsistent conclusions from racial threat theory are more the result of analytical or methodological shortcomings. In a study extending the premise of racial threat theory to attitudes regarding immigration, Newman (2013: 376–7) notes: ‘research on power threat has produced one of the most central puzzles in the contextual research – the notoriously inconsistent findings for group-size based measures of ethnic context on citizens’ attitudes and policy preferences.’ ‘In response to the poor empirical performance of the power-threat hypothesis,’ Newman (2013: 377) writes, ‘the literature has seen the emergence of a new wave of contextual research possessing a sharper focus on stipulating the conditions under which group-size-based measures of racial and ethnic context lead to amity or enmity between groups (Branton and Jones, 2005; Oliver and Mendelberg, 2000; Oliver and Wong, 2003)’.

While earlier scholars such as Przeworski (1974) recognize measurement challenges in the use of aggregate contexts to examine contextual effects, little attention was given to the selection of theoretically meaningful geographic units. Because context can be measured at varying geographic levels, additional sources of variation have been commonly overlooked.<sup>10</sup> Indeed, many studies now find that substantive results depend on the level of measurement related to the contextual unit of analysis. Carsey (1995), for example, reports that the effect of black population densities

on white voter behavior is different at the county/state levels and the precinct/borough levels. Baybeck (2006) also finds different effects at the block-group and city levels. In other words, the commonly reported negative association between minority populations and white racial attitudes may diminish when examined from smaller geo-units. Further, Newman et al. (2015: 172) find a similar pattern when comparing zip codes and county measures, reporting that

citizens’ perceptions of their context are more responsive to their more immediate versus distal residential context. This result also reinforces the concern among the contextual research community that scholars should strive to use smaller geo-units to capture contextual effects, at least when such units correspond to theoretical process presumably operative at the neighborhood level, such as intergroup contact.

Oliver and Wong (2003) urge that ‘when comparing the impact of contact and conflict across racial environments, the racial composition of both the micro and macro contextual units need to be considered’ (p. 570). Again, despite the most consistent evidence supporting racial threat being captured at larger environmental units (counties and metro-regions), racial contact is more likely to be affected by smaller geographic units. Rocha and Espino (2009: 423–424) incorporate levels of residential segregation into the racial environment, ultimately uniting the racial threat and contact hypotheses. They find that segregation complicates the racial context, making ‘the conditions for either racial threat or social contract more likely’, and echo Oliver and Wong (2003) by warning that ‘future research on Anglo racial attitudes cannot rely on simple definitions of racial context, such as the size of the minority population, but also must take account of such influences as the spatial dispersion of minorities’. Adding to this line of thought, Baybeck (2006: 386) argues that ‘racial context needs to be considered as a complex system of overlapping spatial units’. Moreover, he examines how multiple

contexts interact, finding that 'there is no "one" context', and thus advises scholars to 'consider the overlapping political and social boundaries that surround individuals and that these contexts may interact in surprising yet systematic ways' (p. 395).

### MODIFIABLE AREAL UNIT PROBLEM

As stated earlier, many of the areal units that political scientists employ, such as block groups, census tracts and zip codes, are arbitrary and modifiable units developed for purposes of governmental administration and not for purposes of social science (Openshaw and Taylor, 1981: 60).<sup>11</sup> The arbitrary and modifiable nature of many areal objects is problematic, for as Openshaw and Taylor (1979) note, different areal objects can produce fundamentally different relationships between aggregate units or, as they colorfully note, 'a million or so correlation coefficients' (p. 127). This dependence of estimates on the areal objects of analysis is known as the modifiable areal unit problem (MAUP).

The modifiable areal unit problem comprises two problems. The *scale problem* refers to the dependence of findings on the number of areal units into which a spatial plane is divided. A given plane may be divided into any of an arbitrary number of polygons, with results differing fundamentally depending upon the  $n$  that is chosen. The *aggregation problem* refers to the dependence of results on the way that the spatial plane is divided into a particular set number of polygons. Thus, for example, there is a multitude of ways that a spatial plane can be divided into 50 polygons, and estimates of relationships between units will be dependent upon the researcher's choice of how this division is accomplished.

The arbitrary and modifiable nature of many areal objects, such as those discussed above, cannot be remedied; it is an inherent part of their nature. The fact that these units are not unique and fixed, however, would

not be problematic for applied researchers if neither the scale problem nor the aggregation problem obtained. That is, if spatial results did not vary as 500 small polygons were aggregated into 5 large polygons, or depending upon which 5 large polygons were chosen, then areal units would remain modifiable but this would not present a problem for estimation. Unfortunately, there is ample empirical evidence that the scale and aggregation problems are common and can be quite severe (see, e.g., Openshaw, 1983). As but one example, Openshaw and Taylor (1981) show that correlation coefficients for the 99 counties in Iowa varied from  $-0.97$  to  $+0.99$  depending upon how these counties were aggregated. Moreover, equally problematic, as Openshaw (1983: 5) notes, is that there is no general, systematic pattern to the effects on correlation coefficients that can aid with correction of these effects.

As Openshaw and Taylor (1981) show, a variety of solutions have been proposed for the modifiable areal unit problem, but many of these are problematic, as they impose additional, arbitrary criteria at the discretion of the researcher or ignore the fundamentally geographic nature of spatial data. For example, a spatial filtering approach due to Tobler (1969, 1975) may be employed to produce smoothed maps of underlying patterns which remove the noise resulting from aggregation effects. As Openshaw and Taylor note, however, this 'solution' involves an infinite regress since any filtering analysis based upon aggregate data will, by definition, be dependent upon the aggregate areal units employed for the analysis. Even more problematic from a model-based social science perspective is an inductive 'optimal zoning' approach in which the researcher specifies the spatial dependence she expects to observe based upon her understanding of the demographic, political, sociological or other phenomena she seeks to explain. The researcher then compares results using different definitions of the areal objects. The researcher then employs the polygons that are most consistent

with the type of spatial dependence between units (e.g., strongly positive, weakly negative) that she expects given the subject of her analysis (Openshaw and Taylor, 1981: 66–7). Clearly, such an inductive approach runs counter to a model-based social science perspective in which hypotheses are developed independent of the data used to test them.

Much preferable is a theoretically based choice of areal objects. However, as the UCGoP recognizes, such theory is often lacking. As Kwan notes, we can never be certain that we have employed the appropriate contextual units for our question.

The plausibility of this approach will depend upon the researcher's substantive question and the availability of appropriate areal objects. For some analyses, however, there is clear theoretical guidance on the proper polygons to employ in a spatial analysis. A critical question in international relations is the role that geography plays in conditioning the probability that countries will engage in militarized conflict with each other (see, e.g., Starr and Most, 1976, 1983; Most and Starr, 1980, 1982). All else equal, spatially proximate countries should be more likely than spatially distant countries to engage in militarized conflict with each other because proximity affords opportunities for conflict. Here, the choice of polygons – countries – is clear, and it would make little sense either to aggregate or disaggregate these polygons since it is countries that engage in international conflicts. Similarly, if our research question focuses on municipalities' tax policies, we would want to collect data at the municipality level. We might well expect negative spatial autocorrelation in municipality-level tax policies as suburban municipalities pursue low tax strategies to attract economic development away from center cities with higher tax rates. We would not want to collect data within municipalities as a substitute, as these data would exhibit positive spatial autocorrelation because units nested within the same municipality share tax policies decided at the municipal level of government.

For other questions, however, the match between the theoretical areal objects of interest and available areal objects will be less clear. The example of block groups, tracts and zip codes as proxies for neighborhoods is a prime example. Research on appropriate geographic definitions of neighborhoods remains imprecise. One recent area of research has focused on 'bespoke neighborhoods' in which increasing neighborhood domains are built outward from each household unit by including the  $n$  nearest persons to that household, where  $n$  is an arbitrary threshold value such as 50, 500 or 1,000 (see, e.g., MacAllister et al., 2001; Johnston et al., 2005). Although this bespoke neighborhood approach affords some increased verisimilitude by allowing neighborhood definitions to vary by household locations, the use of arbitrary thresholds is unlikely to distinguish precisely between actual neighborhoods.

In the case of neighborhood data, the modifiable areal unit problem will remain a concern until researchers make advances in the definition of neighborhoods *and* data begins to be collected for these areal units. In cases where areal objects remain defined for purposes of government administration rather than social scientific concerns, the researcher is best advised to be guided by theoretical considerations and to employ areal objects that most closely approximate her theoretical conceptions. In all spatial analyses for which the theoretical areal objects of interest are not readily available, scholars should employ multiple areal definitions and report the robustness of their results to these alternative polygon definitions in much the same way as they currently report the robustness of their results to alternative model specifications.

## **THE UNCERTAIN GEOGRAPHIC CONTEXT PROBLEM (UGCoP)**

It's worth repeating here that Kwan defines UGCoP as

the problem that findings about the effects of area-based attributes could be affected by how contextual units or neighborhoods are geographically delineated and the extent to which these areal units deviate from the 'true causally relevant' geographic context (the precise spatial configuration of which is unknown in most studies to date; Diez-Roux and Mair, 2010, 134). (p. 959)

We can, in other words, think of the two components of the modifiable areal unit problem as inevitable consequences of utilizing areal data, while the uncertain geographic context problem refers to the substantive and theoretical identification of the proper areal unit and its use.

Because many areal units were drawn for governmental administrative purposes, they are unlikely to reflect the true contexts that are relevant for behaviors. The actual neighborhood or community contexts that influence behavior are extremely unlikely to line up exactly with administrative boundaries drawn for a different purpose. Moreover, relevant contexts may differ for differing behaviors. Economic competition may occur across a metropolitan area while political competition may occur within a city or a town.

Conceptually distinct contexts such as metropolitan areas, cities and towns lend themselves naturally to theoretical arguments about contextual effects. The UGCoP may have a solution when scholars are working with such contextual units. Not so, however, with many of the areal units that are designed for administrative purposes, such as block groups, census tracts or zip codes. When scholars use these latter areal units it beggars belief to argue that any of these contextual units are the geographic context in which the researcher is actually interested. Neighborhoods and other contexts are often simply not measurable with such administrative units. And as a consequence, scholars employing such units will often wish to employ an alternative approach to measuring context. Doing so can help scholars deal with both UGCoP and MAUP.

## APPROACHES TO ADDRESSING MAUP AND UGCoP

Although both MAUP and UGCoP are presented as 'problems' in the literature, this does not imply that they have solutions. MAUP is an inevitable methodological consequence of employing areal data from a spatial plane that can be partitioned in an infinite number of ways. UGCoP is a substantive problem that we often lack the theoretical knowledge of contextual influences on political behaviors to address. In short, neither MAUP nor UGCoP presents an easy solution.

Scholars have, however, derived various approaches for mitigating the problems posed by both MAUP and UGCoP. Three particularly promising approaches have received considerable scholarly attention. These approaches are bespoke neighborhoods, self-drawn maps and individualized GPS tracking data of political phenomena.

As Johnston et al. (2004: 351) note, the idea of bespoke neighborhoods was developed independently by two sets of researchers (Buck, 2001; Johnston et al., 2000; MacAllister et al., 2001) in the UK in the late 1990s. The basic idea of bespoke neighborhoods is to identify a different contextual environment for every spatial location in the plane. This is done by building out from a survey respondent's location to include a set number of nearest persons to the respondent's home or a set distance from this location. Thus, for example, using the smallest available areal units (say census blocks for US Census data), one then creates progressively larger 'neighborhoods' from respondent *i*'s location utilizing areal units capturing the nearest 50, 100, 500, 5,000, or any other arbitrary increment of people from that location. Alternatively, if one employs a distance metric, one could build out the neighborhoods by utilizing all units whose centroids are within 1 mile, 10 miles, 100 miles, and so on from respondent *i*'s location.

Two advantages of the bespoke neighborhoods approach are that it allows one to

examine neighborhoods of different scales and does so from an individual origin location. The former moves us beyond having a single arbitrary context and allows us to examine the effects of different contextual definitions. However, the contexts can still remain somewhat arbitrary in that there's often no substantive reason why the 50 nearest neighbors would have a greater effect than the 100 nearest neighbors on *i*'s behavior, nor why these are the appropriate cutpoints to examine (the same limitation holds with arbitrary distance cutoffs). Substantive spatial theory remains too imprecise to provide justifications for arbitrary cutpoints such as this (and indeed such cutpoints may be inappropriate in that a set number of nearest neighbors or a specific distance may not be the appropriate metrics for gauging contextual influences). Still, the bespoke neighborhoods approach provides an advantage in considering multiple alternative contextual definitions that can then be chosen based on measures such as RMSE or information criteria.

The second advantage of bespoke neighborhoods is its location-specific origin for the creation of contexts. This is helpful in moving us away from static administrative boundaries to recognize that substantively important contexts for individuals differ within such boundaries and often transcend them. Location-specific origins can provide greater verisimilitude in identifying the contexts that shape individuals' behavior and modeling their effects.

Perhaps ideally, though, one would retain the individual origin component of the bespoke neighborhoods approach while also allowing for greater flexibility in the building of neighborhoods from this origin. Wong et al. (2012) present such an approach via self-drawn maps. In their analysis respondents were given a map and asked to draw their community. They find that respondents' self-defined communities differ from areal units created for governmental administrative purposes such as block groups, that these communities differ across respondents and

that they vary considerably in size across respondents.

Importantly, however, Wong et al. find that respondents' self-defined communities also come with misperceptions about these communities. Specifically, both black and white respondents overestimate the percentage of African Americans in their communities and underestimate the percentage of whites (Wong et al., 2012: 1163). Of course, such misperceptions might be endemic to all contextual units, including administratively defined ones. Velez and Wong (2017) explore this and find that objective administrative boundaries (zip code tabulation areas, ZCTAs) actually predict respondents' demographic perceptions of their contexts better than user-defined boundaries do. This argues that an alternative, more objective approach that is not dependent upon self-reports of context may be needed to properly measure individuals' contexts.

Individualized global positioning system (GPS) tracking of individuals provides just such an approach to measuring context. The idea of this approach is to provide an individualized measure of context, but one based upon objective data drawn from GPS tracking of where subjects were located throughout the day instead of self-drawn (and potentially invalid) maps of subjects' contexts. Beyond employing objective data on individuals' contexts, this approach has the added advantage of providing a dynamic measure of context that recognizes that individuals' contexts differ over the course of the day (Moore and Reeves, 2016). As a result, the behaviors that individuals may be exposed to, e.g., in their neighborhood in the morning or evening may differ from those they encounter during the workday. A GPS tracking measure provides the ability to measure the amount of time spent – and when it was spent – in these various contexts.

Utilizing data on more than 400 individuals, Moore and Reeves (2016: 13) find that GPS tracking data provide a nuanced and dynamic measure of individuals' actual contexts that

more static measures miss. Specifically, they find that static administrative measures of contexts such as census blocks overstate the demographic homogeneity of individuals' contexts. Individuals encounter more members of groups underrepresented in static homogeneous census blocks. Static measures are also found to understate the contextual diversity that individuals encounter in their daily lives. And problems of aggregation are not dependent upon high levels of aggregation, as the same mismeasurement of context occurs at the extremely low level of the block group.<sup>12</sup>

## CONCLUSION

Political scientists have long been interested in contextual influences on political behaviors. Too often, however, we haven't consulted the geographic literature on context. Two central concerns in geography – the modifiable areal unit problem (MAUP) and the uncertain geographic context problem (UGCoP) – are directly applicable to political scientists' study of contextual effects.

Happily, political scientists have been active in developing advances in measuring context. While bespoken neighborhoods have seen only limited use within the discipline, political scientists such as Wong et al. (2012) and Moore and Reeves (2016) have been among those in the vanguard of using self-drawn maps and GPS tracking data to better measure context. For these approaches to gain more widespread use within political science, however, we need to move outside of disciplinary silos and more seriously engage with the geographic literature on the two problems these approaches seek to address – MAUP and UGCoP. In short, we need to take more seriously the insights of geographers on these two problems in our contextual studies in order to more fully utilize the new advances in defining and measuring contexts that are being developed by political scientists and other scholars.

For instance, studies of social, economic and political contexts should more frequently examine how the scale and aggregation problems are affecting their findings. How does the use of different contextual units affect the substantive results that scholars draw? Is there a more theoretically defensible contextual unit that the researcher could employ, one that helps to overcome the UGCoP? How do the results utilizing this contextual definition differ from those in the preceding MAUP-sensitive analysis? Finally, how do the effects of this theoretically based context differ from those based on self-drawn maps and GPS tracking data?

In short, context is central to our understanding of political phenomena. Gone are the days when political scientists felt comfortable treating units – whether survey respondents or countries – as atomistic entities divorced from their surroundings. But as a discipline we still do not take the insights of geographers on context, particularly on MAUP and UGCoP, seriously enough. Until we do, and examine the sensitivity of our results to different contextual definitions, we will not be able to make full use of the very real advances that political scientists and other scholars are developing in measuring context.

# Visualizing Data in Political Science

Richard Traunmüller

## INTRODUCTION

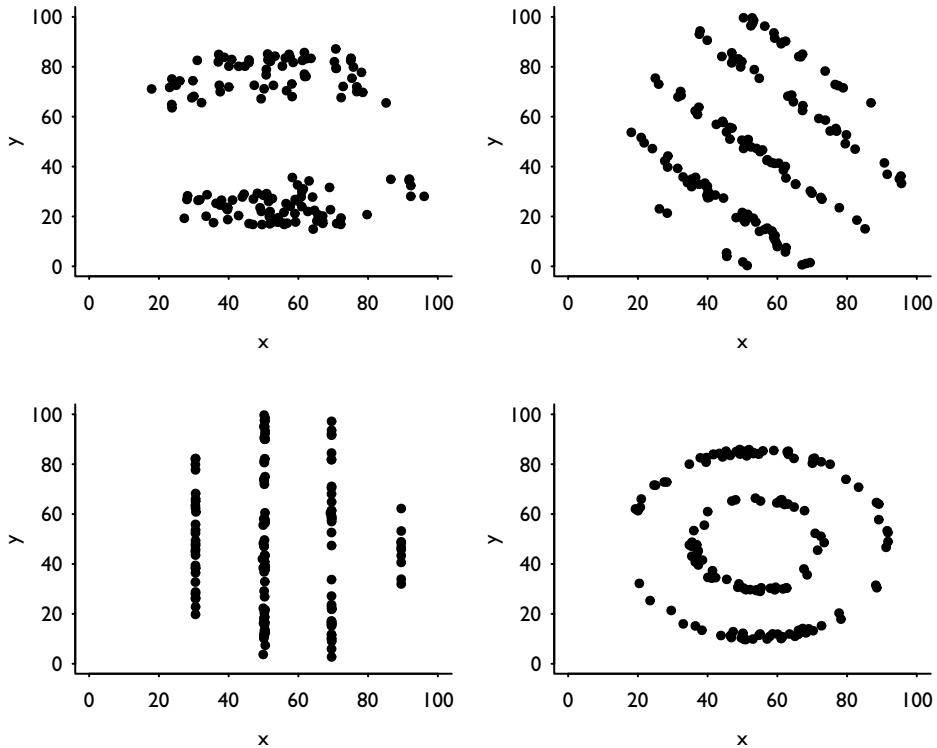

Much of modern political science is concerned with the analysis of data. Both the sheer mass of data and the variety of different data sources that are used to understand political processes have increased dramatically over the past years. Therefore, it should come as no surprise that political science has also developed a growing interest in data visualization. Indeed, few methods can match the utility of data visualization to explore, describe and communicate patterns in quantitative information.

The power of data visualization is easy to demonstrate. Figure 25.1 displays the relation between two variables in four different data sets. We can easily and almost instantly detect four very distinct data patterns: two well separated groups or clusters, different striped patterns that could indicate serial correlation and discrete variables, and a rather peculiar circular pattern.

Interestingly, these striking patterns would have been ignored had we summarized the

data using descriptive statistics that reduce the data points to fewer and more manageable numbers. For instance, we could have calculated the means and find that they are  $X = 54.3$  and  $Y = 47.8$  in all four data sets. Looking at the standard deviations for each variable would have yielded exactly the same in all four data sets:  $\sigma_X = 16.7$  and  $\sigma_Y = 26.8$ , respectively. Looking at the correlation between  $X$  and  $Y$  gives  $\rho_{YX} = -0.1$  in all cases and regressing  $Y$  on  $X$  in a simple linear model would have given the same intercept  $\alpha = 53.8$ , the same coefficient  $\beta = -0.1$  and the same measure of fit  $R^2 = .005$ . These data sets were generated by Matejka and Fitzmaurice (2017) and are a modern version of Anscombe's (1973) quartet that for decades has served scholars as a lesson to look at their data.

Data visualization is concerned with the visual representation of abstract variables and their relations. In this regard it differs from scientific visualization, which is used to visualize concrete physical objects or phenomena

**Figure 25.1** Four scatter plots of four data sets that show wildly different patterns—although summary statistics are identical

such as skeletons, planets or geographical topographies. Data visualization can be understood as a translation tool that assigns abstract numerical values to physical properties such as spatial position along a scale, the length of a bar or the geometric shape and color of a plotting symbol. However, data visualization involves more than simply mapping numbers to visual stimuli. Ideally, data visualization is a method that helps us and our audience understand the political world by assisting analytical thinking. It is common to distinguish two overarching goals of data visualization (e.g. Gelman and Unwin, 2013). *Data visualization for analysis* is mainly used to explore a data set, to diagnose potential problems – such as missing or implausible values – or to uncover unknown patterns and relations which suggest scientific hypotheses and modeling strategies. *Data visualization*

*for presentation*, on the other hand, serves as an efficient means to communicate the results of a data analysis and possibly has the goal of attracting attention and influencing human decisions.

Compared to tabular displays or numerical summaries, data visualization has several advantages (Anscombe, 1973; Cleveland, 1994; Jacoby, 1997; Jacoby and Schneider, 2010; Tufte, 2001; Keim and Ward, 2003; Ware, 2013). First, visualization easily handles large and even huge amounts of quantitative information. The reason is that visualization abstracts from single data points and instead turns them to an emergent new whole – a certain distribution or pattern. In this way virtually millions of data points can be easily perceived and processed. Second, visualization (usually) retains full information and does not rely on assumptions

concerning the distributional nature of the data.<sup>1</sup> Any parametric summary of data leads to a reduction and thus to a loss of potentially interesting information. They may also rely on explicit or implicit assumptions that are incompatible with the data or overly restrictive. Visualization allows for the discovery of unexpected patterns that are either interesting in their own right and thus constitute the end point of an analysis, or, alternatively and crucially, motivate follow-up questions and new directions for exploration. The third advantage of visualization is exactly this: it encourages the search for the sources of observed patterns and the processes that generated them. In this sense visualization can be viewed as an exploratory hypothesis generating device.

In what follows I will provide a selective overview of the state of the art of modern data visualization from a political science perspective. I will begin with a brief empirical analysis of graph use in current political science and then turn to data visualization as an exploratory tool for political science data. Next to table lens plots, I will introduce visual methods that were genuinely designed to display high-dimensional data structures: parallel coordinate plots and small multiple designs. I then turn to recent advances in data visualization that greatly expand the utility of visual methods: the visual exploratory model analysis and visual inference to protect against over-interpretation of random patterns.

For a related up-to-date review of data visualization from a statistical perspective, see Cook et al. (2016); for a sociological perspective, see Healy and Moody (2014). Classic contributions, design advice and sources of inspiration are Bertin (1983), Tufte (2001, 2006) and Cleveland (1994). The important distinction between statistical graphics and infovis is discussed in Gelman and Unwin (2013) and in the ensuing debate. Good introductions to data visualization as an analytical tool are provided by Few (2012) and Unwin (2015). For data visualization as a presentational tool for communication, see Few (2009)

and Kirk (2015). A seminal experiment on the perception of statistical graphs is Cleveland and McGill (1984). Heer and Bostock (2010) replicate and Talbot et al. (2014) extend the results based on crowd-sourced experiments. The best reference for the cognitive psychological foundations of data visualization is Ware (2013). Wilkinson (2005) provides a formalization of data visualization based on the grammar of graphics, which was implemented in the ggplot package by Wickham (2010). Arguably the number one tool for data visualization in political science is the statistical programming language R, for which Murrell (2018), Chang (2012) and Healy (2018) are excellent references. Those interested in producing graphs using STATA should take a look at Mitchell (2012).

## GRAPH USE IN POLITICAL SCIENCE

Counter to many other methodological developments, data visualization is an invention of the social sciences. Historically, graphical methods have co-evolved with the advent of new social, political and economic data collections (Friendly, 2009). Many of the most widely used and successful graphical formats – such as the bar chart, the line chart and the pie chart (but not the scatterplot) – were developed by the Scottish political economist William Playfair to visualize political, economic and social data (Playfair, 1786, 1801). Several important milestones of data visualization – for instance, Minard's map of Napoleon's March to Russia or Nightingale's visualization of the causes of death of British soldiers during the Crimean War – are not only based on social scientific data, but also served very specific political purposes such as influencing policy makers. Finally, the greatest icon of modern data visualization, Edward Tufte, began his career as a political science professor at Yale University.

The reliance on data visualization fell somewhat out of fashion in the 20th century,

**Figure 25.2** Left panel: average number of figures in all articles published in the *AJPS*, 2003–18. Right panel: relative frequency of graphical formats

when ‘serious’ data analysis became associated with significance testing (e.g. Best et al., 2001). Nowadays, and ironically, this dominant mode of conducting statistical inference is itself under attack (Gill, 1999) and data visualization is experiencing a true renaissance. Based on an analysis of all articles published in the *American Journal of Political Science* between February 2003 and March 2018 and on the assumption that these are exemplary for the current state of the art in political science, Figure 25.2 demonstrates that graph use has dramatically increased over the past 15 years.<sup>2</sup> Whereas the average political science article in the discipline’s flagship journal contained roughly one (.92) figure in 2003, graph use has grown to an average of three and a half (3.58) figures per article in 2018. While I rely on figure count as a proxy for graph count, not every figure is necessarily a data visualization display of empirical data; there are also visual representations of mathematical functions, game theoretic decision trees or even just flow charts of theoretical arguments.

Among actual data visualizations, line charts are by far the most popular graphical format in political science: 35% of all graphs published in *AJPS* articles fall into this

category. The second most widely used format is some version of the dot plot (22%), potentially hinting at the influence of Cleveland (1993, 1994) on our discipline. Other common formats are scatter plots (13%) and bar charts (12%). The classical tools for describing continuous distributions – histograms, density plots and Tukey’s box plot – make up 7% of all data visualizations. Although political science has a strong reference to space and geography, maps make up only about 3% of all data visualizations. Finally, 7% fall into a residual category of other visualizations, including, for instance, visual representations of social networks, 3D wireframes and, yes, pie charts. Interestingly, 19% of all visualizations published in the area of political science now make use of color instead of remaining in black and white.

A common visualization technique in political science is to combine several plots into an overall visualization. In fact, only 54% of all visualizations consist of a single plot, whereas 40% combine multiple plots of the same format (in so-called *small multiple designs*, see further below) and 6% multiple plots of different formats (so-called *plot ensembles*, see further below). The average number of plots in these combined visualizations is 4 plots,

but in several instances many more plots are arranged together, with the maximum being no less than 36 tiny plots in one single visualization. Of all dot plots, 53% are used in the context of small multiples or plot ensembles, as are 50% of all scatter plots, 40% of all line charts and 35% of all bar charts.

To better understand the motivation behind graph use in political science, Kastlelec and Leoni (2007) went through every article from five issues of three leading political science journals – the February and May 2006 issues of *American Political Science Review*, the July 2006 issue of *American Journal of Political Science* and the winter and spring 2006 issues of *Political Analysis* – and found that political scientists never use graphs to present regression results. This has certainly changed over the past ten years. In our own sample, no less than 90% of all dot plots are displayed with error bars or confidence intervals and therefore almost 20% of all visualizations in political science are used to display coefficient estimates or experimental group means along with their associated inferential uncertainties. In addition, 32% of all line charts and therefore 11% of all graphs are marginal effect plots and predicted value plots. In this sense, political science uses graphical methods to visualize not only raw data, but also ‘cooked’ data. This is also an indication that data visualization and statistical modeling and inference are best seen as complementary instead of opposites.

Overall, only a limited number of graphical formats are currently used in political science and many of them are well-known standard types. As a result, these are also the graphical formats that, at least a priori, are likely to work best to convey your results to professional peers, conference audiences or reviewers and editors. This is so because they are part of a commonly shared ‘vocabulary’ and therefore incur low cognitive costs for the audience. According to cognitive psychologist and visualization expert Colin Ware (1998: 178), ‘making radically new designs is more interesting for the designer and leads

to kudos from other designers. But radical designs, being novel, take more effort on the part of the consumer’. Therefore, one should not underestimate the power of those simple and common graphical formats. At the same, and speaking from experience, one cannot overestimate editors’, reviewers’, and even co-authors’ reluctance to engage with innovative yet unusual data visualizations.

An interesting question concerns the impact of using graphs in one’s political scientific work. Echoing the late Stephen Hawking (1988), Barabasi (2010) quipped that there ‘is a theorem in publishing that each graph halves a book’s audience’. If this were true, urging political scientists to make heavy use of data visualization would be a rather difficult point to defend. The left panel of Figure 25.3 is a scatter plot of the (jittered) figure count versus the number of citations of the *AJPS* articles in our sample (citations counts are missing for the two most recent volumes). If anything, it seems to suggest that citations decrease with the number of figures included in an article. It also identifies two extreme cases: Taber and Lodge (2006) in terms of citations (747) and Roberts et al. (2014) in terms of number of figures. But clearly publication date confounds this relationship. The right panel therefore shows the same relation net of the fact that more recent publications need a while to be cited (and in addition excludes the two extreme observations). In other words, it shows the residuals of a simple regression of citations on volume number versus the residuals of a simple regression of figure count on volume number using an adjusted variable plot. The line thus corresponds to the regression line of the relation between citations and graph use, controlling for publication date. Each figure included in an *AJPS* article increases the citation count by 1.75 citations, and, with a p-value of .006, ‘significantly’ so (if one cared about this). Clearly, this is not a particularly strong relation, nor is it necessarily causal. Maybe more successful scholars just produce more graphs.

**Figure 25.3** The relationship between graph use and citation counts of *AJPS* articles, 2003–17. Left panel: simple scatter plot with jitter along the x-axis. Right panel: adjusted variable plot relating residuals of figure count to residuals of citations eliminating the effect of publication date

## VISUALLY EXPLORING AND DESCRIBING STRUCTURE IN POLITICAL SCIENCE DATA

Next to the compelling *presentation* of data summaries, statistical results and quantities of interest (Jacoby and Schneider, 2010; Kestellec and Leoni, 2007; King et al., 2001) statistical graphics can be used as *analytic* tools for various purposes and at various stages of the data analysis (Jacoby, 1997, 2000; Bowers, 2004; Bowers and Drake, 2005; Gelman, 2003; Gelman and Hill, 2007; Kerman et al., 2008). Data analysis in political science usually proceeds in several steps: (1) checking, cleaning and pre-processing the data, (2) exploring and describing structure in the data and (3) statistical modeling of the data and making inferences. Data visualization can help in each step of this analytic process: (a) to detect problems and anomalies in the data, (b) to explore and familiarize oneself with the data and generate hypotheses, and (c) to understand, check and diagnose models. Most of the visualizations produced in the process of data checking, initial data exploration and model evaluation won't find their way into journal articles or book chapters. However, because it is increasingly common to provide lengthy appendices and supplemental information online, at least

some of these visualizations could be documented for an interested audience.

A particular challenge in the visual exploration is that data sets in political science grow increasingly larger and more complex. Here largeness and complexity refer to both the number of observations  $N$  and the number of variables  $K$ . Both dimensions bring their challenges to data visualization (Unwin et al., 2006), but dealing with multidimensionality is particularly tricky.

### Table Lens Plots

Table lens plots are a visualization technique that allows the researcher to view a whole and possibly large data set at one glance (Tennekes et al., 2013). As such it gives a good initial overview and is useful for both checking the raw data for anomalies and exploring data to uncover structure. The basic idea of table lens plots is to first divide all  $N$  observations into  $H$  equally sized classes or *bins*. The distributions of the  $k$  dimensions or variables are then shown within each of these bins. For continuous variables, the distribution is shown using a bar for the means (along with the standard deviation). For categorical variables, the distribution of variable values is shown using stacked bar charts. Missing values are treated as their own category.

The example in Figure 25.4 visualizes data taken from the Swiss census 2010. The  $N = 371,221$  observations are first divided into  $H = 100$  row bins and then sorted by the continuous age variable (`AGE_HARM`). The young are at the bottom and the old at the top and we get an impression of the age distribution (panel A). We also immediately see several relations in the data. For instance, women (`SEX_HARM`) are slightly over-represented in the older age cohorts and the share of foreigners without citizenship (`NATIONALITYCAT_HARM`) is higher in younger cohorts. In addition, there is a clear age-specific pattern in employment status (`CURRACTIVITYSTATUSII`), where the young tend to be in education, the middle aged mostly in full-time employment and the elderly retired. Last, missing values seem to only occur in the religious affiliation variable (this information is voluntary in the Swiss census).

Sorting the observations in the table lens plot along the values of a categorical variable – in this case religious affiliation (`RELIGIOUSCOMMAGGII_HARM`) – reveals new patterns and relations (panel B). For instance, we now see that religious groups differ in their mean age. With a mean age of below 40, Muslims are the youngest religious group in Switzerland. Muslims also have the highest shares of non-citizens and the highest unemployment rates. Importantly, we are now also able to see how the missing values in the religious variable are related to missing values in other variables (which we missed in the previous visualization): respondents who did not disclose their religious affiliation (the bright red segment at the bottom of the table plot for religious belonging) are also less likely to indicate their current employment status.

Decreasing the number of bins to  $H = 10$  gives a smoothed and possibly better, because simpler, impression, albeit at the cost of losing detail (panel C). More detail emerges when we increase the number of bins to  $H = 300$  and zoom in on the data to between 54% and 62%, focusing on an interesting part (panel D). This nicely separates the religious groups, in the sense of forming homogenous

bins, and we find that the Jewish community is regionally highly concentrated (`RES_CANTON_HARM`). Filtering out every religious group (i.e. removing them from the visualization) to focus on Jews and ordering by employment status reveals that in this religious group it is overwhelmingly women who stay at home.

Table lens plots illustrate an important point in visual data exploration which they share with more conventional graphical formats, such as histograms or density plots. Exploratory graphs are essentially a model in that the ‘objective is to construct an abstraction that highlights the salient aspects of the data without distorting any features or imposing undue assumptions’ (Jacoby, 1997: 13). By definition, a model is a simplified representation of the world. As such it is always an abstraction that ignores some details. But simplification should not result in misrepresentation. Because table lens plots – just as histograms – divide the data into a discrete number of bins, they are reducing and potentially distorting the information in the raw data. In particular, the choice of the number and widths of the bins,  $d$ , impacts the appearance of the visualization and thus the patterns that become visible.

Thus these data visualizations come with a typical *variance–bias tradeoff* (cf. Jacoby, 1997). Narrow bins or bandwidths produce high-variance, low-bias graphs. That is, the graph closely follows the data (low bias) and shows much detailed variation (high variance). Broader bins or bandwidths produce low-variance, high-bias graphs. They give a smoother picture of the data that eliminates some of the details (low variance), but at the cost of deviating from the actual observed data (high bias). Since it is easy to change bin size and bandwidths it is advisable to always experiment with them to see how the visual pattern changes and what details emerge. A good general strategy is to start with narrow bins and bandwidths to see what the data have to say and then steadily increase them until a good representation which captures the most important features is found.

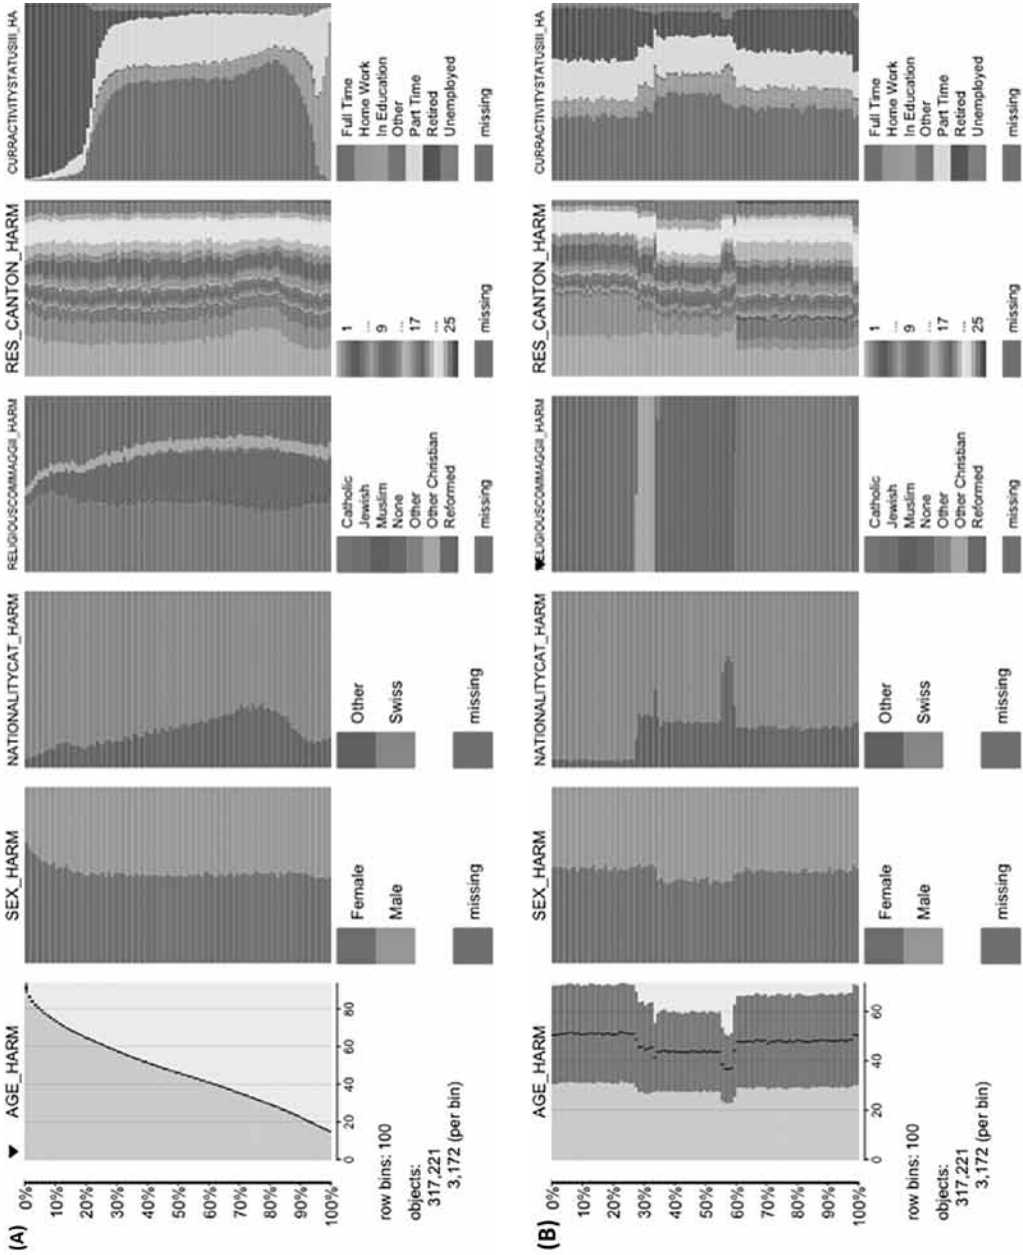

Figure 25.4 Table lens plots of Swiss census data 2010. See main text for description

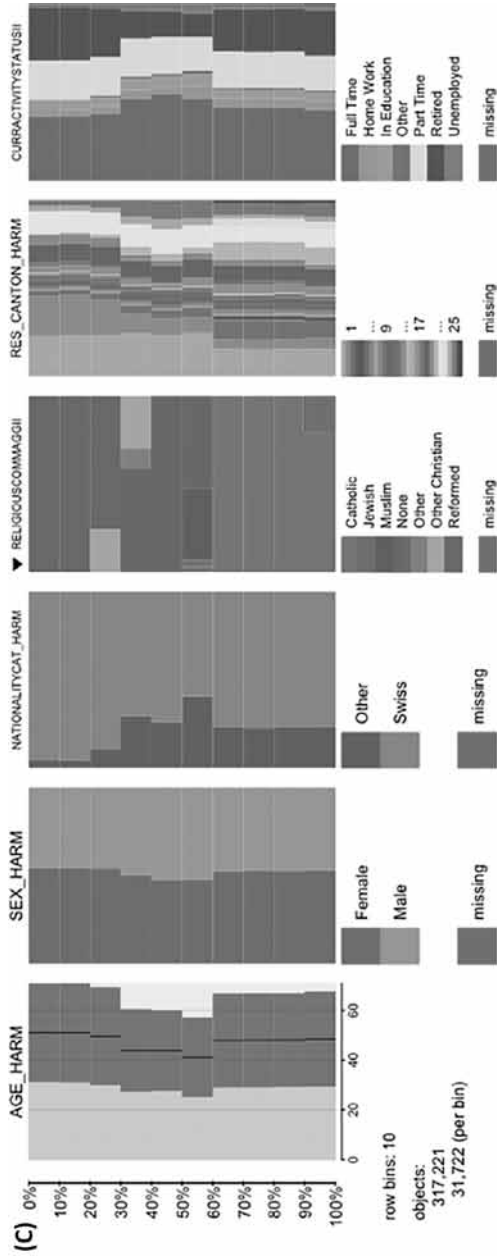

Figure 25.4 Continued

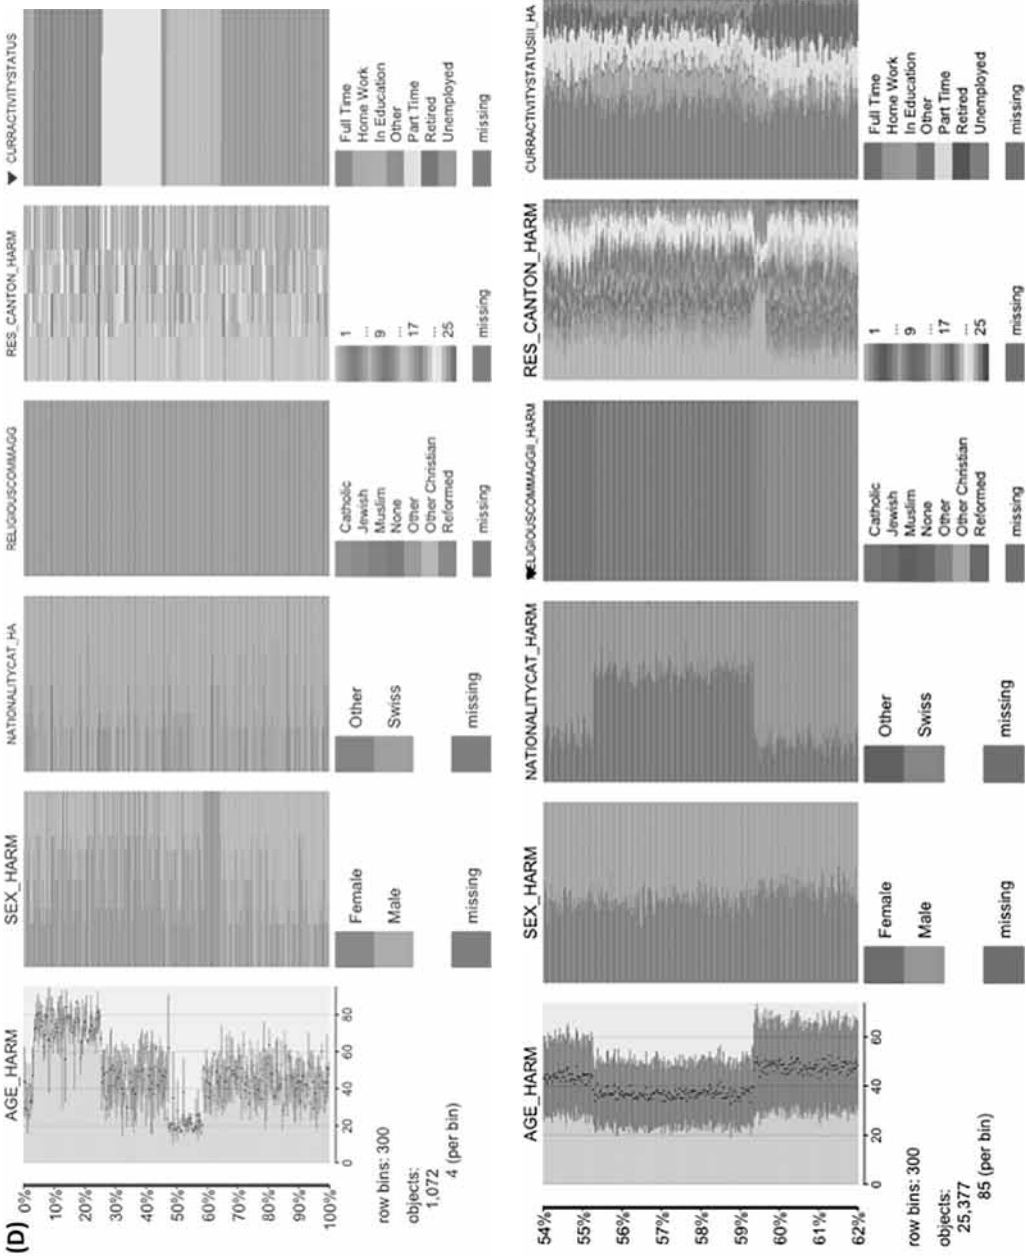

Figure 25.4 Continued

While table lens plots easily accommodate large data sets with many observations,  $N$ , they are limited in terms of the number of variables,  $K$ , they are able to reasonably visualize. Visualization techniques to deal with this ‘curse of dimensionality’ fall broadly into two categories: (a) complex visualization techniques that are explicitly designed to show a high number of dimensions or variables (e.g. *parallel coordinate plots*), and (b) visualization techniques that disaggregate high-dimensional data into a series of simpler, one- or two-dimensional graphics and arrange them in an effective way (e.g. *small multiple designs*).

### **Parallel Coordinate Plots**

A visualization method that is well suited for the analysis of high-dimensional data structures but rarely encountered in political science is the *parallel coordinate plot* (Inselberg, 2008; Wegman, 1990). A parallel coordinate plot solves the problem of the ‘curse of dimensionality’ by doing what its name implies: it maps  $K$  variables along  $K$  coordinates which are aligned in a parallel fashion, instead of orthogonally to each other. A single observation corresponds to a profile line that connects the variable values of the  $K$  variables. Next to overall variable distributions, parallel coordinate plots help find correlations between many variables at the same time and identify high-dimensional clusters in a data set. Negative correlations are visible as crossing, positive correlations as parallel lines. Clusters are visible as separations along an axis and how they are propagated across the plot.

Using a parallel coordinates plot, the example in Figure 25.5 visualizes the policy preferences of  $N=1,069$  candidates for the state elections in Bavaria (2013), Hesse (2013) and Saxony (2014), comparing them across  $K=10$  policy areas.<sup>3</sup> Since the policy items were measured on a five-point Likert scale (higher values indicate higher support

for a policy), this parallel coordinate relies on two additional visualization techniques to deal with the common problem of overplotting – *jittering*, i.e. adding random noise to the variables’ values, and *alpha blending*, i.e. rendering the lines transparent.

At first glance this plot may look intimidating, but several patterns emerge rather quickly. For instance, there seems to be strong consensus among candidates concerning environmental protection (environ) and the rights of same-sex couples (samesex). The bulk of the lines is concentrated on the upper ends of the two axes. More contested policy areas are affirmative action for women (women) and the punishment of criminals (criminal). Here the lines are distributed more or less equally across the five item values. In addition, the crossing of the lines indicates a strong negative correlation. Candidates that favor affirmative action for women tend to be against tighter laws for criminals, and vice versa.

Since the identification of patterns in parallel coordinate plots depends heavily on the sorting of the parallel axes, it is advisable to vary their order. For instance, a random re-sorting in Figure 25.6 shows that preferences for affirmative action for women is also negatively correlated to an immigration policy that stresses migrants’ assimilation (assimilation). Perhaps unsurprisingly, political candidates in favor of regulatory intervention in the economy (polecon, the item is reversed) also show strong support for social security (socsec).

Making use of color, we are able to identify high-dimensional clusters in the parallel coordinate plot. Figure 25.7 colors all observations according to their party affiliation, where the colors correspond to the familiar signature colors of the six most important parties in the German party system (CDU/CSU, SPD, Greens, AfD, FDP, Lefts). As one would expect, policy preferences tend to cluster along party lines. Quite visible are the differences along the classic economic left–right dimension: regulatory intervention

**Figure 25.5** Parallel coordinate plot of the policy preferences of over a thousand political candidates

**Figure 25.6** Parallel coordinate plot of the policy preferences of over a thousand political candidates. Axes have been re-sorted

**Figure 25.7** Parallel coordinate plot of the policy preferences of over a thousand political candidates. Lines are colored according to party affiliation

in the economy (polecon), social security (socsec), and redistribution (redistrib). Ideological party differences are better visible if we reduce the complexity somewhat and concentrate on a comparison of two parties while filtering out the rest (Figures 25.8–25.10). This idea of re-using the same graphic format on different subsets of the

data leads us directly to the next visualization technique.

### ***Small Multiple Designs***

A particularly powerful visual strategy for multidimensional data is to repeatedly

**Figure 25.8** Parallel coordinate plot of the policy preferences of political candidates of the FDP and the Left

**Figure 25.9** Parallel coordinate plot of the policy preferences of political candidates of the CDU/CSU and SPD

**Figure 25.10** Parallel coordinate plot of the policy preferences of political candidates of the AfD and the Greens

apply simple lower-dimensional graphical formats to  $G$  different subsets of the data and to arrange these  $G$  subplots in a meta-visualization. The subsets are themselves defined in terms of variable values or combinations of variable values. This technique has different names, such as *small multiples* (Tufte, 2001), *trellis displays* (Becker et al.,

1996) or *collections* (Bertin, 1983). A special case of this method is a scatter plot matrix that shows all  $G=K(K-1)$  bivariate scatter plots of  $K$  variables in one matrix. The key design feature of small multiples is that the single plots are shrunken in size, have the same appearance and size and also have constant axis scales. In other words,

single displays differ only in the subsets of the data they present. In this way it is possible to make very efficient subgroup comparisons as well as to identify conditional patterns and relations. The efficiency of small multiples is further increased by thoughtful ordering and arrangement.

A well-known political science example of a small multiple design is the visualization of (modeled) survey data on a controversial policy: the support of school vouchers (Figure 25.11, Gelman, 2009). The chosen graphical format is a choropleth map where color shade is used to encode the average support across the US and to give a sense of the geographic variation. Somewhat un-intuitively, green regions show lower support and orange regions higher support for school vouchers. We should also note that this color scheme is unfortunate given the possibility that there will be color-blind individuals in the audience. Be that as it may, the key design feature is the repeated application of the same map format to different subgroups of the data. In this case the subgroups are five different income groups, ranging from low-income on the left to high-income on the right. In this way it becomes clear that support for school vouchers increases with income in all states, with the exception of Wyoming and the Southwest. The small multiple design thus reveals that the relationship between income and policy preference depends on regional characteristics of the states.

We can expand this conditional analysis by bringing in a further variable, ethnic-religious group identity, and by arranging the single graphics in a table or matrix cross-classified by seven identities times five

income groups (Figure 25.12). This shows that the idea of school vouchers is supported by high-income white Catholics and Evangelicals and by low-income Hispanics. Generally speaking, for whites the preference for school vouchers increases with income, whereas for blacks it decreases with income – a classic two-way interaction effect.

As in other visual displays, patterns are easier to detect if we sort the small multiples in a meaningful way (Figure 25.13). Since income groups already exhibit a natural order, whereas this is not the case for ethnic-religious identities, we can sort the rows of the small multiple design (roughly) according to their average political support for school vouchers. The sorting is done informally by eye (Bertin, 1983), but of course more advanced visualization methods could rely on a sorting algorithm to achieve the most efficient plot arrangement (e.g. Hurley, 2004). After sorting, a regional pattern for the policy preferences of the black population pops out. Blacks oppose school vouchers in the South and support them in other regions of the United States.

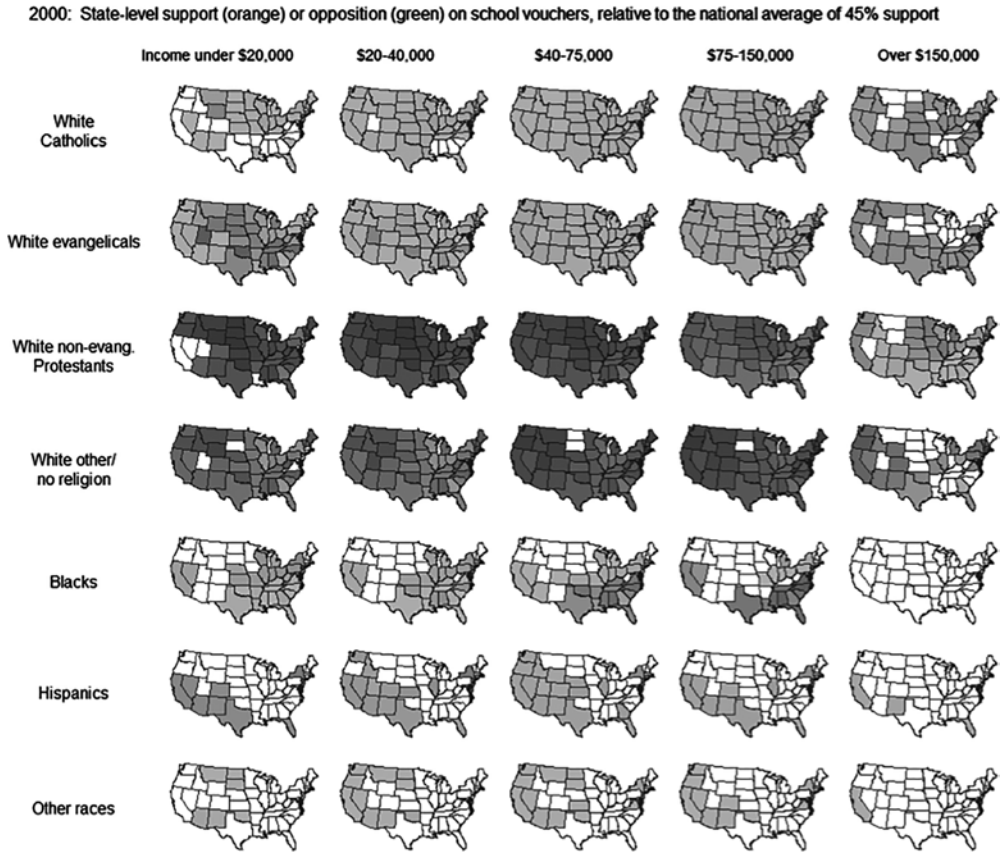

## RECENT ADVANCES IN DATA VISUALIZATION

### *Exploratory Model Analysis*

Exploratory data analysis (EDA) relies primarily on the visual display of data with the goal of discovering unknown structures and unexpected patterns in the data (Tukey, 1977). In a similar vein, visualization can be used to explore the unknown structures and unexpected implications of statistical models.

**Figure 25.11** Small multiples of support for school vouchers by geography and income (Gelman, 2009)

**Figure 25.12** Small multiples of support for school vouchers by geography, income and ethno-religious group (Gelman, 2009)

Exploratory model analysis (EMA) refers to the application of the methods and ideas of exploratory data analysis to statistical models (Gelman, 2003, 2004; Kerman et al., 2008; Unwin et al., 2003; Wickham, 2007; Wickham et al., 2015). Wickham et al. (2015) distinguish a total of five levels at which statistical models can be visualized, namely the model level ( $M$  measures of model fit), the model-estimate level ( $M \times K$  estimated coefficients, standard errors and t-values), the estimate level (summary of  $K$  estimates over many models), the model-observation level ( $M \times N$  residuals and influence measures) and finally the observation level ( $N$  original data and summaries of residual behavior).

The following example draws its motivation for using EMA from the requirements of robustness analysis, where we are interested in learning about parameter stability in many and potentially a huge number of different model specifications (Neumeier and Plümper, 2017). To illustrate, we re-analyze an influential sensitivity analysis conducted by Hegre and Sambanis (2006) on the determinants of civil war onset. In particular, we will look at all model specifications resulting from all possible combinations of 18 potential explanatory variables. The complete model space consists of just over a quarter million ( $2^{18}-1 = 262,143$ ) model specifications, excluding the empty intercept only model.

2000: State-level support (orange) or opposition (green) on school vouchers, relative to the national average of 45% support

**Figure 25.13** Small multiples of support for school vouchers by geography, income and ethno-religious group (Gelman, 2009). Rows have been re-sorted by support

Figure 25.14 (upper left panel) shows a *plot ensemble* that combines different graphs of different aspects of the model specifications (cf. Unwin, 2015). This way, more information is revealed than in any single plot alone. The plot ensemble combines two plots: (a) a scatter plot of the standardized coefficient estimates of the variable ‘military personnel’ (milper) across all models versus the models’ fit measured in terms of decrease in deviance, and (b) a parallel coordinate plot showing the standardized coefficient estimates for all 18

explanatory variables across all models. As we can see, there seem to be three broad clusters of model specifications that produce quite different coefficient estimates of the relationship between army size and the propensity for civil war.

To get a better understanding of which model specifications produce these three distinct clusters, we can rely on methods of interactive data visualization such as *brushing and linking* (Becker and Cleveland, 1987; Cook and Swayne, 2007; Theus and Urbanek,

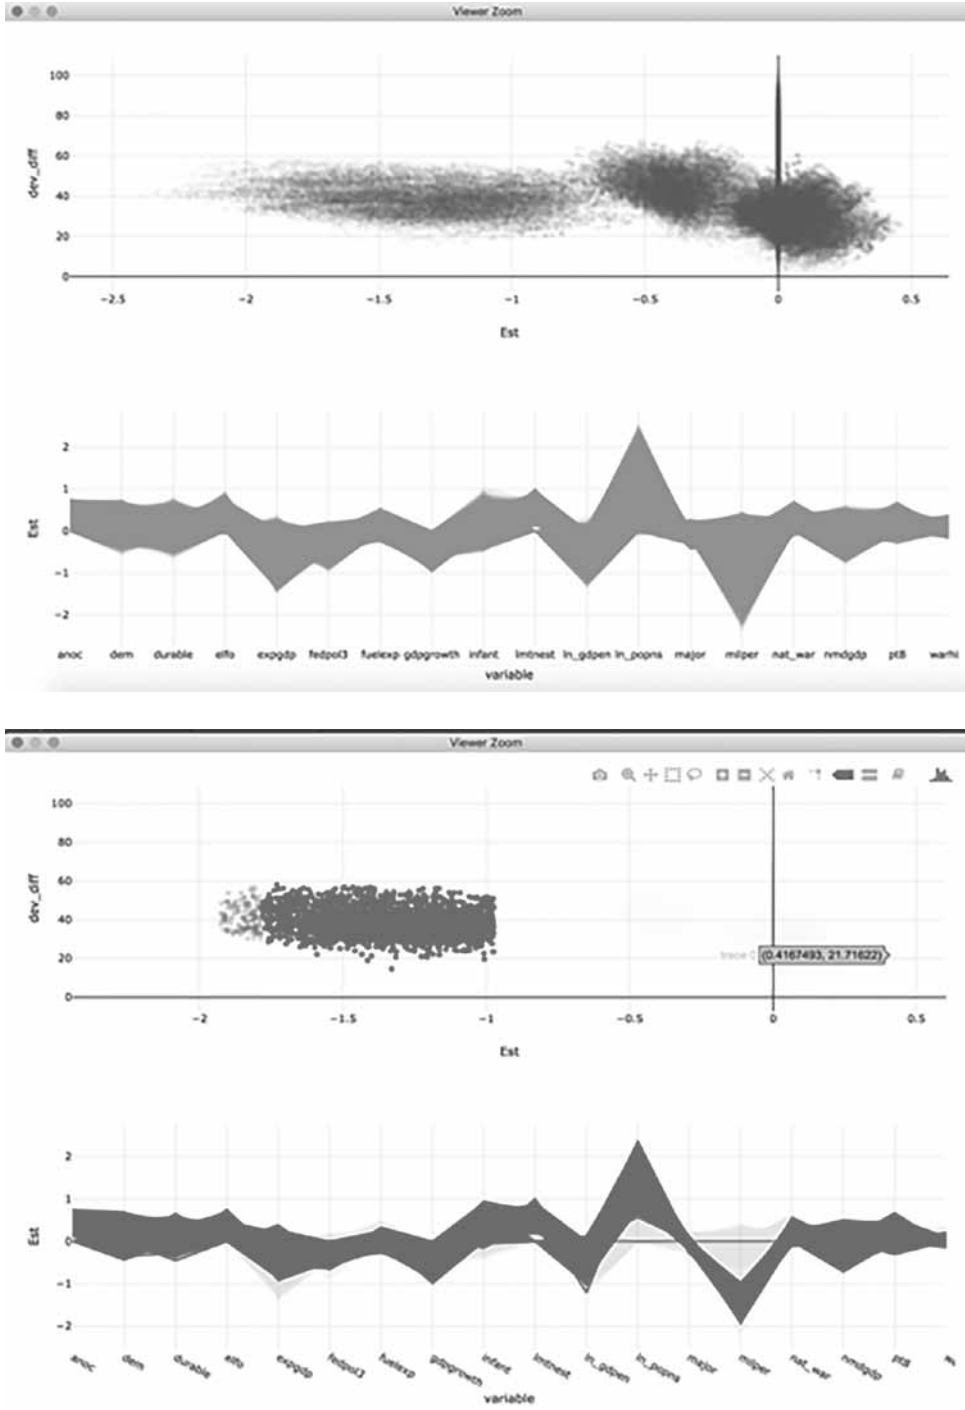

Figure 25.14 Plot ensemble for exploratory model analysis of the determinants of civil war onset. Scatter plots of model fit versus coefficient estimates for army size in over 200,000 models are interactively linked to parallel coordinate plots of coefficient estimates of all 18 explanatory variables

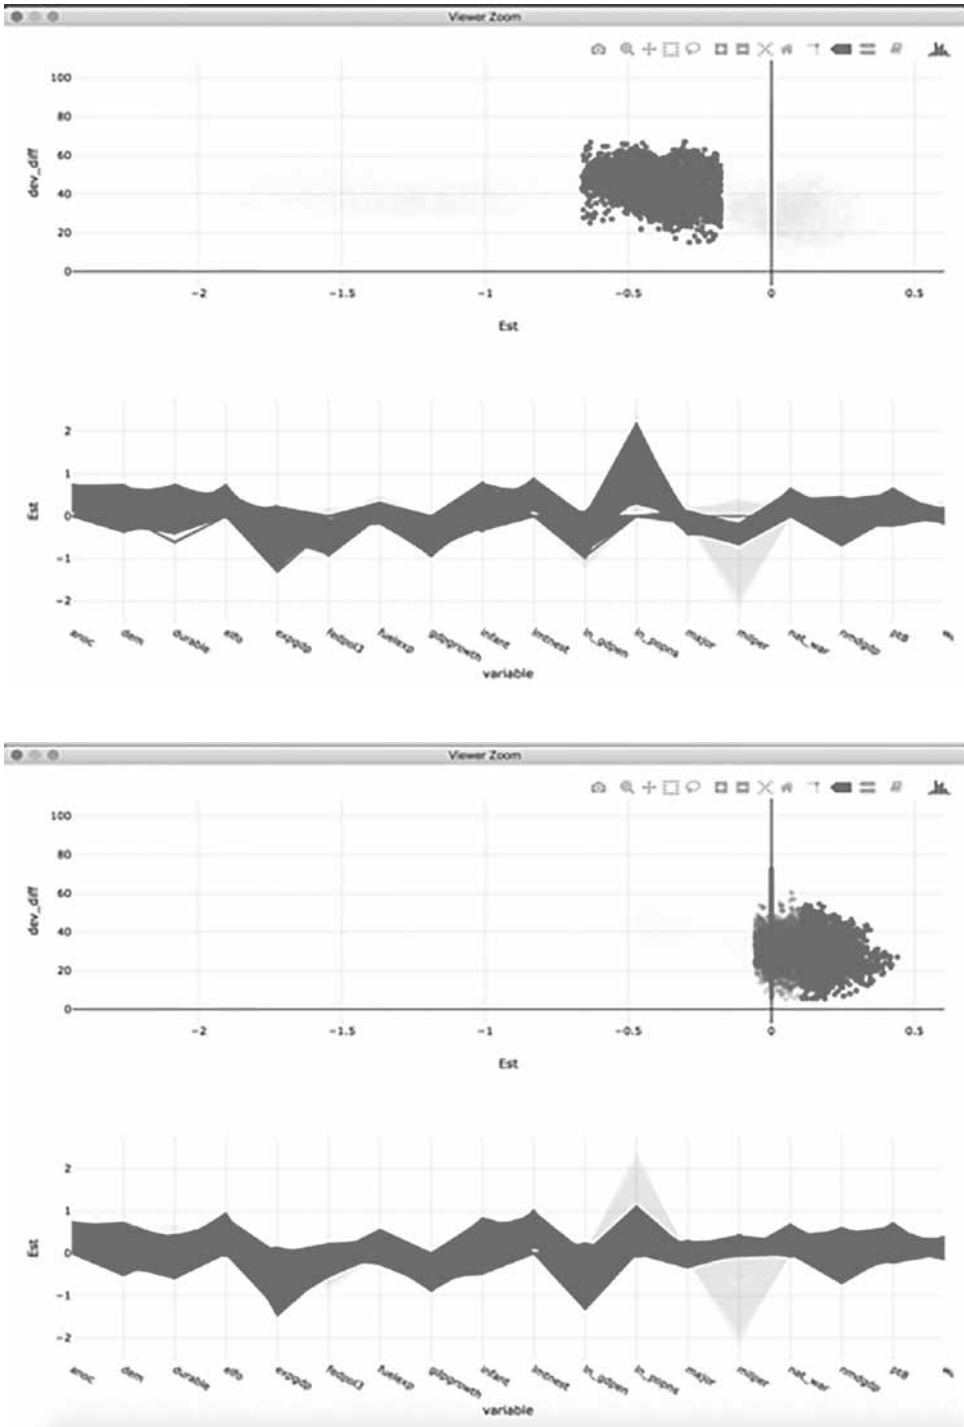

Figure 25.14 Continued

2009). This technique refers to the selection and color highlighting of a subset of the data in one plot. This subset is then simultaneously highlighted in another plot showing a different view of the same data. In this way a link between both views is established and the data is seen from different perspectives. In our EMA example, we find that the coefficient of army size is related to the behavior of log population. Models with large negative coefficients for military personnel tend to also have large positive effects of log population on civil war onset (upper right panel). Conversely, models with no or even positive effects of military size also tend to show no or smaller effects for log population. Clearly, the model exploration should now look more deeply into each of these specifications.

### **Visual Inference**

Despite the clear benefits of turning abstract data structures into visible patterns, a long-standing reservation against data visualization holds that it is merely an ‘informal’ approach to data analysis (cf. Best et al., 2001; Healy and Moody, 2014). The fear expressed in this view is that beautiful pictures may not correspond to any meaningful patterns of substantive scientific interest. Instead, it is argued, serious scientists should base their inferences on more ‘formal’ methods of hypothesis testing to discern signal from noise. Indeed, exploratory data analysis, according to one of its founders, ‘is about looking at data to see what it seems to say. It concentrates on [...] easy-to-draw pictures [...] Its concern is with appearance, not with confirmation’ (Tukey, 1977: v). Consequently, a criticism that frequently arises is that graphical displays lead researchers to over-interpret patterns that are in fact due to mere randomness.

One approach to overcome these reservations is *visual inference*, a new visual method that was only recently developed in statistics and information visualization (Buja et al., 2009; Wickham et al., 2010; Majumder et al.,

2013). The basic idea of visual inference is that graphical displays can be treated as ‘test statistics’ and compared to a ‘reference distribution’ of plots under the assumption of the null hypothesis. The null hypothesis usually posits that there is no systematic structure in the data and that any pattern is really the result of randomness. If the null hypothesis were indeed correct, the plot of the true observed data should not look any different from the plots showing random data. If, however, the plot of the true data clearly stands out from the rest, this could be taken as a rejection of the null hypothesis of no structure. In other words, visual inference brings the rigor of statistical testing to data visualization. To the best of my knowledge this approach has not yet been used in political science (although Bowers and Drake (2005) hint at it).

A so-called Line-up protocol involves the simulation of  $M-1$  null plots (for instance using variable permutations) and randomly placing the plot of the real observed data among them, resulting in a total of  $M$  plots. A human viewer is then asked to choose the plot that looks the most different from the rest. Ideally this human viewer is an impartial observer who has not yet seen the true plot, such as a colleague, student research assistant or crowd worker. If the test person succeeds and picks the plot showing the actual data, then this visual discovery can be assigned a  $p$ -value of  $1/M$ . In other words, the probability of picking the true plot just by chance is  $1/M$ . Setting  $M=20$  and thus simulating  $M-1=19$  null plots thus yields the conventional Type I error probability of  $\alpha = .05$ . We can further decrease the probability of making Type I errors by either increasing the number of null plots,  $M-1$ , or by increasing the number of observers,  $Q$ . Figure 25.15 gives an example of how this inferential process works. Try it for yourself: which of the 20 histograms stands out from the rest, and why?

How about the histogram in the last row and the last column? In fact, none of the histograms is the true plot showing actual data.

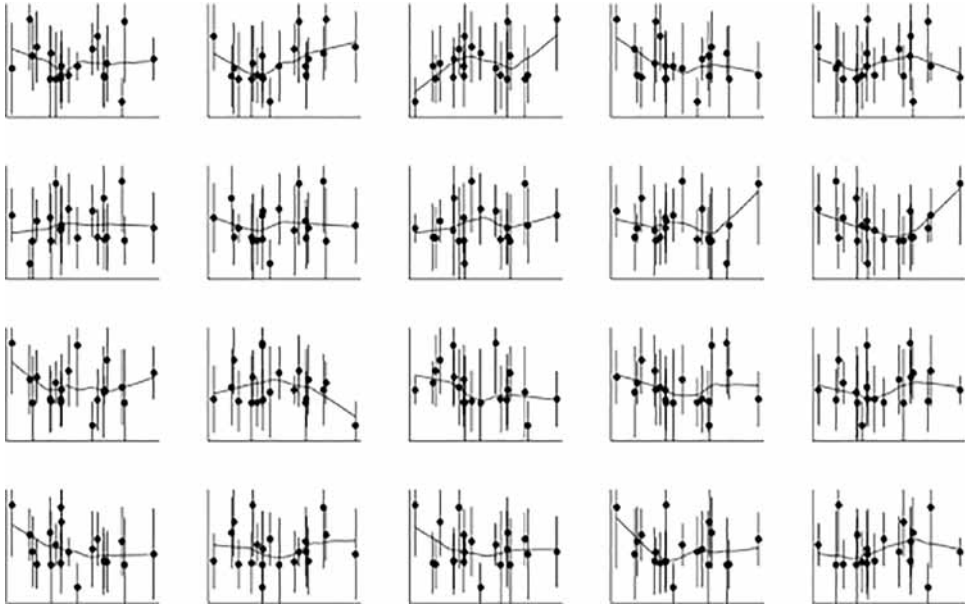

**Figure 25.15** Line-up visual inference with 20 histograms. Which plot is the most different?

All 20 histograms show 100 random draws from a uniform distribution  $U(0, 1)$ . Clearly, this demonstrates how easy it is to over-interpret patterns that are in fact due to mere randomness.

A real application follows Bowers and Drake (2005) and looks at the relation between education and political participation in the US and how this individual-level relation is conditioned by state-level educational context. A typical concern with this kind of analysis is that the number of contextual units is too small to rely on the asymptotic assumptions of classical statistical inference. Therefore, Bowers and Drake (2005) suggest visual methods instead of formal tests. Yet their visual inference remains informal: ‘when we detect a feature with our eyes, we will try to only report it as a feature rather than noise if we feel that any reasonable political scientist in our field would also detect this feature’ (Bowers and Drake, 2005: 317). Applying visual inference, we can swap assumptions concerning the reasonableness of political scientists for

a formal visual test. The null hypothesis in this example is that there is no relationship between the educational context in a state (i.e. the share of highly educated) and the effect of individual education on political participation. The ‘test statistic’ is a scatter plot version, where each dot is a state-specific individual-level effect of education on participation which is plotted along with vertical lines for the 95% confidence intervals. The size of this individual-level effect is on the y-axis. On the x-axis is the share of highly educated in the state. In addition, the plot includes a non-parametric scatter-plot smoother to help reveal any relation between state-level feature and individual-level effect. To construct a ‘reference distribution’ under the null, I randomly re-shuffle the state-level education variable and create 19 new data sets that will have no systematic relation between this variable and the coefficient by repeating this process 19 times. Figure 25.16 below shows the 19 null plots based on this simulated data along with the true plot. Which one stands out?

**Figure 25.16** Line-up for the relation between the individual education effect on political participation (y-axis) and state-level education (x-axis). Which plot is the most different?

I asked nine political scientists and ten crowd workers, and not a single respondent in my sample managed to identify the plot showing the real data.<sup>4</sup> We clearly cannot reject the null hypothesis that individual educational effects are unrelated to state-level education.

Another example comes from political culture research and is inspired by the famous *World Values Survey Cultural Map*, which displays value orientations related to human development and democracy for a range of societies across the globe (see for instance Inglehart and Welzel, 2005). The ‘map’ is really a scatter plot that shows not geographic but cultural proximity by plotting countries along two value dimensions derived by factor analysis. The dimension of so-called survival versus self-expression values is plotted on the x-axis and the dimension of traditional versus secular–rational values on the y-axis. In addition, countries are colored according to their cultural zone

or civilizational heritage: African, Islamic, Latin American, South Asian, Protestant European, Catholic European, Orthodox and English-speaking.

One finding of theoretical interest suggested by the plot is that cultural zones form more or less distinct clusters with similar value orientations: culture matters. The question is whether this pattern is really systematic. The null hypothesis in this case would be that there are in fact no such civilizational clusters and that societies belonging to the same cultural zone do in fact not show similar survival versus self-expression and traditional versus secular–rational values. The reference null distribution can be constructed by a simple random permutation of the vector of cultural zones and thus the color of the dots in the scatter plot. Figure 25.17 presents 19 such null plots along with the true data plot. Can you pick the true cultural map?

The true plot clearly stands out.<sup>5</sup> Indeed, all of the political scientists and 90% of the

**Figure 25.17** Line-up for the relation between survival vs. self-expression values (x-axis) and traditional vs. secular-rational values (y-axis) clustered by cultural zone. Which plot is the most different?

crowd-sourced respondents correctly identified the observed cultural map, yielding a p-value of essentially zero. This allows us to reject the null hypothesis of no cultural value clusters around the world.

## CONCLUSION

Data visualization is an incredibly powerful method to explore, understand and communicate quantitative information. In times where political science accesses increasingly diverse and promising new data sources (e.g. text, social media and digital trace data), data visualization certainly holds a central place in the data analytic toolkit. In addition, communicating political science research to a broad, non-technical lay audience is an important skill. Data visualization is also likely to play a key role in this regard. Looking at its most important applications, key goals and central

actors, data visualization has always had a home in political science. It is hoped that the discipline will reconnect to this proud heritage and move forward to gauge the potential of data visualization for a better understanding of political processes.

## Notes

- 1 Many common visual methods for data exploration, such as histograms and box plots, are actually already abstractions from the data, due to binning decisions in the first case and the five number summary in the latter.
- 2 I thank Felix Jäger and Christian Moreau for excellent research assistance.
- 3 I thank Thomas Zittel for kindly sharing his data from the project 'Parliamentary candidates in the German states: socio-demographics, recruitment, attitudes and campaigning', funded by the German Research Foundation.
- 4 The true plot is in row three and column two.
- 5 The true cultural map is in row two and column four.

# Text as Data: An Overview

Ken Benoit

## INTRODUCTION

When it comes to textual data, the fields of political science and international relations face a genuine embarrassment of riches. Never before has so much text been so readily available on such a wide variety of topics that concern our discipline. Legislative debates, party manifestos, committee transcripts, candidate and other political speeches, lobbying documents, court opinions, laws – not only are all recorded and published today, but in many cases this is in a readily available form that is easily converted into structured data for systematic analysis. Where in a previous era what political actors said or wrote provided insight for political observers to form opinions about their orientations or intentions, the structured record of the texts they leave behind now provides a far more comprehensive, complete and direct record of the implications of these otherwise unobservable states. It is no exaggeration, as Monroe and Schrodt (2009: 351) state, to

consider text as ‘the most pervasive – and certainly the most persistent – artifact of political behavior’. When processed into structured form, this textual record provides a rich source of data to fuel the study of politics. This revolution in the quantity and availability of textual data has vastly broadened the scope of questions that can be investigated empirically, as well as the range of political actors to which they can be applied.

Concurrent with textual data about politics becoming ubiquitous has been the explosion of methods for structuring and analysing this data. This wave has touched the shores of nearly all social sciences, but political science especially has been at the forefront of innovation in methodologies and applications of the analysis of text as data. This is most likely driven by a characteristic shared by some of the most important concepts in our discipline: they are fundamentally unobservable in any direct fashion, despite forming the foundation of our understanding of politics. Short of psychic powers or science fiction devices

for reading minds, we will never have access to direct, physical measures of the content or intensity of such core concepts as ideology, commitment to democracy or differing preferences or priorities for competing policies. Moreover, it is far from clear that every political actor even has such views or preferences, since many – such as political parties, coalition governments or nation-states – are hardly singular actors. Even singular actors may be unaware or self-deceptive about their intentions. Behaviour provides insights into these inner states, but what political actors *say*, more than the behaviour they exhibit, provides evidence of their true inner states.

For those facing the jungle of available textual data, navigating the thicket of different approaches and methodologies for making sense of this data can be no less challenging. Widely available computational tools combined with methods from machine learning allow unprecedented insight to be drawn from textual data, but understanding and selecting from these tools and methods can be daunting. Many recent authors have surveyed the range of methodologies and their applications (e.g. Wilkerson and Casas, 2017; Lucas et al., 2015; Slapin and Proksch, 2014; Grimmer and Stewart, 2013). Rather than retrace or duplicate the efforts of my expert colleagues, here I take a slightly different tack, focusing primarily on an overview of treating text ‘as data’ and then exploring the full implications of this approach. This involves clearly defining what it means to treat text as data, and contrasting this with other approaches to studying text. Comparing the analysis of text as data in the study of politics and international relations to the analysis of text as text, I place different approaches along a continuum of automation and compare the different research objectives that these methods serve. I outline stages of the analysis of text as data, and identify some of the practical challenges commonly faced at each stage. Looking ahead, I also identify some challenges that the field faces moving forward, and how we might meet them in

order to better turn the world of language in which we exist every day into structured, useful data from which we can draw insights and inferences for political science.

## TEXT, DATA AND ‘TEXT AS DATA’

### *Text as Text versus Text as Data*

Text has always formed the source material for political analysis, and even today students of politics often read political documents written thousands of years ago (Monroe and Schrodt, 2009). But for most of human history, the vast bulk of verbal communication in politics (as well as in every other domain) went unrecorded. It is only very recently that the cost of preserving texts has dropped to a level that makes it feasible to record them, or that a large amount of verbal activity has taken place on electronic platforms where the text is already encoded in a machine form that makes preserving it a simple matter of storage. Official documents such as the Congressional Record that transcribes what is said in the US legislature is now supplemented by records of email, diplomatic communications, news reports, blog posts, social media posts, public speeches and campaign documents, among others.

There is a long tradition of analysing texts to gain information about the actors who produced them (e.g. Berelson, 1952), dating from an era before computerised tools became available to facilitate even traditional methods of ‘content analysis’ (Krippendorff, 2013), defined as the human coding of texts into researcher-defined categories. In a different tradition, qualitative scholars may read critically into texts as discourses to uncover the patterns and connections of knowledge and power in the social structures that produced the texts (e.g. Foucault, 1972; Fairclough, 2001; see van Dijk, 1997 for an overview). Such data have always formed the empirical grist for the analytical mill of political

science, but only in the past two decades has the approach begun to shift when it comes to treating text as something not to be read, digested and summarised, but rather as inputs to more automated methods where the text is treated as data to be processed and analysed using the tools of quantitative analysis, even without necessarily being read at all.

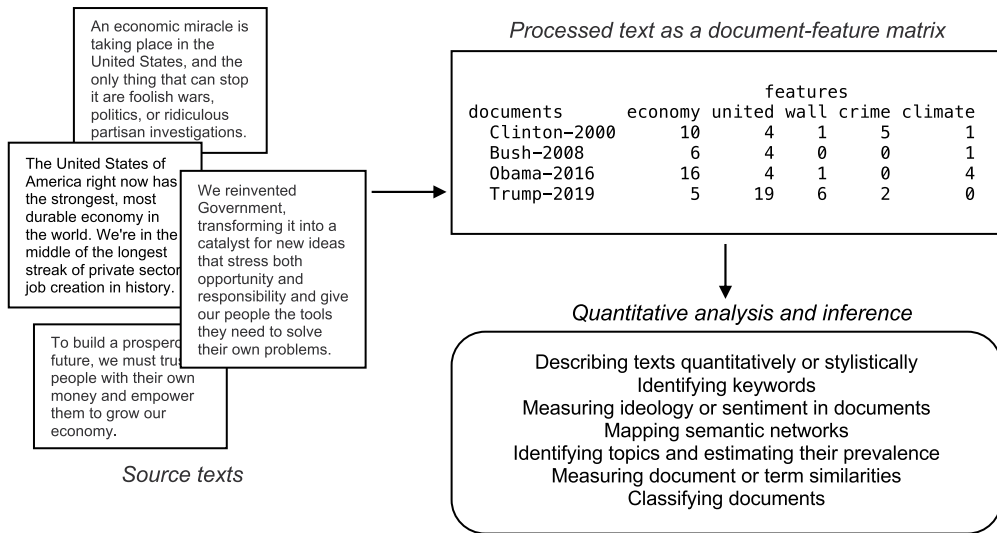

The very point of text is to communicate something, so in a sense, all forms of text contain information that could be treated as a form of *data*. Texts are therefore always informative in some way (even when we do not understand how). The primary objective of verbal activity, however, is not to record information, but to *communicate*: to transmit an idea, an instruction, a query, and so on. We can record it and treat it as data, but the purpose of formulating our ideas or thoughts into words and sentences is primarily communication, not the recording of our ideas or thoughts as a form of data. Most data is like this: the activity which it characterises is quite different from the data itself. In economics, for instance, it may be the economic transactions (exchanging goods or services using a medium of value) that we want to characterise, and the data is an abstraction of these transactions in some aggregated form that helps us to make sense of transactions using standardised measures. Through agreeing upon the relevant features to abstract, we can record and thus analyse human activities such as manufacturing, services or agriculture. The process of abstracting features of textual data from the acts of communication follows this same process, with one key difference: because raw text can speak to us directly through the language in which it is recorded, text does not first require processing or abstraction in order to be analysed. My argument here, however, is that this process of feature abstraction is the distinguishing ingredient of the approach to treating text as data, rather than analysing it directly as text.

Text is often referred to as ‘unstructured data’, because it is a (literally) literal recording of verbal activity, which is structured not

for the purposes of serving as any form of data but rather according to the rules of language. Because ‘data’ means, in its simplest form, information collected for use, text starts to become data when we record it for reference or analysis, and this process always involves imposing some abstraction or structure that exists outside the text itself. Absent the imposition of this structure, the text remains *informative* – we can read it and understand (in some form) what it *means* – but it does not provide a form of *information*. Just as with numerical data, we have to move from the act itself (speaking or writing) to a transformed and structured form of representing the act in order to turn the text into useful information. This is standard practice when it comes to other forms of data, but because we cannot read and understand raw numerical data in the same way that we can raw text, we have not yet fully equated the two processes. No one would hesitate to transform interval data such as age or income into ordinal categories of age or income ranges. (This improves accuracy at some cost of precision, as well as lessening the potential embarrassment of some survey respondents upon being asked to divulge how old they are or how little (or much) they earn.) The essence of treating text as data is that it is *always* transformed into more structured, summary and quantitative data to make it amenable to the familiar tools of data analysis.

Figure 26.1 portrays this process in three simple stages: raw texts; their processing and conversion into a quantitative form; and the analysis of this quantitative form using the tools of statistical analysis and inference. (I return in detail to the steps of this process below, but it is useful at this point to identify the essential stages of this process here.) Treating texts as data means arranging it for the purpose of analysis, using a structure that probably was not part of the process that generated the data itself. This step starts with collecting it into a *corpus*, which involves defining a sample of the available texts, out of all other possible texts that might have

**Figure 26.1** From text to data to data analysis

been selected. Just as with any other research, the principles of research design govern how to choose this sample, and should be guided by the research question. What distinguishes text from *textual data*, however, is that it has been selected for a research question to begin with, rather than simply representing a more fundamental act of communication by its producer. Once selected, we then impose substantial selection and abstraction in the form of converting the selected texts into a more structured form of data. The most common form in quantitative approaches to text as data is to extract *features* in the form of selected terms and tabulate their counts by documents: the 'document-feature matrix' depicted in Figure 26.1. This matrix form of textual data can then be used as input into a variety of analytical methods for describing the texts, measuring or mapping the targets of interest about which they contain observable implications or classifying them into politically interesting categories.

Quantitative text analysis thus moves textual data into the same domain as other types of quantitative data analysis, making it possible to bring to bear well-tested statistical and machine learning tools of analysis and prediction. By converting texts into a matrix

format, we unlock a vast arsenal of methods from statistical analysis designed for analysing matrix-type data: the comparison of distributions; scaling and measurement models; dimensional reduction techniques and other forms of multivariate analysis; regression analysis; and machine learning for prediction or identifying patterns. Many of these approaches, furthermore, are associated with well-understood properties that can be used for generating precise probability statements, such as the likelihood that an observed sample was generated from an assumed distribution. This allows us to generate insights from text analysis with precise confidence estimates, on a scale not otherwise possible.

Ironically, generating insight from text as data is only possible once we have destroyed our ability to make sense of the texts directly. To make it useful as *data*, we had to obliterate the structure of the original text and turn its stylised and oversimplified features into a glorified spreadsheet that no reader can interpret directly, no matter how expert in linear algebra. No similar lament is issued when processing non-textual data, because the form in which it can be recorded as data in the first place is already a highly stylised version of the

phenomena it represents. Such data began as a numerical table that we could not interpret directly, rather than as a direct and meaningful transcription of the act it recorded, whether it consisted of demographical data, (numerical) survey responses, conflict data, roll call votes or financial indicators. Quantitative analysis is the starting point of making sense of non-verbal data, and perhaps for these reasons has never proven controversial. With text, on the other hand, we often question what is lost in the process of extracting stylised features for the purpose of statistical analysis or machine learning, because we have a reasonable sense of what is lost in the meat grinder that turned our beautiful language into an ugly numerical matrix.

This point is so important that it warrants repeating. We hardly find it strange to be unable to make sense globally of a matrix of economic indicators, which we also recognise are imperfect and incomplete representations of the economic world involving the arbitrary selection of features from this world – such as the official definition of a basket of typical goods whose prices are used for measuring inflation. There is no controversy in acknowledging that while we might be able to interpret a specific figure in one cell of dataset by matching a column called inflation and a row with other columns whose values match ‘Canada’ and ‘1973q3’, to make sense of more general trends we need analytical synthesis using machines. With text, on the other hand, we cannot ignore the semantic violence to our raw material and its consequences of processing our raw text into textual data, with the necessarily imperfect and incomplete representation of the source language that this requires. Machines are stupid, yet treating text as data means letting stupid machines process and perhaps analyse our texts. Any human reader would know right away that *terror* has nothing to do with political violence in sentences such as ‘ending inflation means freeing all Americans from the *terror* of runaway living costs’.<sup>1</sup> We can only hope that our process

of abstraction into textual features is smart enough not to confuse the two concepts, since once our texts have become a document-feature matrix as portrayed in Figure 26.1, it will be hardly more interpretable than a set of raw inflation figures. In our discussion of the choice of appropriate procedure for analysing textual data, we return to this concern in more detail. The key point is that in order to treat text as data rather than text as text, we must destroy the immediate interpretability of source texts, but for the higher purpose of enabling more systematic, larger-scale inference from their stylised features. We should recognise this process unflinchingly, but also not lose any sleep over it, because the point in analysing text as data was never to interpret the data but rather to mine it for patterns. Mining is a destructive process – just ask any mountain – and some destruction is inevitable in order to extract its valuable resources.

### ***Latent versus Manifest Characteristics from Textual Data***

In political science, we are often most interested not in the text itself, but rather in what it tells us about a more fundamental, *latent* property of the text’s creator. In the study of politics (as well as psychology), some of our important theories about political and social actors concern qualities that are unobservable through direct means. Ideology, for instance, is fundamental to the study of political competition and political preferences, but we have no direct measurement instrument for recording an individual or party’s relative preference for (for example) socially and morally liberal policies versus conservative ones. Other preferences could include being relatively for or against a specific policy, such as the repeal of the Corn Laws in Britain in 1846 (Schonhardt-Bailey, 2003); being for or against further European integration during the debate over the Laeken Convention (Benoit et al., 2005); or being for or against a no confidence motion (Laver and

Benoit, 2002). These preferences exist as inner states of political actors, whether these actors are legislators, parties, delegates or candidates, and hence cannot be directly observed. Non-verbal indicators of behaviour could also be used for inference on these quantities, but it has been shown that what political actors *say* is more sincere than other forms of behaviour, such as voting in a legislature that is subject to party discipline and may be highly strategic (Herzog and Benoit, 2015). Textual data thus may contain important information about orientations and beliefs for which non-verbal forms of behaviour may serve as poor indicators. The field of psychology has also long used verbal behaviour as an observable implication of underlying states of interest, such as personality traits (e.g. Tausczik and Pennebaker, 2010). Absent coercive methods or mind-reading technology to discern the preferences, beliefs, intentions, biases or personalities of political and social actors, the next best alternative is to collect and analyse data based on what they are saying or writing. The target of concern is not so much what the text contains, but what its contents reveal as data about the latent characteristics for which the data serves as an observable implication.

Textual data might also focus on *manifest* characteristics whose significance lies primarily in how they were communicated in the text. Much of the field of political communication, for instance, is concerned not with the latent characteristics indicated by the texts but rather with the form and nature of the communication contained in the text itself. To take a classic example, in a well-known study of articles by other Politburo members about Stalin on the occasion of his 70th birthday, Leites et al. (1951) were able to measure differences in groups with regard to communist ideology. In this political episode, the messages signalled not only an underlying orientation but also a degree of political manoeuvring with regard to a leadership struggle following the foreseeable

event of Stalin's death. The messages themselves are significant, and these could only be gleaned from the public articles authored by each Politburo member, written in the full knowledge that they would be reprinted in the party and general Soviet press and interpreted as signals by other regime actors. To take another example, if we were interested in whether a political speaker used populist or racist language, this language would be manifest directly in the text itself in the form of populist or racist terms or references, and what would matter is whether they were used, not so much what they might represent. In their study of the party political broadcasts of Belgian political parties, for instance, Jagers and Walgrave (2007) established how much more overtly populist the language used by the extreme-right Vlaams Blok party was, compared to that of other Belgian parties.

In practice, the quality of a characteristic observable from text as being manifest versus latent is not always sharply differentiated. Stylistic features, for instance, might be measured as manifest quantities from the text but might be of interest for what they tell us about the author's more fundamental traits that led to the features' use in communication. In studies using adaptations of *readability* measures applied to political texts, for instance, we might be interested either in the latent level of political sophistication as a measure of speaker intention or in speaker characteristics, as evidenced by the observed sample of texts; alternatively, we might be interested in the manifest differences in their readability levels as more direct indicators of the medium of communication. In a study of historical speeches made in the British parliament, for instance, Spirling (2016) attributes a shift to simpler language in the late 19th century to the democratising effects of extending the franchise. Using similar measures, Benoit et al. (2019) compared a sample of US presidential State of the Union addresses delivered on the same day, by the same president, but in both spoken and written forms to show that the spoken forms used

easier language. The former study might be interested in language easiness as an indicator of a more latent characteristic about the political representation, while the latter analysis might be more focused on the manifest consequences of the medium of delivery. For many research designs using textual data, the distinction is more a question of the research objective than of some intrinsic way that the textual data is structured and analysed.

### **What 'Text as Data' Is Not**

We defined 'textual data' as text that has undergone selection and refinement for the purpose of more analysis, and distinguished latent from manifest characteristics of the text as the qualities about which the textual data might provide inference. While this definition is quite broad, it excludes many other forms of text analysis. It is useful, then, to identify the types of textual analysis that we do not consider as involving the analysis of text as data.

In essence: the study of text that does not extract elements of the text into a systematic form – into *data* – is not treating the text as data. Interpretivist approaches that focus on what a text *means* are treating the text as content to be evaluated directly, not as source material for systematic abstractions that will be used for analysis, only following which will its significance be evaluated. This is true even when the object of concern may ultimately be far greater than the text itself, such as in critical discourse analysis, whose practitioners' concern with text is primarily with social power and its abuse, or dominance and inequality as they are sustained or undermined by the text (van Dijk, 1994: 435). While this approach shifts attention to the texts as evidence of systemic injustices, the concern is more about the ability to construct a narrative of evidence for these systemic biases to be interpreted directly, rather than about extracting features from the text as data that will then be used in some analytic

procedure to produce evidence for or against the existence of injustices. The difference is subtle, but has to do with whether the interpretation of a direct reading of the text (no matter how systematic) is the end result of inquiry, versus an analysis only of extracted features of the text using a procedure that does not involve direct interpretation (such as reading) of those features. The latter treats the text as data, while the former is more focused on the text as text, to be interpreted and analysed as text.

Treating text as data is not strictly limited to quantitative approaches. Some of the most popular methods for analysing text as data in fact rely on qualitative strategies for extracting textual features. Classical *content analysis*, for instance, requires reading and understanding the text. The purpose of this qualitative strategy, however, is to use content analysis to extract features from textual data, not for analysing directly what is read and understood. In reading units of the text and annotating them with pre-defined labels, content analysis uses human judgement not to make sense of it directly, but instead only to apply a scheme to convert the text into data by recording category labels or ratings for each unit of text. Any analysis then operates on this data, and this analysis is typically quantitative in nature even if this only involves counting frequencies of keywords or category labels. But there is nothing to say that the process of extracting the features of the text into data needs to be either automated or statistical, and in thematic and content analytic approaches, they are neither. Most direct analysis of the text without systematically extracting its features as data – text as text – is by contrast almost always qualitative because raw text is inherently qualitative. This explains why text as data approaches are associated with quantitative analysis and interpretative approaches with qualitative analysis, but to equate them would be to obscure important qualitative elements that may exist as part of a text as data research design.

Many direct forms of analysing text as text exist. The analysis of political *rhetoric*, for

instance, can be characterised as the science and art of persuasive language use through ‘effective or efficient speaking and writing in public’ (Reisigl, 2008: 96). It involves a form of discourse analysis of the text, especially with respect to the use of tropes, symbols, allegories, metaphors and allusions. The study of anaphora in Martin Luther King’s ‘I Have a Dream’ speech (the repetition of ‘Now is the time...’ at the beginning of sentences), for instance, involves analysing the form of its language directly, not abstracting it into data that will only then be analysed. When elements of the speech are extracted systematically into features, however, and these features are subject to an analytic procedure whose interpretation can be used as an *indicator* of rhetorical quality, then the same input text *has* been treated as data.<sup>2</sup> This involves an act of literary brutality – the disassembly and matrix decomposition of one of the most moving speeches in US political history – but it allows us to compare Martin Luther King’s speech to other pieces of political oratory on a large scale and on a common methodological footing, in a way that would have been infeasible through direct interpretation.<sup>3</sup>

Finally, it is worth mentioning how the rapidly expanding field of natural language processing (NLP) from computer science fits within the boundaries of the text as data definition. Most computer scientists are puzzled by our use of the label, as if treating text as a form of data using quantitative tools were something new or special. This is because computer scientists’ approaches *always* involve some form of automated extraction of textual features and the processing or analysis of these using algorithmic and mathematical methods. The difference between many applications in NLP and the uses of textual data in political science lies not in whether the text is treated as data, but rather in the purposes for which this data is used. Computer scientists are frequently concerned with engineering challenges, such as categorising structure and syntax in language, classifying or summarising documents, mapping

semantic spaces, machine transition, speech recognition, voiceprint authentication, and so on. All of these are driven by textual data, but for objectives very different from the political scientist’s goal of making inferences about politics. Much research in NLP concerns the use of (big) textual data to make inference about patterns in natural language. Text for political scientists, by contrast, is just one more type of informative behaviour about politics, not something whose innate properties interest us in their own right. The main advantage and objective of analysing text as data in political science is to make inferences about the same phenomena that we have long studied using non-textual data.

The key dividing line, then, involves whether the analytic procedure – whether this is interpretation, critical discourse analysis, rhetorical analysis, frequency analysis or statistical analysis – is applied to directly to the text, or whether some intermediate step is applied to the text to extract its salient features which only then are analysed for insight. Within this broad definition, there are many forms this can take, and in what follows I contrast these along a continuum of automation and research objective, or what I call the target of concern (Table 26.1).

**Table 26.1 A map of approaches to the analysis of political text**

<i>Approach</i>	<i>Method</i>	<i>Target of concern</i>
Literary	Discourse analysis	Meaning Rhetoric Power relations Hidden biases Rhetoric Symbolism
Qualitative	Thematic analysis Content analysis	Topics Positions
Hybrid quantitative	Dictionary analysis	Affect
Purely quantitative	Statistical summary Machine learning	Authorship Intent Similarity Events

## VARIETIES OF TEXT ANALYSIS

We can distinguish three main variants of text analysis, differing in whether they treat the text as information to be analysed directly versus whether they treat the text as a source of data to be systematically extracted and analysed. Their situation along the continuum of text as text versus text as data can be contrasted on the basis of the degree of automation and on the target of concern to which the analysis is applied. This is a vast oversimplification, of course, but serves to contrast the essential differences between approaches.

### *Literary Analysis*

The first area is the one furthest from the approach of treating text ‘as data’ described here: literary analysis. This approach is aimed not at treating the text as an observable implication of some underlying target of interest, but rather as the target of interest itself: text as text. In extreme forms, this may treat the text as the sole object of interest, holding the characteristics or intention of the author of the text as irrelevant. This was the view of the ‘New Criticism’ school of literature theory advanced by Wimsatt and Beardsley (1946) in their influential essay ‘The Intentional Fallacy’, which argued against reading into author intentions or experiences, and advocated instead focusing exclusively on the text itself.

A great many other schools of literary thought exist, of course, including postmodernist approaches that do just the opposite of avoiding reading beyond the texts, and instead examine them critically as situated in their social context. What do the texts reveal about the structures of power in a social system, especially in relation to marginalised individuals or groups? Critical discourse analysis is concerned less (or not at all) with description of the text or inference from data extracted from the text, but rather with features underlying the system in which

the text occurred, even if its analysis takes place through analysing the text as text. A critical discourse of presidents’ speeches, for example, could focus on its commands and threats and how these are aimed at ‘managing the minds of others through a manipulation of their beliefs’ (van Dijk, 1994: 435; for an example in this context see Chilton, 2017). Treating presidential speeches as data, by contrast, could consist of a computerised analysis of the words used to contrast sentiment across time or to compare different individuals (e.g. Liu and Lei, 2018). The former is interested in the text as evidence for a philosophical and normative critique of power, while the latter is concerned with supplying more empirical data on the ability to describe and compare the preferences or styles of political actors in the context of open-ended scientific propositions. Discourse analysis may be very systematic, and indeed this was a key contribution of Fairclough (2001), who developed a sophisticated methodology for mapping three distinct dimensions of discourse onto one another. The key point here is with respect to the role of the text in the analysis, whether it forms the end object of inquiry as a text versus whether it will be used as a source of data, with the text itself of secondary or instrumental value.

### *Qualitative Text Analysis*

What I have labelled as *qualitative* approaches to the analysis of political text are distinguished from discourse analysis by focusing not on what the texts mean, either about the authors or about their attempts to influence the audience or to shore up or wear down the structures of the social system, but instead on gaining more neutral empirical data from the texts by using qualitative means to extract their features. ‘Qualitative’ is used here in its simplest form, to mean that the analytical tool does not involve statistical or numerical analysis and, at its core, involves human judgement and decision rather than machines.

These methods include *content analysis* and *thematic analysis*.

Sometimes called ‘qualitative content analysis’, content analysis is the human annotation of textual content based on reading the texts and assigning them categories from a pre-defined scheme. Many of the most widely cited comparative political datasets are generated from content analytic schemes of this type, such as the Manifesto Project (e.g. Budge et al., 1987, 2001) and the Comparative Policy Agendas Project (Walgrave and De Swert, 2007; Baumgartner et al., 2008). Both employ human coders to read a text, segment that text into sentences or phrases and apply fixed content codes to the segments using a pre-defined scheme that the coders have been trained to use.

Thematic analysis is essentially the same procedure, but involving a more iterative process whereby the annotation scheme can be refined during the process of reading and annotating the texts. These two approaches are closely related, since most content analytic schemes are developed by starting with a core idea and then are refined through a thematic process of attempting to apply it to a core set of texts. Thematic analysis resembles discourse analysis, and may even involve the same computer assisted tools for text annotation. It differs however in that both it and content analysis aim at a structured and more neutral and open-ended empirical approach to categorising, in the words of early political scientist Harold Lasswell (1948), who says what, to whom, and to what extent. Qualitative text analysis in this tradition aims not at a critique of discourse, but rather as ‘a research technique for the objective, systematic and quantitative description of the manifest content of communication’ (Berelson, 1952: 18).

Qualitative text analysis is labour intensive, but leverages our unique ability to understand raw textual data to provide the most *valid* means of generating textual data. Human judgement is the ultimate arbiter of the ‘validity’ of any research exercise, and if human judgement can be used to generate

data from text, we tend to trust this procedure more than we would the results of a machine – just as we would typically trust a bilingual human interpreter to render a correct translation more than we would Google Translate. This conclusion belies the unfortunate fact that humans are also notoriously unreliable, in the sense of not usually doing things in the exact same way when confronted with the same situation. (There are special psychological designations for those who do, including autism and obsessive-compulsiveness.) Two different human annotators, moreover, have naturally different perspectives, judgements, proclivities and experiences, and these invariably cause them to apply an analytic scheme in different ways. In tests to replicate the Manifesto Project’s scheme for annotating the sentences of manifestos, even among trained expert coders, Mikhaylov et al. (2012) found levels of inter-rater agreement and reliability so low that had the coders been oncologists, their levels of tumour misdiagnosis would have been professionally and financially catastrophic. Methods exist to increase coder reliability, such as formulating explicit rules and carefully training coders, but even these are imperfect. Machine methods, by contrast, may generate results that are invalid or systematically wrong (if poorly designed), but at least they will be perfectly reliably wrong. This allows valuable and scarce human effort to remain focused on testing and calibrating machine-driven methods, without the frustration of knowing that wrong answers might be due to random and uncontrollable factors.

### ***Hybrid Quantitative: Dictionary Analysis***

Dictionary analysis provides a very good example of a method in between qualitative content analysis and fully automated methods. The spread of computerised tools has made it possible to replace some or all of the analytic process, using machines that are perfectly reliable (but that don’t know Karl

Marx from Groucho Marx, much less what they are doing). One of the pioneering projects in what are known as *dictionary* approaches, the *General Inquirer* (Stone et al., 1966), arose in the late 1960s as an attempt to measure psychological qualities through texts as data, by counting words in electronic texts according to their membership in pre-defined psychological categories including positive and negative affect or ‘sentiment’. Because the field of psychology also has the problem that many of its most important concepts are inner states that defy direct measurement, psychology has also long been concerned with the use of language as observable implications of a speaker or author’s inner states, and some of the earliest and most ambitious dictionary-based projects have arisen in that field (e.g. also Martindale, 1975; Tausczik and Pennebaker, 2010).

In the ‘dictionary’ approach to analysing text as data, a canonical concept or label (the dictionary ‘entry’ or, in the terminology I prefer, *key*) is identified with a series of patterns to which words in a text will be matched. These patterns, which I will call *values*, are usually considered equivalent instances of the dictionary key. A key labelled *posemo* (for positive emotion) might contain the values *kind*, *kindly* and *kindn\**, for instance, to match references to the emotional characteristic of ‘having or showing a friendly, generous, and considerate nature’.<sup>4</sup> The last value (with the ‘\*’) is an example of a ‘glob’ pattern match, where the *wildcard* character will match any or no additional characters up to the end of the term – for instance, *kindness* or *kindnesses*. The false positives – words we detected but should not have – of *kindred* or *kindle* are excluded by these patterns, but so are *kindliness* and its variants – what we could call ‘false negatives’, or terms we should have detected but failed to do so.

This illustrates the key challenge with dictionary approaches: calibrating the matches to dictionary concepts in a valid fashion, using only crude fixed patterns as indicators of semantic content (meaning). The difficulty

lies in constructing a text analysis dictionary not only so that all relevant terms are matched (no false negatives), but also that any irrelevant or wrong terms are not (no false positives). The first problem is known as *specificity*, and is closely related to the machine learning performance measure known as *precision*. The second problem is known as *sensitivity*, and relates to the machine learning concept of *recall*. Match too broad a set of terms, using for instance the pattern *kind\**, and the matches attributed to positive emotion could wrongly include references to a popular electronic book reader. Match too specific a set of terms, such as *kind* only, and we would fail to match its adverbial form ‘kindly’.

Thus far we have focused on variants distinguished by spelling, but the problem can be even more fundamental because many words spelled identically may have completely different meanings. This quality is known as *polysemy*, and especially afflicts text as data approaches in English. To continue our example, *kind* may also be a noun meaning ‘a group of people or things having similar characteristics’, such as ‘more than one *kind* of text analysis’, or an adverb meaning ‘to some extent’, such as ‘dictionary calibration can get *kind* of tricky’. To illustrate, I used a part-of-speech tagger and some frequency analysis to distinguish the different meanings from the State of the Union corpus of presidential addresses. Of the 318 uses of *kind*, nearly 95% were the noun form while only 4% referred to the adjective denoting positive emotion (three more matches were to the ‘kind of’ usage). It is unlikely that human annotators would confuse the noun form with the adjective indicating a positive emotion, because their qualitative data processing instruments – their human brain, with its higher thoughts structured by language itself – would instantly recognise the difference. Human judgement is also inconsistent, however, and in some rare cases a qualitative annotator could misinterpret the word, might follow their instructions differently or might simply make a mistake. The computer, on the

other hand, while mechanistically matching all occurrences in a text of the term *kind* with the category of positive emotion, will produce 95% false positive matches by including the term's non-emotional noun form homograph, but do so with perfect consistency.

This discussion is not meant to disparage dictionary approaches, as they remain enormously popular and extremely useful, especially for characterising personality traits or analysing political sentiment. They also have the appeal of easy interpretability. While building the tools to efficiently count matches of dictionary values to words in a text might require some deft engineering, the basic idea is no more complicated than a counting exercise. Once counted, the analysis of these counts uses the same simple scales that are applied to content analysis counts, such as the percentage of positive minus negative terms. Conceptually, dictionary matches are essentially the same as human-coded content analysis, but in a cruder, more mechanistic way. Content analysis uses human judgement to apply a set of category labels to units of texts using human judgement after reading the text. Dictionary analysis replaces this with automated pattern matching to count category labels using automatic matching of the values defined as matches for those labels with words or phrases in the text. Both methods result in the construction of a matrix of texts by category counts, and from that point onward, the methods of analysis are identical. The target of concern of both approaches, as well as of the purely quantitative approaches discussed below, may be topics, positions, intentions or affective orientations, or even simple events, depending on the coding or dictionary scheme applied and the methods by which the quantitative matrix is scaled.

Dictionary methods are listed as 'hybrid' approaches because while they involve machines to match the dictionary patterns to the texts, constructing the set of matches in the dictionary is entirely a matter for human judgement. At some point, some human analyst made the judgement call to put *kind* as a

match for 'positive emotion' rather than (for instance) *kind*\*, but decided not to include (or simply overlooked) *altruistic* and *magnanimous*. Depending on the educational level of the texts to which this dictionary is applied, it will fail, to various degrees, to detect these more complicated, excluded synonyms. Many dictionaries exist that have been used successfully in many highly cited publications, but this is no guarantee that they will work for any untested application. In their attempt to use the venerable Harvard Psychosociological Dictionary to detect negative sentiment in the annual reports of public corporations, Loughran and McDonald (2011) for instance found that almost three-fourths of their matches to the unadjusted Harvard dictionary category of 2,010 negative words were typically not negative in a financial context: words such as *tax*, *cost*, *liability* and *vice*. Only through a careful, qualitative process of inspection of the word matches in context were they able to make significant changes to the dictionary in a way that fit their application, before trusting the validity of results after turning the machine loose to apply their dictionary to a corpus of 50,000 corporate reports.

### ***Purely Quantitative: Statistical Summaries***

Statistical summary methods are essentially quantitative summaries of texts to describe their characteristics on some indicator, and may use statistical methods based on sampling theory for comparison. The simplest identify the most frequently occurring words, and summarise these as frequency distributions. More sophisticated methods compare the differential occurrences of words across texts or partitions of a corpus, using statistical association measures, to identify the words that belong primarily to sub-groups such as the words associated with male- versus female-authored documents, or Democratic versus Republican speeches.

Measures of similarity and distance are also common in characterising the relationships between documents or terms. By treating each document as a vector of term occurrences – or, conversely, each feature as a vector of document occurrences – similarity and distance measures allow two documents (or features) to be compared using bivariate measures such as the widely used cosine similarity measure or Pearson’s correlation coefficient, or one of the many other distance measures such as the Euclidean or Jaccard distance. Such metrics form the backbone of the field of information retrieval but also allow comparisons between documents (and authors) that might have a more substantive political measure, such as ideological proximity. When generalised by comparing ‘local alignments’ of word sequences, similarity measures also form the basis of *text reuse* methods, which have been used to study the origins of legislation by Wilkerson et al. (2015) and the influence of interest groups by Hertel-Fernandez and Kashin (2015). Other quantitative summary measures are designed to characterise specific qualities of texts such as their *readability* – of which the Flesch (1948) reading ease measure is probably the best known – or *lexical diversity*, designed to measure vocabulary diversity across a text. While such indexes are not traditionally associated with stochastic distributions, it is possible to compute confidence intervals for these based on bootstrapping (Benoit et al., 2019) or averaging measures computed across moving windows of fixed text lengths (Covington and McFall, 2010), to judge statistically whether an observed difference between texts is significant.

### ***Purely Quantitative: Machine Learning***

#### ***Supervised machine learning***

In the final step along the continuum of automation versus human judgement, we have machine learning methods that require no

human analytical component, and are performed entirely by machine. Of course, human judgement is still required to select the texts for input or for training the machine, but this involves little more than a choice of which texts to input into the automated process. In purely quantitative approaches to text as data, there are choices about the selection and processing of inputs to be made, but not in the design of the instrument for processing or analysing the data in the way that dictionary approaches involve.

In purely quantitative approaches, it may not only be unnecessary to read the texts being analysed, but also be unnecessary for it to be *possible* to read them. Provided we have the means to segment the texts (usually, into words), then unsupervised approaches to scaling positions, identifying topics or clustering texts can happen without any knowledge of the language itself. Even supervised methods do not require the training texts to be read (although it is reassuring and preferable!), provided that we are confident that the texts chosen are good representatives of the extremes of the positions we would like to scale. For unsupervised scaling methods, no reading knowledge is required, *if we are confident that the texts are primarily about differences over well-defined issues*. For topic modelling, not even that is required. Of course, validation is crucial if we are to trust the results of automated methods, and this almost always involves human judgement and interpretation. Having skipped human judgement as part of the analytical process, in other words, we bring back our judgement at the conclusion of the process in order to make sense of the results. If our better judgement indicates that something is askance, we may choose to adjust the machine or its inputs and repeat the process until we get improved results. This cycle is often repeated several times, perhaps with different model parameters, for such tasks as classification, topic models (especially for choosing number of topics), document selection for unsupervised scaling or more fine-grained adjustment

such as feature selection. The choice of machine and its settings are important, but the ability to make sense of the words has become unimportant. This approach works with any language, because in stark contrast to the literary methods in which the meaning of words is the target of concern, 'it treats words simply as data rather than requiring any knowledge of their meaning as used in the text' (Laver et al., 2003: 312). In fully automated and quantitative approaches, the words are merely signals to help us interpret the political phenomena that gave rise to them, much as astronomers interpret minute variations in light wavelengths to measure the fundamental targets of concern that influence them, such as planetary sizes and orbits.

*Supervised machine learning* is based on the idea that a procedure will 'learn' from texts about which the analyst declares some external knowledge, and the results of this learning are then mapped onto texts for which the analyst lacks this knowledge. The objective is inference or prediction about the unknown texts, in the same domain as the input knowledge. Classifiers based on supervised examples start with a *training set* of texts with some known label, such as *positive* or *negative*, and learn from the patterns of word (feature) frequencies in the texts to associate orientations of each word. These orientations are used for projections onto a *test set* of documents whose label is unknown, based on some aggregation of the learned word feature orientations given the observed frequencies of the words in the unknown documents. While they perform this learning and prediction in different ways, this basic process is common to classifiers such as Naive Bayes (Pang et al., 2002), SVMs (Joachims, 1999), random forests (Fang and Zhan, 2015), neural networks (Lai et al., 2015) and regression-based models (e.g. Taddy, 2013).

When applied to estimating quantities on a continuously output scale rather than class prediction, supervised machine learning techniques may be adapted for *scaling* a dimension that is 'known' by virtue of the

training examples used to fit the model. This is the approach of the *Wordscores* model (Laver et al., 2003) that has been widely used in political science to scale ideology, as well as its more modern descendant, *class affinity* scaling (Perry and Benoit, 2018). Both methods learn word associations with two contrasting 'reference' classes and then combine these with word frequencies in texts whose positions are unknown, in order to estimate their positions with respect to the reference classes.

Supervised *scaling* differs from supervised *classification* in that scaling aims to estimate a position on a latent dimension, while classification aims to estimate a text's membership in a latent class. The two tasks differ in how greedily they demand input data in the form of more features and additional documents. Typically, classification tasks can be improved by adding more training data, and some methods, such as convolutional neural networks (Lai et al., 2015), require very large training sets. To minimise classification error, we may not care what features are used; as long as the model is not overfit, the primary goal is simply to correctly predict a class *label*. Scaling, on the other hand, is designed to isolate a specific dimension on which texts are to be compared and provide a point estimate of this quantity, on some continuous scale. Validating this quantity is much harder than in class prediction, and typically involves comparison to external measures to establish its validity.

Unlike classification tasks where accuracy is the core objective, supervised scaling approaches have been shown capable of producing valid and robust scale estimates even with relatively small training corpora (see Klemmensen et al., 2007; Baek et al., 2011). The key in scaling applications is more the quality of training texts – making sure they contain good textual representations of the opposing poles of a dimensional extreme (Laver et al., 2003: 330) – rather than their quantity. For scaling applications, training texts only need to contain strong examples

of lexical usage that will differentiate the dimensional extremes, such as strong ‘conservative’ language in one set contrasting with strong ‘liberal’ language in another, using the same lexicon that will be used in the out-of-sample (or, in the words of Laver et al. (2003), ‘virgin’) texts. One advantage of not being concerned with classification performance is that scaling is robust to irrelevant text in the virgin documents. Training texts that contain language about two extremes of environmental policy, for instance, are unlikely to contain words about health care. Scaling an unknown text using a model fitted to these environmental texts will therefore scale only the terms related to (and hence only the dimension of) environmental policy, even if the document being scaled contained out-of-domain text related to health care. For unsupervised methods, by contrast, irrelevant text will seriously affect unsupervised scaling approaches.

Most political scientists are interested more in measurement and scaling than in classification, which is typically of only instrumental value in estimating or augmenting a dataset for additional testing. In their study of echo chambers on the Twitter social media platform, for instance, Colleoni et al. (2014) used supervised learning trained on Tweets from around 10,000 users known to be Republican or Democrat, to predict the party affiliation of an additional 20 million users. They used the supervised classifier to augment their dataset of social media with a label of party affiliation, which is not part of the social media data but which was nonetheless central to their ability to measure partisan homophily in communication networks. Classification in social science is generally more useful in augmenting data rather than representing an interesting finding in its own right. While classifying a legislator’s party affiliation might be an interesting engineering challenge for a computer scientist, this typically yields no new insight for a political scientist, as this information is already known (which does not mean that it has not

been done, however: see Yu et al., 2008). Estimating the sincere political preference of a legislator whose vote is uninformative because of party discipline, by comparison, is typically of great interest in political science.

### *Unsupervised machine learning*

Unsupervised learning approaches are similar to supervised methods, with one key difference: there is no separate learning step associated with inputs in the form of known classes or policy extremes (if scaling). Instead, differences in textual features are used to infer characteristics of the texts, and these characteristics are interpreted in substantive terms based on their content or based on their correlation with external knowledge. A grouping might be labelled based on its association with different political party affiliations of the input documents, for instance, even though the party affiliations did not form part of the learning input. Examples of unsupervised methods associated with text are clustering applications, such as *k*-means clustering (see Grimmer and Stewart, 2013: §6.1), designed to produce a clusters of documents into *k* groups in a way that maximises the differences between groups and minimises the differences within them. These groups are not labelled, and so must be interpreted *ex post* based on a reading of their content or the association of the documents with some known external categories. Because this is primarily a utility device for learning groups, it has few applications in political science outside of a data augmentation tool, although it has been used as a topic discovery tool in some applications, such as in the case of Sanders et al. (2017), who used clustering as one method to identify economic policy topics from UK select committee oversight hearings.

An unsupervised learning method that has received wide application is the Latent Dirichlet allocation (LDA) *topic model* (Blei et al., 2003). Topic models provide a relatively simple, parametric model

describing the relationship between clusters of co-occurring words representing ‘topics’ and their relationship to documents which contain them in relative proportions. By estimating the parameters of this model, it is possible to recover these topics (and the words that they comprise) and to estimate the degree to which documents pertain to each topic. The estimated topics are unlabelled, so a human must assign these labels by interpreting the content of the words most highly associated with each topic, perhaps assisted by contextual information. No human input is required to fit the topics besides a document–feature matrix, with one critical exception: the number of topics must be decided in advance. In fitting and interpreting topic models, therefore, a core concern is choosing the ‘correct’ number of topics. There are statistical measures (such as *perplexity*, a measure based on comparing model likelihoods, or *topic coherence*, based on maximising the typical pairwise similarity of terms in a topic) but a better measure is often the interpretability of the topics. In practice the precise choice of topics contains a degree of arbitrariness, and often, to recover interpretable topics, some extra ones are also generated that are not readily interpretable.<sup>5</sup>

Political scientists have made widespread use of topic models and their variants, including some novel methodological innovations driven by the specific demands of political research problems. Quinn et al. (2010) shifts the *mixed membership* model of topics within documents to a time unit (days in the US Senate) and estimates the membership of texts with each time unit (speeches made on that day) as representing a single topic. Combined with some prior information, this model can produce estimates of the daily attention to distinct political topics, to track what the Senate is talking about over a long time series. Another variation is Grimmer’s (2010) *expressed agenda model*, which measures the attention paid to specific issues in senators’ press releases, based on the idea that each senator represents a mixture of

topics and will express these through individual press releases. Another innovation of which political scientists should be proud is the *structural topic model* (Roberts et al., 2014), which introduces the ability to add covariates in the form of categorical explanatory variables to explain topic prevalence. In their paper introducing this method, Roberts et al. (2014) apply it to open-ended survey responses on immigration questions to show differences in the estimated proportions of topics pertaining to fear of immigration, given the treatment effect of a survey experiment and conditioning variables related to whether a respondent identified with the Democratic or Republican party. In each of these innovations, political scientists have adapted a text mining method to specific uses enabling inference about differences between time periods, individuals or treatments, turning topics models from an exploratory tool into a method for testing systematic propositions that might relate to fundamental political characteristics of interest.

Another unsupervised method that is not only widely applied but also developed by political scientists is the unsupervised *Wordfish* scaling model (Slapin and Proksch, 2008). This model assumes that observed counts in a document–feature matrix are generated by a Poisson model combining a word effect with a parameter representing a position on a latent dimension, conditioned by both document and feature fixed effects. It produces estimates of a document’s latent position, which can be interpreted as left–right ideology (Slapin and Proksch, 2008), preference over environmental policy (Klüver, 2009) support or opposition to austerity in budgeting (Lowe and Benoit, 2013) or preferences for the level of European integration (Proksch and Slapin, 2010). One limitation of this model, however, is that it permits estimation on only a single dimension (although other dimensional estimates using similar methods are possible, as Monroe and Maeda (2004) and Däubler and Benoit (2018) have demonstrated). In a

detailed comparison of scaling model estimates to ratings of the same texts by human coders, Lowe and Benoit (2013) showed that an anti-system party appeared wrongly (according to the human raters) in the middle of the scale of support or opposition to the budget, because of its differences on a dimension of politics not captured in a single government–opposition divide. Because they are anchored according to extremes identified by the user, supervised scaling methods such as Wordscores can extract different positional estimates from the same texts (provided the training inputs for these texts were different). Unsupervised scaling, however, will always produce only one set of estimates for the same texts. When an analyst wants to estimate multiple dimensions, the only recourse is to input different texts. When Slapin and Proksch (2008) used the method to scale policy positions from German party manifestos on three separate dimensions of economic, social and foreign policy, they first had to segment each manifesto into new documents containing only text relating to these themes (which required reading the texts, in German, and then manually splitting them). To control the outputs from unsupervised methods, one must control the inputs.

Poisson scaling (e.g. the Wordfish method) is very similar to older methods to project document positions onto a low-dimensional space, after singular value decomposition (and some additional transformation) of the high-dimensional document–feature matrix. Such older methods include *correspondence analysis* (CA: Greenacre, 2017) and *latent semantic analysis* (LSA: Landauer et al., 1998), both forms of metric scaling that can be used to represent documents in multiple dimensions (although LSA is more commonly used as a tool in information retrieval). These lack some advantages of parametric approaches, such as the ability to estimate uncertainty using outputs from the estimation of statistical parameters, but have nonetheless seen some application in political science because of their ease of computation

and ability to scale multiple dimensions (e.g. Schonhardt-Bailey, 2008).

Because unsupervised scaling methods take a matrix as input, and this matrix might just as easily have been transposed (swapping documents for features), these methods also permit the measurement and scaling of word features as well as documents. The metric scaling from CA, for instance, allows words' locations to be identified in the same dimensional spaces as documents (see Schonhardt-Bailey, 2008, for instance). Wordfish scaling also allows us to estimate the policy weight and direction, similar to a discrimination parameter from an item-response theory model, for each feature. When features are policy categories, this can provide information of substantive interest in its own right, such as how different policies form the left–right 'super-dimension' and how these might differ across different political contexts (Däubler and Benoit, 2018).

### ***Distributional Semantic Models and 'Word Embeddings'***

A final exciting area deserving mention are text as data approaches based on matrices of observed words but weighted by their 'word vectors', estimated from fitting a *distributional semantic model* (DSM) to a large corpus of text, often a corpus separate to the text to be analysed as data in a given application. The notion of distributional semantics was famously articulated by the linguist John Firth, who stated that 'You shall know a word by the company it keeps' (Firth, 1957: 11). Using a 'continuous bag-of-words model' to estimate word co-occurrences within a specified context (for instance, a window of five words before and after), models can be fit to estimate a vector of real-valued scores for each word representing their locations in a multi-dimensional semantic space. Known collectively as *word embedding* models, such methods provide a way to connect words according to their usages in a way that offers

potentially vast improvements on the context-blind ‘bag-of-words’ approach.

Relatively new methods for fitting DSMs include the ‘word2vec’ model (Mikolov et al., 2013), which uses a ‘skip-gram’ neural network model to estimate the probability that a word is ‘close’ to another given word; the ‘GloVe’ (‘gloval vectors of words’: Pennington et al., 2014) model, which predicts surrounding words using a form of dynamic logistic regression; and the ELMo model (‘Embeddings from Language Models’: Peters et al., 2018). All of these methods are widely available in open-source software implementations.

Word embedding models are usually not thought of as methods on their own for analysing text as data, but rather as extremely useful complements to representations of text as data based on word counts. They have been shown to greatly improve performance for applications such as text classification, sentiment analysis, clustering or comparing documents based on their similarities or document summarization. Estimated from a user’s own corpus, furthermore, word embeddings allow the direct exploration of semantic relations in their own verbal context, to determine the associations of terms far more closely related to their meanings than possible using only simple clustering or similarity measures from bag-of-words count vectors.

For users that cannot fit local embedding models to a corpus, pre-trained word vectors are available that have been estimated from large corpora, such as that trained on six billion tokens from Wikipedia and the ‘Gigaword’ corpus (Pennington et al., 2014). This allows a user analysing text to represent his or her texts not just from the corpus at hand, but also augmented with quantitative measures of the words’ semantic representations fitted from other contexts. This provides an interesting twist on the discourse analytic notion of *intertextuality* (e.g. Fairclough, 1992), a process in which the meaning of one text shapes the meaning of another. Incorporating semantic representations fitted from large corpora into the analysis of text is

a literal recipe for reinforcing the pre-dominant social relations of power as expressed in language, a problem that has not gone unnoticed. Bolukbasi et al. (2016) and Caliskan, Bryson and Narayanan (2017) show that word embeddings encode societal stereotypes about gender roles and occupations, for instance that engineers tend to be men and that nurses are typically women. Data and quantification do not make our textual analyses neutral, and we should be especially aware of this when incorporating semantic context into text as data approaches.

## THE STAGES OF ANALYSING TEXT AS DATA

We have described the essence of the approach of treating text as data as involving the extraction and analysis of features from text to be treated as data, either about the manifest characteristics of the text itself or latent characteristics for which the text provides observable implications. In this section I describe this process in more detail, outlining the steps involved (Table 26.2) and the key choices and issues faced in each stage.

### *Selecting Texts: Defining the Corpus*

A ‘corpus’ is the term used in text analysis to refer to the set of documents to be analysed, and that have been selected for a specific

**Table 26.2** Stages in analyzing text as data

1. Selecting texts and defining the corpus.
2. Converting the texts into a common electronic format.
3. Defining documents and choosing the unit of analysis.
4. Defining and refining features.
5. Converting textual features into a quantitative matrix.
6. Analyzing the (matrix) data using an appropriate statistical procedure.
7. Interpreting and reporting the results.

purpose. Just as with any other research design, research built on textual data begins with the analyst identifying the corpus of texts relevant to the research question of interest and gathering these texts into a collection for analysis. Texts are generally distinguished from one another by attributes relating to the author or speaker of the text, perhaps also separated by time, topic or act. A year of articles about the economy from *The New York Times*, for instance, could form a sample for analysis, where the unit is an article. A set of debates during (one of the many) votes on Brexit in the UK House of Commons could form another corpus, where the unit is a speech act (one intervention by a speaker on the floor of parliament).

German-language party election manifestos from 1949 to 2017 could form a corpus, where a unit is a manifesto. A set of Supreme Court decisions from 2018 could form a corpus, where the unit is one opinion. In each example, distinguishing external attributes, chosen by the researcher for the purpose of analysing a specific research question, are used to define the *document* distinguishing one unit of textual data from another.

In many political science applications using textual data, the ‘sample’ of texts may, in fact, be every known text generated by the political universe for that application. In tracking the words spoken on abortion per day in the US Congress, for instance, a study might examine every spoken utterance in the Senate from 1997 to 2004. Yet even in such situations where a researcher may not face overt decisions to sample texts from a larger population that is too large to cover in its entirety, such as how many newspaper articles to select from which set of days, it is still important to be aware of selection issues that shape what sort of text becomes a recorded feature of the social system. Such ‘social bookkeeping’ has long been noted by historians seeking texts to gain leverage on events long past, but it may also feature in many forms of observed political text, especially spoken text in structured settings such

as legislatures. Historical coalition political manifestos, for instance, are notoriously difficult to obtain because they tend to disappear once a coalition has broken down, creating a potential sample bias slanted toward more stable coalitions. The key is to be aware of the mechanisms governing the generation of text, with the aim of making sure that the observable text provides representative coverage of the phenomenon that it will be used to investigate.

Some sampling choices may be motivated on practical grounds, especially resource limitations. In text as data approaches pre-dating the availability of computerised tools, it was not uncommon to suggest examining 100-word samples from a text for measuring such quantities as the readability of a text (e.g. Gunning, 1952) or taking ‘all the words in 16 two-page groups spread uniformly throughout the book’ for a measure of lexical diversity (Herdan, 1955: 332). In the modern era, by contrast, down-sampling may be required due to access limitations or because of the sheer volume of available data. The Twitter streaming API, for instance, has an overall rate limit of 1% of all Tweets for those without access to Twitter’s exclusive ‘firehose’ of all Tweets. Even researchers who have captured the tens of millions of daily Tweets available within this rate limit may decide to work on a random sub-sample of this dataset, because of the computational and storage costs involved in trying to analyse the larger dataset.

### ***Converting the Texts into a Common Electronic Format***

This step is purely technical, involving no research design decisions, but it can nonetheless pose one of the stickiest problems in text analysis. Strictly speaking, it is not necessary to work with computers to treat texts as data. The old-school methods for computing textual readability – for instance Gunning’s FOG index referenced above, or applying the

complex rules from Spache (1953) to match words in a text to a list of ‘familiar’ terms – could involve working with pen, printed text, an abacus and a lot of coffee (possibly while working by candlelight and wearing a hair-shirt). In almost all contemporary applications, however, texts are sourced and processed using computers. The problem is that there are vast differences in the formats for recording electronic texts, including Adobe’s ‘pdf’ format, which is actually a collection of different variants and versions; markup languages (such as HTML or XML); word processing formats (such as Microsoft Word, which also exists in many different versions); spreadsheet formats (such as Microsoft Excel); key-value schemes (such as JSON); or, if one is really lucky, plain text (.txt) files requiring no special handling. Even plain text files, however, can require a form of conversion, since the machine *encoding* of text has many different forms, especially in the pre-Unicode era from about 1970–2000 when the same set of 8-bit numeric values were mapped to different characters depending on the platform and the national context.<sup>6</sup> Unicode has replaced this, by providing a single, comprehensive mapping of unique code points to every known character in the world’s writing systems, present and past, including emoji and special symbols. Because Unicode is a standard, however, rather than an *encoding*, it still needs to be implemented on machines, and Unicode also covers standards for this encoding, such as UTF-8 (the most common).

Conversion of images into text is another possible headache, especially for older documents that may have been scanned. To convert these ‘image-only’ documents, which may exist in pdf form but not contain actual text, *optical character recognition* may be needed: the conversion of images of characters into electronically encoded text. Depending on the quality of the images, this can require a great deal of manual correction and cleaning. To the human eye, there may be no essential difference between *OCR* and

*OCR*, but to a computer these are completely different words. Other challenges can involve typographic ligatures (such as the ‘fi’ often used in such words as *find*) and other typographic relics such as the medial *s*, printed as *f*, which was disused by around 1800 but widely found in 19th-century printing. Most *OCR*, however, will not recognise that *Congrefs* is the same as *Congress*.<sup>7</sup>

### **Defining Documents and Choosing the Unit of Analysis**

This step is a refinement from the selection of the corpus in that prior to extracting textual features for analysis, the unit of analysis may need further definition, through selection or sampling or through aggregating documents into larger units or splitting them into smaller ones. The attributes that differentiate source texts, in other words, may not form the ideal units for analysing the text as data. (Note that by ‘units’ here we refer to the document units, not textual features, which are covered next.)

For example, while we might have a corpus of social media posts, these might be better aggregated over some time period, such as a day, or by user. This not only ameliorates a possible problem with overly short documents, but also focuses attention on the unit of interest. Whether this is time or a user (or speaker or other unit of authorship) will depend on the research problem. For other problems, segmenting a document into smaller units might be the answer. These could be structural, such as sentences or paragraphs, or some fixed-length chunk of tokens (segmented words). Fixed-length chunks are especially useful for sampling schemes, for instance in measuring textual characteristics using a moving average across a fixed window size of a text (e.g. Covington and McFall, 2010). Some schemes may combine these approaches, such as Labbé et al.’s (2004: 209) analysis of Charles de Gaulle’s broadcast speeches from June 1958 to April

1969: first they combined these into a single ‘document’ where each speech was in the order of broadcast, and then they applied a form of moving average measure of lexical diversity on segments that overlapped the original document boundaries defined by the speech dates.

Identifying units of analysis may also be done qualitatively, based on reading the texts and identifying politically relevant units of text. The best known example in political research is the ‘quasi sentence’ that forms the unit of analysis for the long-running Comparative Manifesto Project. Quasi sentences are textual units that express a policy proposition and may be either a complete natural sentence or part of one. Because some authors may express two distinct policy statements within a single natural sentence, the use of quasi sentences supposedly permits a more valid and complete representation of the content of the textual data. The trade-off, however, is that the same human decision process that interprets the sentence structure to identify text units also causes the procedure to be unreliable and often difficult or impossible to replicate (Däubler et al., 2012). This trade-off between reliability – whether repetition of a procedure produces stable results – and validity – whether the measurement or analysis reflects the truth of what is being measured or represented by the textual data – is a recurrent theme in research involving textual data. This affects not just the identification and preparation of units for analysis but also the design of coding frames and measurement and scaling models for analysing textual data.

The ability to redefine documents in terms of the smaller textual units they contain illustrates a curious feature of textual data: that the units of analysis are defined in terms of collections of the features. If we think of this data in matrix form (such as the intermediate stage of Figure 26.1), then the units of analysis are represented by the rows of documents and the features as columns derived from terms – indeed, this matrix is usually

called a *document–term matrix*. Since a document is just an arbitrary collection of terms, however, it means that the more we segment our document into smaller collections, the more it approaches being the unit of a feature defined by the column dimension of the data. Grouping documents does the opposite. Redefining the boundaries of what constitutes a ‘document’, therefore, involves shifting data from columns into rows or vice versa. This ability to reshape our data matrix because one dimension is defined in terms of a collection of the other is unique to text analysis. We could not perform a similar reshaping operation on, say, a survey dataset where we would not spread an individual’s observed responses across additional rows, because we cannot split an individual as a unit and because that individual is defined in terms of a sampled, physical individual, not as an arbitrary collection of survey questions.

Ultimately, how we reshape our documentary units by grouping or splitting them will depend on our research question and the needs of our method for analysing the data. Knowing how the sampling procedure for the textual data selection relates to the sampling units and the units of analysis may have implications for subsequent inference, given that the units of analysis are not randomly sampled textual data, irrespective of the sampling units. Determining which are most suitable will depend on the nature of the analytical technique and the insight it is designed to yield, and sometimes the length and nature of the texts themselves.

### ***Defining and Refining Features***

Features start with the basic semantic unit of text: the word. There are many forms of ‘words’, however, and these typically undergo a process of selection and transformation before they become features of our textual dataset. Words might also simply form the basis for recording an abstraction

triggered by the word, such as a dictionary key, or even a category assigned by a human annotator (in manual content analysis).

First, we should become familiar with some terms from linguistics. Words as they occur in a text are commonly known as *tokens*, so that the text ‘one two one two’ contains four tokens. *Tokenization* is the process of splitting a text into its constituent tokens, as in the second column of Figure 26.2 (which includes punctuation characters as tokens). Tokenisation usually happens by recognising the delimiters between words, which in most languages takes the form of a space. In more technical language, inter-word delimiters are known as *whitespace*, and include additional machine characters such as newlines, tabs

and space variants.<sup>8</sup> Most languages separate words by whitespace, but some major ones such as Chinese, Japanese and Korean do not. Tokenising these languages requires a set of rules to recognise word boundaries, usually from a listing of common word endings. Smart tokenisers will also separate punctuation characters that occur immediately following a word, such as the comma after *word* in this sentence. To introduce another term, *word types* refer to uniquely occurring words. So in our example, the four-token text contains only two word types, *one* and *two*. Comparing the rates of types and tokens forms the foundation for measures of lexical diversity (the rate of vocabulary usage), with the most common such measure comparing

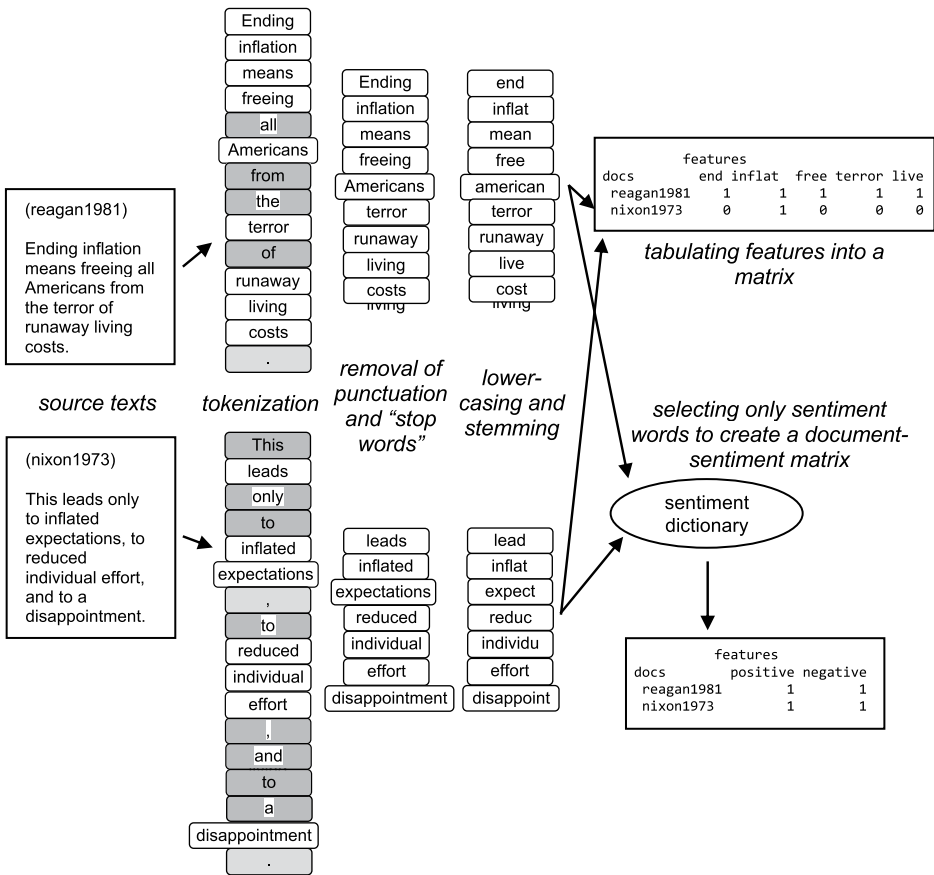

Figure 26.2 From text to tokens to matrix

the number of types to the number of tokens (the ‘type–token ratio’).

For a token to become a *feature* of textual data, it typically undergoes transformation in a step often called ‘pre-processing’ (although it should really be called processing). The most common types of token processing are *lower-casing*, which treats words as equivalent regardless of how they were capitalised; *stemming*, which reduces words to their stems, which is a cruder algorithmic means of equating a word with its *lemma*, or canonical (dictionary) form; and the elimination of words either through the use of pre-defined lists of words to be ignored or based on their relative infrequency. The first form of textual data pre-processing treats words as equivalent when they differ only in their inflected forms, so that, for example, the different words *taxes*, *tax*, *taxation*, *taxing*, *taxed* and *taxable* are all converted to their word stem *tax*. The second common textual pre-processing practice is to remove words that are considered unlikely to contribute useful information for analysis. These words, commonly called *stopwords*, are usually function words such as conjunctions, prepositions and articles that occur in the greatest frequency in natural language texts but add little specific political meaning to the text that would be deemed useful to analyse from textual data. (See Figure 26.2.) The problem with excluding words from a pre-set list, however, is that there exists no universally suitable list of words known to contribute nothing useful to all textual data analyses. For instance, the pronoun *her*, as Monroe et al. (2008) found, has a decidedly partisan orientation in debates on abortion in the US Senate. For these reasons, it has been noted that a general trend in preparing textual data for analysis has been gradually to reduce or eliminate reliance on stopword lists (Manning et al., 2008: 27). Another approach to restricting the focus of textual data analysis from all words to only potentially informative words is to filter words by indices constructed from their relative frequency across as well as

within documents, through a weighting or trimming scheme based on frequencies (discussed below), but this first requires a matrix of all eligible features to be formed.

Other methods of processing tokens include converting text to ‘*n*-grams’, defined as sequences of *n* consecutive tokens to form not words but phrases. This is a brute force method of recovering politically meaningful *multi-word expressions* that might contain identical unigrams but that as phrases mean exact opposites, such as *command economy* versus *market economy*. Also known as *collocations*, such expressions can be detected by statistical methods (e.g. Dunning, 1993). Detecting specific multi-word expressions is generally preferable to simply forming all *n*-grams, since the *n*-gram approach increases the number of features by (nearly) a multiple of *n*, and most of these will occur very rarely or represent frequently occurring but uninteresting combinations such as *let us*.

*Types* represent unique words, but we should remember that this uniqueness is typically based on their forming unique combinations of characters. Especially in English, *homographs* (words that are different but that spelled identically) will appear falsely as the same word type, at least to the machines we are using to process them. We could be more specific in distinguishing these by using a *part-of-speech* (POS) tagger that will at least distinguish homographs that are not the same parts of speech. In the example we cited earlier of the different uses of the term *kind*, for instance, a part-of-speech tagger could have annotated our tokens to distinguish these types (and this is indeed how I computed the proportions of its different forms in that example). Annotating tokens using a POS tagger can help us distinguish terms with opposite meanings such as *sanctions* in the sentence: *the President sanctions the sanctions against Iran*, by treating these as ‘sanctions/VERB’ and ‘sanctions/NOUN’, one meaning permission and the other meaning a penalty. Despite the obvious advantages,

however, differentiating word types using POS taggers in bag-of-words approaches to text as data is done seldomly, if ever.

It is not uncommon to read in a published application based on the analysis of text as data, perhaps in a footnote, that the authors took ‘the standard pre-processing steps’ to prepare their input texts. In truth there is no standard, and without details of the specific steps a researcher took, such summary references as to what invasive procedures were applied to the text are uninformative. Each application will have different needs for feature processing, with different consequences as a result of the choices made at this stage. In one of the few systematic studies of feature processing choices and their consequences, Denny and Spirling (2018: 187) replicated several published text analyses from political science using a variety of alternative feature processing steps. Their results show that ‘under relatively small perturbations of preprocessing decisions ... very different substantive interpretations would emerge’. Researchers in practice should be aware of these decisions, critically examine the assumptions of their methods and how these relate to feature selection and, test the robustness of these results.

### ***Converting Textual Features into a Quantitative Matrix***

This is mainly a mechanical step, resulting in a matrix whose dimensions are determined by the choices relating to the definitions of documents and features. We have already mentioned that some schemes call it a *document–term matrix*. (Some might even call it a *term–document matrix*, but there are great advantages in fixing the ‘documents’ to be row units and saving our efforts to promote diversity for more important problems.) We have been using the term *feature* thus far, but it is worth noting why and how this is different from just speaking about ‘terms’. Computer scientists use *feature* to refer to

what social scientists have long called *variables*: attributes of our units of analysis that differ across units. Because calling them *features* emphasises how they differ from terms or words (and may no longer even be words), I use this term to denote the selections and transformations made from token-based units that become the data used for analysis. I prefer the term *features* since the tokens have invariably been transformed in some way before they are shaped into a matrix, or may be abstractions from tokens such as annotations or dictionary keys rather than even transformed tokens.

Most matrices containing feature frequencies are characterised by a high degree of *sparsity*, meaning that they are mostly zeroes. Document–feature matrices are affected by what is known in machine learning as the *curse of dimensionality*: new observations also tend to grow the feature set, and each new term found in even a single document adds a new column to the matrix. There is even a ‘law’ named for this in linguistics: *Heap’s Law*, which states that the number of types grows exponentially with the number of tokens.<sup>9</sup> Forming a matrix of the (lower-cased) word features from the pre-2020 US presidential inaugural address corpus, for instance, creates a matrix of 58 inaugural speech documents by 9,273 features, but nearly 92 percent of the cells in this matrix of 537,834 cells are zeros. In fact, more than 41% of the features in this matrix are *hapax legomena*, defined as words that occur only a single time, such as the term *aborigines* in Ulysses S. Grant’s (politically incorrect) promise ‘to bring the aborigines of the country under the benign influences of education and civilisation’.

One strategy for mitigating the problem of exponentially increasing dimensionality is to trim or to weight the document–feature matrix. Trimming can be done on various criteria, but usually takes the form of a filter based on some form of feature frequency. Weighting schemes convert a matrix of counts into a matrix of weights. The

most common of these is relative term frequency, a weighting process also known as document *normalisation* because it homogenises the sum of the counts for each document. Since documents in a typical corpus vary in length, this provides a method for comparing frequencies more directly than counts, which are inflated in longer documents (although these frequencies are also subject to length effects related to Heap's law). Other popular weighting schemes are *tf-idf*, or term frequency-inverse document frequency, popular as a method in information retrieval for down-weighting the terms that are common to documents. In addition to the term frequency already discussed, *tf-idf* adds a weight that approaches zero as the number of documents in which a term appears (in any frequency) approaches the number of documents in the collection.<sup>10</sup> When we have selected our texts because they pertain to a specific topic – as we usually will – then inverse document frequency weighting means zeroing out most of our topical words, since these will appear in most or all documents. In texts of debates over health care, for instance, *tf-idf* weighting is likely to eliminate all words related to health care, even when they might occur at very different rates across different documents. If we think that it is not the occurrence, but rather the relative frequencies of words that are informative, then using *tf-idf* weighting is the opposite of what we want. While it will automatically remove 'stop words' without using a list, *tf-idf* weighting will also throw out the substantive baby with the linguistic bathwater. Except for classification tasks where removing all but the most discriminating features can improve performance, *tf-idf* weighting is usually inappropriate for the analysis of political texts.<sup>11</sup>

Because the rows and columns of the document–term matrix are unordered, the features that were originally carefully ordered words, in carefully ordered sentences, are now stored in a matrix object with no representation of order. In natural language

processing, this approach is known as 'bag-of-words', because it has disassociated the words from their context. For this reason, some text as data analyses use a different representation of documents based on token *vectors*, since these preserve order. For token vectors to be used in most analyses, however, such as computing a similarity score between token counts, these need to be aligned into what is effectively a matrix representation. Other forms of analysis, such as forming co-occurrence matrixes, require iterating over the token streams and tabulating counts that are later combined into matrix form.

We have already noted the curious inter-relationship between features, and documents as collections of features. Some matrix representations do away with the notion of documents altogether, forming feature-by-feature matrices counting how features co-occur within a defined context. This context might be the original document, or a moving local window for each target feature, for instance the five tokens found before or after the target feature. (Note here that I am very specifically using *token* to refer to a word when it exists as a segmented textual unit, but *feature* when it has been shaped into a matrix.) Known as a *feature co-occurrence matrix*, this matrix is a special variant of our document–feature matrix, where the documents have been redefined as features themselves, and the counts are tabulated within a context that we define. This is the basis for input into network analysis, for instance the inter-relationships of words based on their co-occurrence.

For simplicity, the focus here is on features based on a bag-of-words approach, but matrix representations can be generalised to include weights based on word embedding vectors, possibly redefining documents as new units such as sentences or paragraphs. We have already mentioned the popularity of vector representations of term features estimated from word embedding models. One option at the stage of creating the document–feature matrix is to combine the counts with weights or scores from these word vectors,

especially for comparing documents (for semantic similarity, for instance) or for text classification using predictive models. Methods exist for combining word vectors with *tf-idf* weights to turn documents into more semantically meaningful matrix representations, extending the notion of the document–feature matrix into a more complex representation than the simpler version depicted in Figure 26.2.

### **Analyzing the Textual Data Using an Appropriate Quantitative or Statistical Procedure**

The key here is *appropriate*: does the procedure for analysing the textual data produce reliable and valid insights into the question motivating the analysis? It is worth keeping in mind that by the time we have reached this stage of the analysis, we have already proceeded on the basis of some strong assumptions, namely:

- 1 The texts accurately represent the underlying target of concern.
- 2 Our sample of texts are a typical or at least complete representation of the phenomena that is our target of concern.
- 3 Our conversion of the texts into data has retained the essential information we need to provide insight on our target of concern.

The first assumption is by no means obvious in politics, where much verbal activity could be dismissed as ‘cheap talk’ or as insincere promises or false or misleading claims,<sup>12</sup> but we have good reason to think that text is more sincere than other forms of behaviour, especially in a legislative setting (Herzog and Benoit, 2015). Our selection from these also needs to be based on sound principles, just as data selection does in any research exercise. The third choice is something we have just discussed but involves many additional and deeper issues. It also interacts with a fourth strong assumption made at the analysis stage:

- 4 The analytic procedure yields a reliable and valid basis for inference on our target of concern.

The main risks with respect to reliability come when human judgement forms part of either the process of extracting data features or performing the analysis. In content analysis, for instance, human coders may be responsible for both defining the units of textual data and for assigning them annotations (‘codes’) based on their reading the textual units and judging the most applicable category from a set of instructions. The former process is known as *unitization* and the second as *coding* (Krippendorff, 2013 – although computer scientists typically call this text *annotation*). Both processes can pose severe challenges for even trained and highly educated human coders to apply at conventionally acceptable rates of reliability and inter-coder agreement (Mikhaylov et al., 2012). With respect to the potential unreliability of the analytic procedure, this is seldom a problem in text as data designs, because even the simplest procedures – such as comparing the relative rates of negative versus positive sentiment – involve quantitative comparisons that would not differ according to the judgement or personality of the analyst.

The validity of the analytic procedure in terms of providing insight on the target of concern is strongly influenced by the choices made at the feature extraction stage. Often, identical choices might be suitable for one analytic purpose but unsuitable for others. Consider the following three sentences, which we might wish to compare using a measure of textual similarity, such as *cosine similarity*, a measure that ranges (for text counts) between 0.0 to indicate the absence of any correlation and 1.0 to indicate two texts with identical feature proportions.

- (a) *Party X embraces protection of citizens through universal health care.*
- (b) *Party Y prioritises economic growth, even at the cost of environmental protection.*
- (c) *Party Y prioritises environmental protection, even at the cost of economic growth.*

The cosine similarity of text (a) with the second text is fairly low (at 0.32), as we might expect given that it concerns a different area of policy (but both are still statements about a party and both use the term *protection*). If we wanted to measure differences in the policy areas receiving *attention*, a measure of similarity based on vectors of word occurrences might suit our purposes well. But if we wished to measure differences in policy *position*, then cosine similarity in this example would be a poor instrument, as it indicates perfect similarity (1.0) between texts (b) and (c), despite these indicating exactly opposite political priorities. We can think of ways to differentiate them that might involve using sentence structure rather than simple bag-of-words approaches, but this only underscores the point that the appropriate choice of analytical procedure is influenced by choices made at the feature extraction stage.

Often there is an iterative process between the feature extraction and analysis stages, in which, following a preliminary analysis, we need to return to the feature extraction and processing stage in order to make adjustments before repeating the analysis. Sometimes, this might result from examining unintended or anomalous results of an analysis and deciding that these would be better avoided through different feature processing choices. Observing clusters of the same root terms with different inflections, for instance, could motivate stemming the tokens and repeating the analysis. Likewise, anyone who has plotted a *word cloud* of unselected features (where these appear in sizes proportional to their relative frequency) will quickly return to more aggressive feature selection when they see the words *the* and *and* dominating the plot. Other feature processing decisions can especially influence unsupervised methods such as topic models, because unsupervised approaches necessarily attempt to learn from all supplied information. Or, observing a set of topics sharing high proportions of stopwords might be cleaned up by removing

stopwords from features prior to fitting the topic model (and removing stopwords almost always improves the interpretability of topics fit using topic models). In their study of the effects of these choices, Denny and Spirling (2018: 187) found that key ‘modelling choices, such as the optimal number of topics, were also startlingly dependent’ on decisions made at the feature processing stage. Other techniques may be more robust to this, especially supervised methods or those that automatically down-weight uninformative features through their conditional probabilities or by applying a regularisation penalty. The best fine-tuning will be a combination of theoretically motivated choices of feature processing, confirmed by careful inspection following the analysis.

Should we be concerned that this cycle might encourage dishonesty, by tweaking our feature extraction until we get the results we want? In short no, although of course we should not contrive results. Residual diagnostics have long been a feature of basic statistical analysis, and often these serve to detect anomalies that indicate errors to be corrected before re-running the results, or fixes to be applied to get our data to conform more closely to the assumptions of our model (such as applying a log transformation to skewed variables or applying weights to heteroskedastic residuals in least-squares regressions). In working with textual data, this process is all the more important. Natural language often shows a slippery resistance to neat transformation into numerical data, because of features such as polysemy or the fact that many words in non-compounding languages lose an important part of their meaning when separated from the multi-word expressions in which they occur. Or it might be a simple matter of spelling or OCR mistakes indicating we have a cluster of words that should be the same but whose characters need correcting because an ‘i’ was rendered as an ‘l’ or a ‘o’ as a ‘0’, or because we did not remove running page footers from texts converted from pdf format. We should never underestimate

just how messy can be the process of converting text, no matter how clearly we can read it, into clean features of textual data. Often, the best – or the first – stage at which this becomes fully apparent is during analysis, and when detected it often means returning to earlier stages, cleaning things up or making better choices and repeating the analysis. This is a far more valid and honest approach than sticking with results that we know are wrong and could have fixed had we only gotten cleaner electronic texts to begin with or been better informed about the full consequences of our feature processing decisions.

Many of the analytic procedures we apply to textual features take the form of advanced statistical models that impose strong assumptions on the data-generating process, such as assuming that conditional word counts are identical and independently distributed as a Poisson (e.g. Slapin and Proksch, 2008), a negative binomial (e.g. Lo et al., 2016) or a multinomial process (e.g. Roberts et al., 2013). We know with certainty that words are not conditionally or positionally independent and that the degree of this will vary from mild to extreme in non-systematic ways, depending on the stylistic choices of a speaker or writer as well as characteristics of the language being used. To apply the tested and well-known properties of statistical data analysis to text, we must impose assumptions about the data-generating and stochastic processes that come with statistical approaches. The problem is, there exists no neat, parsimonious model of the data-generating process for natural language, so we rely on models whose assumptions are violated in sometimes painfully obvious ways. Fitting models that violate statistical assumptions is hardly new in social science, but because we so directly and intimately understand the nature of the source data (natural language) we are likely to be more acutely aware of these problems.

The good news is that even when violating statistical assumptions wholesale, we still get a tremendous amount of useful juice from models that are highly simplistic from a

linguistic point of view. The ‘naive’ in ‘Naive Bayes’, after all, is an overt recognition that its class conditional probabilities are wrong, because the assumption of independence required to compute the joint probabilities from word counts is blatantly fictional. Yet, Naive Bayes remains a highly useful tool for classifying texts (Zhang, 2004). It is hard to summarise this better than have Grimmer and Stewart (2013: 4):

The complexity of language implies that all methods *necessarily* fail to provide an accurate account of the data-generating process used to produce texts. Automated content analysis methods use insightful, but wrong, models of political text to help researchers make inferences from their data ... Including more realistic features into quantitative models does not necessarily translate into an improved method, and reducing the assumptions used may not imply more productive analyses. Rather, subtleties of applying the methods to any one data set mean that models that are less sophisticated in the use of language may provide more useful analysis of texts. (emphasis in original)

Two additional considerations often guide our choice of analytical method for analysing the features of textual data. One is interpretability, something we discuss more in our final stage. A second consideration is computational efficiency. Even with cheap, efficient computing resources, some models can be enormously expensive to fit. The advantages in low computational cost of fitting simpler, efficient models such as linear SVMs or Naive Bayes might well outweigh marginal gains in classifier performance from more advanced, but more computationally expensive models such as recurrent or convolutional neural network models. In addition, simpler methods often prove more robust in the sense of avoiding overfitting, a risk which every computer scientist acknowledges but which few explore in published applications (which typically aim at demonstrate how a new method has outperformed all other methods at some specific task for a specific dataset). As social scientists, we must give far greater priority to robustness and its

transparent demonstration in our choice of method for analysing text as data.

### ***Interpreting and Summarising the Results***

Summarising and communicating findings forms the end stage of any analysis, and the analysis of text as data is no different. Because it involves making sense following abstraction and analysis of raw input data that we could make direct sense of to begin with, however, interpreting the results of textual data analysis can involve some special challenges. Because the analytical stage involved using a trusted methodology, we typically stake our claim of validity of results on the basis that they inherit the trusted procedural properties of the methodology. But because the application of text analysis methods always involves choices at earlier stages, there is an additional measure of trust to establish upon interpreting results, namely that the researcher has appropriately processed the texts and correctly applied the analytic method. This is usually established through additional tests showing the robustness of the conclusions to different choices or demonstrating that the parameters of one's model (such as the number of topics) are optimal. Robustness checks are common in econometric analyses of non-textual data, but only recently have begun to form parts of textual data analyses in the political and social sciences.

Especially when text analysis is exploratory, such as demonstrating a new application or methodology, validation is a crucial part of interpreting one's results. For supervised scaling methods, this is tricky because there is seldom an objective measure with which text-based point estimates can be compared. Instead, we typically rely on comparison to some external measures obtained through alternative, often non-textual means, such as expert survey estimates of policy positions in the case of scaling ideology. Validating

supervised classification methods is easier, because we could have objective labels for verifying predicted classes (such as observed party affiliation), numeric scores (from a survey question) or labels assigned through human annotation.

Interpreting the results of unsupervised methods is trickier, because these results often involve reading into the textual contents of topics or word weights and deciding whether they accord with some reasonable interpretation of the world. Point estimates from unsupervised scaling can be compared to the same sorts of external measures as supervised scaling estimates, or to summaries of detailed human readings of the scaled texts (e.g. Lowe and Benoit, 2013). Topic models are trickier, but typically involve reading the word features that are the most frequent in each topic and assigning a label to that topic. Roberts et al. (2014: 1073) for instance interpreted their 'Topic 1' as 'the "crime" and "welfare" or "fear" topic', because its most frequently used word features included *illeg*, *job*, *immigr*, *welfar* and *crime*. Their second topic, which they interpreted as emphasising 'the human elements of immigrants', also contained among its most frequent word features *immigr*, *illeg*, *border* and *worri*. These distinctions are hardly clear-cut, and any labels attached to topics are ultimately subjective. Model-based diagnostics for setting an optimal number of topics, furthermore, may be unrelated or even negatively correlated with topics' semantic coherence (Chang et al., 2009). The best application of unsupervised methods will produce results that are semantically coherent with our understandings of the texts and with the world that our analysis of them aims to represent.

As analytical tools become increasingly sophisticated, we now have access to powerful methodologies whose procedural workings may be non-transparent. No one has figured out the data-generating process of language, but with modern approaches for classification, this has become unnecessary. Some of the best performing classification

methods for text, for instance, use ‘deep learning’ models fit to the level of characters. When fed with enormous amounts of data, convolutional neural network models can outperform other approaches (Zhang et al., 2015) but it is impossible to assess their operation in any application in the way one would diagnose even an advanced computational method such as fitting a Markov chain Monte Carlo model. Because social science eschews black boxes, we often stick to interpretable models even when better-performing alternatives exist, especially if we have large quantities of data. If a huge amount of training data are available, ‘then the choice of classifier probably has little effect on your results’ (Manning et al., 2008: 337), and we should be guided by the principle of parsimony to prefer more transparent and simpler models over more opaque and complex ones, even at the cost of small trade-offs in performance. Just as our concern in social science is explanation rather than prediction, we generally prefer model specification based on theory and isolating the effect specific explanatory factors, not attempting to include every possible variable to maximise variance explained. Because the goals of explanation or measurement differ from the (typical machine learning) objective of prediction, it is worth reminding ourselves of this preference.

Communicating the results of text analysis in a compact and effective way is practically challenging because numerical tables only poorly capture the full nuances of language, and we typically have too many features and documents (or topics) to fit these easily into a format that will not overwhelm a reader. Graphical presentation of text analytic results is especially important, and should offer special opportunities given that we can read and interpret word features when they form the elements of a plot. Despite this potential, however, innovation in visual presentation of text analytic results has been slow to non-existent, moving little beyond the ‘word cloud’ and its variations. Designed to show the most frequent terms, the word cloud plots

features in sizes proportional to their relative frequency in the textual dataset, producing a plot with some visual appeal but often no clear communication of any particular result. This is slightly improved by using a ‘comparison’ word cloud that partitions word plots according to external categories, such as the Twitter hashtags used in Figure 26.3 according to whether the user was predicted to support Brexit or not (Amador Diaz Lopez et al., 2017). Other methods exist, of course, especially for characterizing the semantic content of topics from topic models, probably the area in which the most innovations of visual presentation in text analysis have occurred (e.g. figure 5 from Reich et al., 2015). Given the unique interpretability of word features, however, it is justified to feel that we should have developed more imaginative graphical ways to include words in our plots (and not just on the axis labels).

A final word on presentation and interpretation concerns how we characterize the *uncertainty* of our text analysis results. In addition to inheriting procedural validity established by decades of statistical theory, the quantitative analysis of text as data also makes it possible to quantify the uncertainty of our results. In the analysis of text as data, this can take two forms: parametric and non-parametric. Parametric methods rely on the assumptions we have imposed on the data through some model of its stochastic process, in the context of an established procedure for producing estimates – such as maximum likelihood or simulations from Bayesian posterior distributions. These are typically too small because of unmodeled heterogeneity in our model of text data, but even this bias can be quantified. Another approach is non-parametric, through bootstrapping a text by resampling from its elements. In exploring different methods of characterising uncertainty for measurement models of text, Lowe and Benoit (2013) advocate repeating the analysis with different versions of a text that have been reassembled after resampling their sentences

**Figure 26.3** Word cloud of influential hashtags from a sample of Tweets about Brexit

Source: Amador Diaz Lopez et al. (2017).

with replacement – bootstrapping documents from their sentences, in other words. This method has begun to appear in different applications, such as Benoit et al.’s (2019) use of it to compute confidence intervals for document-level readability statistics, but it has been slow to catch on despite its almost universal applicability to text as data analyses. Measuring uncertainty in the analysis of text as data remains one of the most important challenges in this field (Grimmer and Stewart, 2013: 28), and should be a requirement if we are to give the quantitative analysis of text full methodological status alongside that of non-textual data.

## CONCLUSION AND FUTURE DIRECTIONS

Treating text as data means converting it into features of data and analysing or mining

these features for patterns, rather than making sense of a text directly. This process turns text from something directly meaningful into data that we cannot interpret in its raw form, but whose analysis produces meaningful insights using structured rules in ways and at magnitudes that would be impossible without having treated the text as data. This approach to text analysis has become increasingly mainstream in the political and social science, and the methods and applications increasingly innovative. This trend, which is likely to continue, has been driven by several forces.

First, as in so many other areas of human activity, in textual analysis the rise of the machines has enabled scholars to automate key parts of the analytic process, a process formerly performed using qualitative methods by unreliable humans who actually knew what they were doing. With text analytic methods, humans can now mine large quantities of textual data, using sophisticated

methods, implemented by perfectly reliable computer automatons.

A second force driving the textual revolution has been one of scale: the incredible volume of texts available today requires automated, quantitative approaches if we are to analyse more than a small subset of this data. The growth of electronic publications has made machine-readable text ubiquitous, and along with it comes the promise of a huge wealth of information about the characteristics of the political and social actors that generate these texts. Such texts include legislative speeches, political party manifestos, legal decisions, election campaign materials, press releases, social media posts, correspondence and television and radio transcripts, to name but the key ones. Resource limitations may still cause us to sample from available texts, but this involves much larger samples than in previous eras. Miners want to extract all, not just a sample, of the rich resources available, and the logic of text mining points to the same conclusion. Methods that require reading a text, or determining what it 'means', are simply not applicable to a scale of tens or hundreds of thousands or more texts. Instead, we need tools that can turn unstructured text into structured information, using inexpensive and efficient methods for parsing, annotating and categorising the elements of text to prepare it for analysis and then to perform this analysis.

Of course, access to big textual data and the machines to process it are only as useful as the methodologies that the machines can implement. A final enabler (and driver) of the shift to treating text as data has been the development and application of sophisticated statistical learning methods for extracting information and generating inferences from textual data. These are extensions of statistics and machine learning but with specific applications to textual data.

Many challenges lie ahead, and these should be met in the same way as most other breakthroughs in social science methodology: through innovations required to solve specific

research problems as part of our agenda to understand the political and social world. Some challenges have already been identified, such as a need for improved validation of our models of textual data under a broader range of circumstances, and a more realistic way to characterise uncertainty in textual data analysis. Some are just emerging, such as how to incorporate named entity recognition and part-of-speech tagging to distinguish alternative meanings, or how to identify and make use of multi-word, non-compositional phrases (how to distinguish, in other words, *Homeland Security* from *social security*). Other recent innovations include the merger of human qualitative input for processing textual data with statistical scaling or machine learning for analysis, possibly using crowd-sourcing for text annotation through an agile, 'active learning' process. As advances continue in other fields such as machine learning and natural language processing in computer science, we must keep a firm grip on political science research objectives and standards while at the same time borrowing what is useful to our discipline. As we gain experience and understanding through both theory and applications, textual data analysis will continue to mature and continue to produce valuable insights for our understanding of politics.

## ACKNOWLEDGEMENTS

I am deeply grateful for the patience shown by the editors of this *Handbook* and for their invaluable feedback on earlier versions. For feedback and comments I also thank Audrey Alejandro, Elliott Ash, April Biccum, Dan Hopkins, Cheryl Schonhardt-Bailey, Michael Laver, Stephan Ludwig, Ludovic Rheault, Arthur Spirling and John Wilkerson. The code required to produce all of the analysis in this chapter can be viewed at <https://gist.github.com/kbenoit/4593ca1deeb4d890077f3b12ba468888>.

## Notes

- 1 From Ronald Reagan's 1981 inaugural address: see <https://www.presidency.ucsb.edu/documents/presidential-documents-archive-guidebook/inaugural-addresses>.
- 2 Exactly such an analysis has been applied by Nick Beauchamp to the 'I Have a Dream' speech. Beauchamp's 'Plot Mapper' algorithm segments the text into sequential chunks, creates a chunk-term count matrix, computes the principal components of this matrix, standardises the resulting scores and plots the first two dimensions to show the rhetorical arc of a speech. See <http://www.nickbeauchamp.com/projects/plotmapper.php>.
- 3 For another cringeworthy example of procedural barbarity committed against a great political text, see Peter Norvig's 'The Gettysburg Powerpoint Presentation', <https://norvig.com/Gettysburg/>.
- 4 This example is taken from a very widely used psychological dictionary known as the Linguistic Inquiry and Word Count (2015 version): Tausczik and Pennebaker (2010).
- 5 For a deeper general discussion of these issues, see Steyvers and Griffiths (2007).
- 6 The history of encoding is a long and complicated saga that most practitioners of text analysis would happily ignore. It has to do with how the original 7-bit (containing 128 characters, or  $2^7$ ) 'ASCII' character set needed adaptation to new languages and symbols by adding an eighth bit. There was very little standardisation in how the resulting additional 128 characters were mapped, so that text sent in, for example, encoded in Windows-1250 (for Central and East European languages) would look garbled on a system using the similar, but not identical ISO-8859-2 for words like źródło.
- 7 This also explains the apparently widespread usage in the 1700s of the 'f-word': not even Google Books has been able to distinguish it from the work *suck*. See [https://books.google.com/ngrams/graph?content=fuck&year\\_start=1700&year\\_end=2000](https://books.google.com/ngrams/graph?content=fuck&year_start=1700&year_end=2000)
- 8 Not Klingons, but rather the variations on the simple space character included in the Unicode 'Separator, Space' category, such as U+205F, the 'Medium Mathematical Space'.
- 9 Technically speaking, Zipf's Law states that  $M = kT^b$ , where  $M$  is the vocabulary size (the number of unique word types),  $T$  is the number of tokens, and  $k$  and  $b$  are constants for computational linguists to estimate and argue about (but that are usually  $30 \leq k \leq 100$  and  $b \approx 0.5$   $30 \leq k \leq 100$ ). Manning et al., 2008: 88).
- 10 Perhaps surprisingly, there is no universal definition of *tf-idf* weighting, and formulas may differ

depending on whether the *tf* is a count or a proportion, what sort of constant may be added, or what logarithmic base and constant are applied to the inverse document frequency. A good measure, however, is  $tf_{ij} * \log_{10} \frac{N}{df_j}$ , where  $tf_{ij}$  is the count of feature  $j$  in document  $i$ ,  $N$  is the number of documents in a collection, and  $df_j$  is the number of documents in which feature  $j$  occurs (Manning et al., 2008: 118). A feature occurring in all  $N$  documents thus receives a weight of zero since  $\log(1) = 0$ .

- 11 We could also add that many models commonly used in political science – such as the 'Wordfish' Poisson scaling model or variants of Latent Dirichlet allocation (topic) models – only work with counts as inputs, so that *tf-idf* or other weighting schemes are inapplicable.
- 12 See Kessler, Rizzo and Kelly (2019), 'President Trump made 8,158 false or misleading claims in his first two years', *Washington Post*, 21 January. <https://www.washingtonpost.com/politics/2019/01/21/president-trump-made-false-or-misleading-claims-his-first-two-years>

# Scaling Political Positions from Text: Assumptions, Methods and Pitfalls

Benjamin C.K. Egerod and Robert Klemmensen<sup>1</sup>

## WHY DO WE WANT TO SCALE TEXTS?

Virtually all instances of political conflict can be thought of in spatial terms. In everyday language as well in academic discourse we use metaphors relating to space when describing politics. Indeed, it is difficult to even talk about politics without ‘using the notions of position, distance, and movement’ (Benoit and Laver, 2006: 12). In politics, the left–right distinction – by definition a spatial notion – may be the most enduring organizing principle (Bobbio, 1996), and the underlying conceptualization of political preferences distributed along different latent dimensions is closely linked to the spatial models of politics often associated with Downs (1957), Smithies (1941) and Hotelling (1990). While the prevalence of the left–right distinction has made it natural to focus on political ideology, most instances concerning differences between preferences can be thought of in spatial terms. For instance, interest group scholars often conceptualize

the degree to which special interests attain their preferences in terms of how policy proposals move relative to the stated positions of groups (Dür, 2008; Bernhagen et al., 2014; Klüver, 2009). Indeed, there is good reason to believe that spatial models are not just good ways of representing multidimensional data, but good approximations of how humans think about preferences (Armstrong et al., 2014). Therefore, considerable amounts of energy have been devoted to developing methods which can reliably and validly place actors in political spaces. Scaling methods are devoted to precisely that, and have a long history of successfully placing legislators, political parties and judges in ideological spaces (e.g. Martin and Quinn, 2002; Poole and Rosenthal, 1985, 2000). More recently, the surge in computational power and availability of new forms of data has provided the possibility of scaling political preferences of extremely diverse sets of actors (Bonica, 2013, 2014; Barberá, 2015; Bond and Messing, 2015; Crosson et al., 2018).

It is in this landscape that the scaling of political positions from text fits. The techniques that are used to scale texts are in large part parallel to the ones used for estimating positions from other data sources, and the use of text scaling has evolved in a similar fashion. While scaling positions from hand-coded databases has a long and successful history (Klingemann et al., 2006), we have seen a surge in the application of computationally intensive methods for scaling texts without first manually coding them. This is due both to the explosion of texts available, and to an increase in the techniques and the computational power that allows us to use them (Martin and Yurukoglu, 2017; Monroe and Maeda, 2004; Lo et al., 2016; Slapin and Proksch, 2008; Laver et al., 2003). Computational text scaling offers an extremely wide range of potential applications, and while its use is constantly growing and new estimators are continuously invented and applied to innovative data sources, there is no doubt that the field will continue its development for many years to come.

This chapter is dedicated to introducing computational techniques for scaling policy positions from political texts. Because text scaling is similar in theory to other forms of scaling, but also presents its own challenges, we introduce the reader not only to how common models can be applied, but also to the particular assumptions they make – and how they can be broken.

We start by discussing how text scaling relates to the broader field of measurement theory as it has evolved in political science, and the core assumptions that are needed to scale a set of texts. This structures our review of specific methods for text scaling. We discuss how techniques vary in their assumptions, and illustrate their use with a diverse set of political texts. We discuss the work done by Laver et al. (2003), which introduced the use of automatic scaling of text to political science. We proceed to review the Poisson scaling model (Monroe and Maeda, 2004; Slapin and Proksch, 2008), which

scales policy position with practically no input from the researcher. The techniques we discuss in this chapter represent but a small subset of the universe of potential scaling techniques. Therefore, we also discuss how each estimator has been extended. While it is impossible to cover all possible estimators in a single chapter, we hope that this chapter can serve as a starting point for the reader. Finally, to illustrate some of the potential pitfalls when scaling texts, we include two simulation studies investigating (a) how short texts can be, and (b) how differently they can use their words before common methods are no longer able to meaningfully place them in space. The final section concludes with a discussion of how our existing toolbox can be extended by incorporating new methods for taking word context into account, and how we can think about measurement error more productively than by simply discarding models.

## **TEXT SCALING AS INFERENCE ABOUT LATENT POSITIONS**

The goal of methods for scaling positions is to use some observed set of outcomes to draw inferences about an actor's (in the widest sense of the word) unobservable position on a latent dimension relative to other actors. Position is here to be understood as the political preference on some dimension. To get at such a position, the observed outcomes must reveal some kind of preference on the part of the actor. While this holds regardless of the nature of the observed data and the context in which it was produced, different types of data obviously require varying models of the data generating process. Without a good theoretical model of how the observed outcome can discriminate between different latent positions, it simply becomes unclear what exactly it is that is being scaled. The spatial model of politics is probably the model most widely used to

relate behaviors – including textual behaviors – to positions. While it obviously is not the only possible model of any single data generating process, it is highly appealing because it is well tested through years of refinement. In scaling techniques that rely on variations of the spatial model, actors are assumed to choose the outcomes that are most closely aligned with their ideal point (their political preference).<sup>2</sup> For example, donors contribute to campaigns of candidates, legislators cast their vote for policies and Facebook users follow political pages – and all choose the ones that are most closely aligned with their preferences. Actors receive monotonically decreasing utility from choosing outcomes (candidates, policies, Facebook follows) as they increase in distance from their ideal point. The process of choosing a candidate, a roll call vote or a page follow, however, is inherently random in nature, which is typically modeled with some distributional assumption (for a more thorough review, see Armstrong et al., 2014).

When scaling the political positions of a corpus of texts, similar assumptions are needed, and the spatial model generalizes well to this setting. Here, we can view the choice of words as the outcome. Whenever certain statements are associated with particular political positions, we can use them to discriminate between positions in a certain political space. In other words, the use of a particular (set of) word(s) provides us with a revealed preference for a specific (kind of) policy. Whenever we can think of the data generating process in these terms, the spatial model of politics is likely to provide a good approximation, and scaling a set of documents might be feasible.

### ***Which Assumptions Are Needed to Scale a Text?***

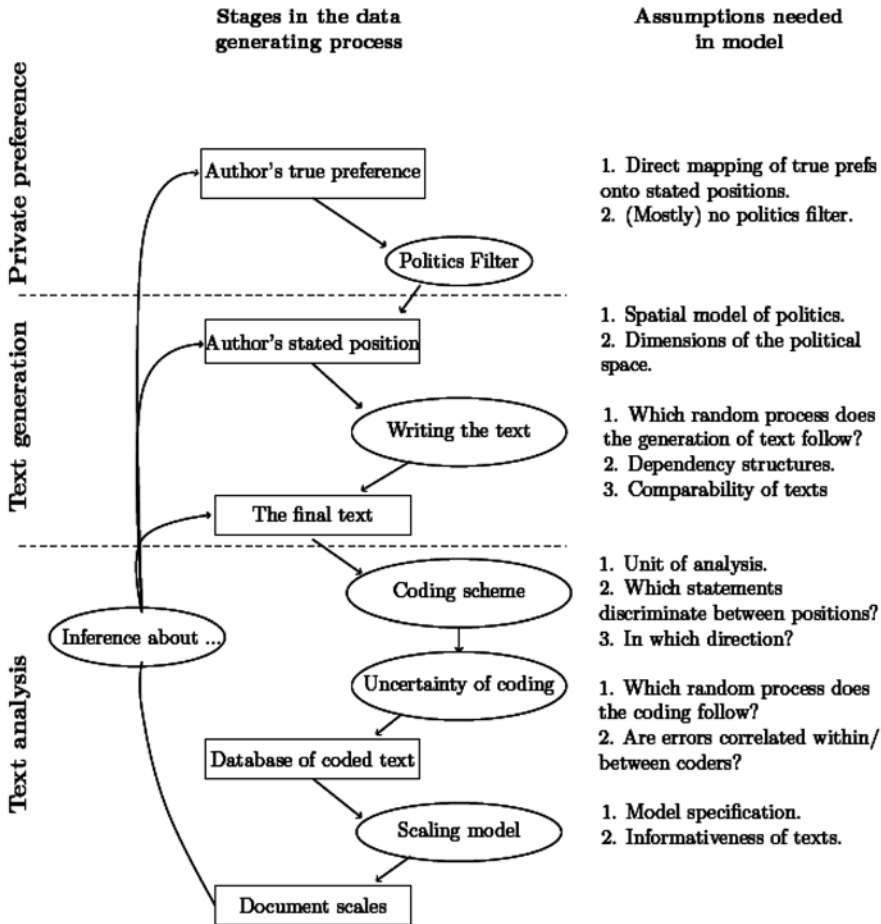

To infer from the text in a document to a political position, we need assumptions about three stages in the data generating process,

which together operationalize the spatial model of politics in the setting of text scaling. First, we make assumptions about the author's private preference and intent with the analyzed document. The second set of assumptions is about how those preferences are expressed in any particular document, and how that document relates to the others in the corpus, which in combination make up the relative political space we want to estimate.

While the first two sets of assumptions are about modeling the causal process that relates text generation to political position, we also need the third set of assumptions to translate text into data and from data to scales. Specifically, we need a statistical model that operationalizes the considerations in the underlying causal model about how preferences are communicated in text, and how this relates to the latent position of the document. Table 27.1 presents the stylized version of the full text and data generating process proposed in Benoit et al. (2009).

**True Preferences and the Politics Filter:** First, even though it is called text scaling, what we most commonly want to draw inferences about is not the political position articulated in the text, but the preference held by the author. But if the cost to articulating a position is low, authors might engage in cheap talk. Conversely, if costs are high, they might choose not to articulate the position for strategic reasons. All of the techniques we review here assume that authors do not censor their statements for political reasons. Therefore, we sideline this discussion, even though it obviously can cause significant measurement error.

**Model of the Political Space:** Second, we need to make assumptions about how any given author translates her position into text, and how that relates to the other authors in the corpus. Specifically, the language used in the texts must discriminate between the intended messages of different authors. In other words, the authors should receive varying levels of utility from their choice of words, and this

**Table 27.1 A stylized model of political text generation and model assumptions in each step**

Note: The stylized model of data generating process is based on Benoit et al. (2009).

variation should be related to the political space we want to measure. If authors of different preferences receive the same utility from similar choices of words, we cannot use the texts to discriminate between their positions. The documents should be informative about the political differences we seek to estimate (Slapin and Proksch, 2014). Particularly in contexts where there are strong common norms about how to phrase a document (as with highly technical legislative or legal documents) or the texts do not communicate any preference at all, it can be difficult to scale documents. An interesting special

case of incomparability is when authors simply use different languages. Importantly, De Vries et al. (2018) have shown that – at least when it comes to topic models – automated translation software (e.g. Google Translate) provides a good way of making languages comparable.

With regard to the relation between documents, a set of texts is only scalable if the texts can be placed in the same Euclidian space. This is an often undiscussed assumption, and it can be broken in three ways. One way is if political preferences are discrete views, not matters of continuous differences.

Another violation would be if the language used in the documents is incomparable in the way meaning is ascribed to words. Analyzing text that is produced under very different conditions or in varying contexts; that is from different time periods or actors; or that has very different audiences in mind would make it difficult to place the texts relative to each other – let alone in the same space (Slapin and Proksch, 2014). Finally, we need to make assumptions about the dimensionality of the space.

**Stochastic Writing Process:** Third, whereas the particular spatial model constitutes the assumptions about the systematic component of the data generating process, scaling also requires assumptions regarding the stochastic part. An important assumption in most scaling techniques is that the analyzed units are conditionally independent. When the unit of analysis is word frequencies, this is labeled ‘the bag of words’ assumption (Grimmer and Stewart, 2013). Conditional on the statistical model, any relation between the use of words is purely noise, and their ordering is inconsequential to the positions that we obtain through our scaling techniques. This assumption allows us to determine differences across texts based on the relative frequencies with which words occur in a text. The main difference in the scaling techniques we review in this chapter is how these frequencies are converted into positions. While this assumption is certainly wrong, it provides an effective simplification, and often scaling techniques work well despite the obviously wrong assumption (Grimmer and Stewart, 2013).

Finally, the writing process is inherently stochastic: the same writer would not write the same text if she sat down to communicate the same message repeatedly. Even if a perfect model of political text could be constructed, and no assumptions were violated at all, the randomness of the writing process would still produce uncertainty in the resulting position estimates. We cannot observe all possible texts the actors could have written, but we can estimate the variance in their

positions. While this is clearly not the same as uncertainty, it can help us identify a range within which the author’s intended message is likely to be.

**The Model Specification:** Finally, each assumption about the data generating process has to be incorporated into a combined scaling model. This requires assumptions about how the use of words is related to the latent policy position through a functional form and a statistical distribution. This is the step which operationalizes the theoretical considerations in the text generation process. If we use frequencies of individual words, we need to specify our expectations about how a change in frequency helps us discriminate the underlying position. For example, is the relationship log-linear? How does utility decrease as words are further removed from the author’s ideal point? We should also consider which other parameters (such as controls, prior information, etc.) to include in the model. Together, the assumptions about functional form, distribution and relations between words represent principal statistical assumptions, which implement the theoretical model of text generation.

Most of the estimators which we will discuss here are highly greedy in their data requirements, however. Thus, an additional and crucial assumption is that the texts to which we apply scaling techniques contain sufficient information for the technique to pick up differences across texts. The limiting factor is of course how words are distributed in the document-term matrices which are the analytic underpinnings of the methods we discuss. There have to be different distributions of words, and these distributions have to be meaningfully linked to the latent dimensions that we are trying to estimate.

## Summary

In this section, we discussed how *text* scaling in particular relates to the broader discipline of estimating latent political preferences.

We saw how this requires assumptions about the political context, and how it shapes the manner in which authors state their preferences through text. We discussed which assumptions are needed to implement a theoretical model of the political space in the context of text data, and how this forms the basis of scaling the positions of a set of documents. It is worth reiterating that while all of these assumptions are wrong, the model might still be useful in the sense that the estimate of the latent variable may correlate well with the true political preference of an author.

In the next sections, we review the scaling techniques that have been used by political scientists. We relate each technique to the spatial model of politics, and discuss its assumptions about how observed text is related to the author's latent position. This continuously reminds us that while most of the *visible* discretion when scaling a text is contained in the choice of unit of analysis and preprocessing, the choice of even off-the-shelf scaling techniques involves making a number of model assumptions.

## USING MACHINE LEARNING TO SCALE DOCUMENT POSITIONS

Before analysis we need to make the choice of scaling technique, each of which embodies a set of assumptions about the data generating process. While most techniques resemble statistical ideal point models, we can further distinguish between supervised and unsupervised models. Supervised models use human input, typically in the form of a set of training texts. These estimates can then be used to predict the positions of texts the model has not encountered previously. The training set also serves to define the policy space that the researcher seeks to estimate. Unsupervised techniques simultaneously learn about the latent space and estimate document positions in it, without input from the researcher.

When using any kind of computational technique, preprocessing of the documents is the first step in the modeling process, as it involves making the decision about where in the text we expect the signal about policy positions to be located. A first problem that any scaling needs to deal with is how to translate words into numeric values. That is, what is our unit of analysis, and how do we quantify the prevalence of certain phrases? The techniques we review in the following sections have traditionally used counts of individual words (unigrams) as their units of analysis. Pairs of consecutive words (bigrams) and words in all possible three contiguous sequences (trigrams) have also been used in political science. But one could use any length of word string (n-grams), which are more common in the broader field of natural language processing. Additionally, noise is often sifted out by removing extremely common words (so-called stopwords), numbers, punctuation and symbols as well as by reducing words to their stem. Especially for unsupervised models, it can be a good idea to remove highly infrequent words. It is extremely important to note that all of these choices regarding preprocessing have consequences, and should not reflect some standardized procedure but rather be seen as a step in building the model (Denny and Spirling, 2018). The output of this is typically a document-term matrix, where documents are identified along the rows, terms (words, bigrams, n-grams etc.) are in columns and the frequencies are in the cells. This is the input on which we estimate our statistical scaling models.<sup>3</sup> We use the *quanteda* package (Benoit et al., 2018), which is available in R and comes with an excellent online tutorial that walks the reader through each step in a computational scaling model.

An important caveat when using ideal point models for scaling is that even if all assumptions held, and we could think of a perfect statistical model of text, the incidental parameters problem – that there are too many parameters to estimate relative to

observations – would still mean that our position estimates would be wrong. In this regard, it is important to note that the use of computational techniques is no substitute for careful reading of the text and understanding of the subject matter. Automated scaling serves to amplify human ability, not replace it, and its use should be subject to careful subject-specific validation (Grimmer and Stewart, 2013).

## SUPERVISED TECHNIQUES: WORDSCORES

The Wordscores algorithm is a one-step approximation of a reciprocal averaging estimator for correspondence analysis on words (Lowe, 2008). Originally developed by Laver, Benoit and Garry (LBG) (2003), it was pioneering because it was one of the first attempts to introduce computational scaling techniques to a wider political science audience. And the model has been hugely successful for a number of reasons. First of all, the model is easy to implement because the authors made their software available to the wider public. Second, it relies on prior information in the form of reference texts with known positions. This makes it very stable compared to, e.g., unsupervised techniques. This also partially defines the latent political space before estimation, which makes it extremely flexible. Third, the algorithm is very clear and simple, which further broadens the group of potential users.

### *The Wordscores Model and Assumptions*

Wordscores begins from the premise that we have access to a set of texts  $R$  with known positions on the dimension we are interested in. Hence the precondition for a Wordscores model is that we have reliable and valid measures of the positions in a set of reference texts. Wordscores works through the core

assumption that each word  $w$  has a specific political position, and that the position of a document can be found by averaging over these word scores. The simple idea is that if we first ascribe positions to each word  $w$  by observing their frequencies in our reference texts  $r$ , where document positions are known, then we can use those word scores to predict the positions of out-sample texts by simply observing frequencies of words that also occurred in the reference texts. This is done by developing a measure of the probability of observing a given word  $w$  in our reference texts  $r$ , and using this to infer the positions of a set of out-of-sample texts from their word frequencies.

Specifically, LBG propose to calculate a score  $S$  for each individual word in the text using the following equation.

$$S_{wd} = \sum_r P_{wr} \cdot A_{rd}, \quad (1)$$

where  $P_{wr}$  is the probability ( $P$ ) of word ( $w$ ) occurring in text ( $r$ ), and  $A_{rd}$  is the position given to reference text  $r$  on the dimension  $d$ . Now we have values for each word in our text and we can therefore use the in-sample word scores to infer the position of the out-of-sample texts by using the frequencies of the word, whose positions we know:

$$S_{vd} = \sum_w F_{wv} \cdot S_{wd}, \quad (2)$$

where  $F_{wv}$  is the word frequency in the out-of-sample texts  $v$ . Lowe (2008) outlines the conditions under which bias in policy positions estimated in this fashion is minimized:

- 1 Positions of reference texts are equally spaced and extend over the range of the positions of individual words.<sup>4</sup>
- 2 Positions of individual words in the reference texts are equally spaced and extend *past* document positions in both direction.
- 3 All words are equally informative.

While it is obvious that the first two conditions cannot hold simultaneously in any

real-world setting, they provide guidance when choosing reference texts in a way that minimizes bias. Specifically, the conditions suggest that there should be sufficient overlap between distributions of words in the reference texts, and that they should include a sufficient range of potential word positions in the out-of-sample texts.

As mentioned previously, a strong assumption when scaling in general is that the vocabulary does not change radically over texts. When using Wordscores alongside a good choice of reference texts (defined by the above conditions), estimates are generally less sensitive to differences in the meanings and uses of words. We illustrate this point later.

### ***Using Wordscores***

To illustrate the use of Wordscores, we draw on data from Baturo and Mikhaylov (2013), who use speeches by Russian governors to estimate levels of alignment with Putin and Medvedev, respectively. By leveraging the fact that the main policy dimension in a Wordscores estimation is defined a priori through the use of reference texts, they are able to estimate where each governor's address to the local parliament falls on a scale from Medvedev to Putin. This use of prior information is what makes supervised techniques like Wordscores extremely flexible. In terms of the spatial model of politics, we can think of the underlying policy space as one in which two leaders compete for control, and state slightly different policy preferences. The assumed utility function of the authors is one in which the governors prefer to converge on the policy position of the most powerful national leader. Thus, we have defined a coherent policy space, and have a clear idea about how written words reveal a preference. In combination, this provides us with a foundation for mapping words onto a latent position in this particular space. This is an interesting case, in part because it shows how broadly we can construe the spatial

model of politics. An additional interesting feature is that it does not necessarily assume that authors communicate their sincere preferences.

We use the texts made available by Baturo and Mikhaylov (2013), which exclude segments on foreign policy. Otherwise, the only preprocessing we do is to remove punctuation. We set the reference scores of Putin and Medvedev to be 1 and  $-1$ , respectively. Thus, we fully replicate the original study. Figure 27.1 shows how alignments estimated through Wordscores changed over time.

To validate the Wordscore estimates, we follow Baturo and Mikhaylov (2013) and use monthly expert evaluations of how powerful Putin and Medvedev are, respectively. To get a direct estimate of partisan alignment, we compute the difference between the Wordscores estimate and Putin's reference position. We use the monthly averages of this difference to facilitate comparison with the expert survey. Figure 27.2 shows the results. It is clear that when the average governor's speech is more aligned with Putin, expert perception of Medvedev's influence is lower. The correlation is strong and precisely estimated. The correlation between expert perception and the alignment of governor speeches with Putin's position is somewhat lower. This is likely because there is relatively little variation in both estimates of Putin's influence – he remains continuously powerful by both estimates.

### ***Extensions to Wordscores***

The original incarnation of Wordscores was strong in its simplicity, but made many of its assumptions implicitly. Lowe (2008) clarifies the underlying assumptions and provides a statistical model for Wordscores, which also serves to relate it to the broader family of statistical ideal point estimators and correspondence analysis. Perry and Benoit (2017) implement a scaling technique using an affinity class model, which is highly similar

**Figure 27.1 On a scale from Medvedev to Putin**

*Note:* Each point represents the Wordscores estimate of a governor's speech at a given point in time. The dimension is identified using the most recent parliamentary address by Medvedev (reference score = -1) and Putin (reference score = 1), respectively. The solid line is a Loess smoother, and the shaded region is a 95% pointwise confidence interval.

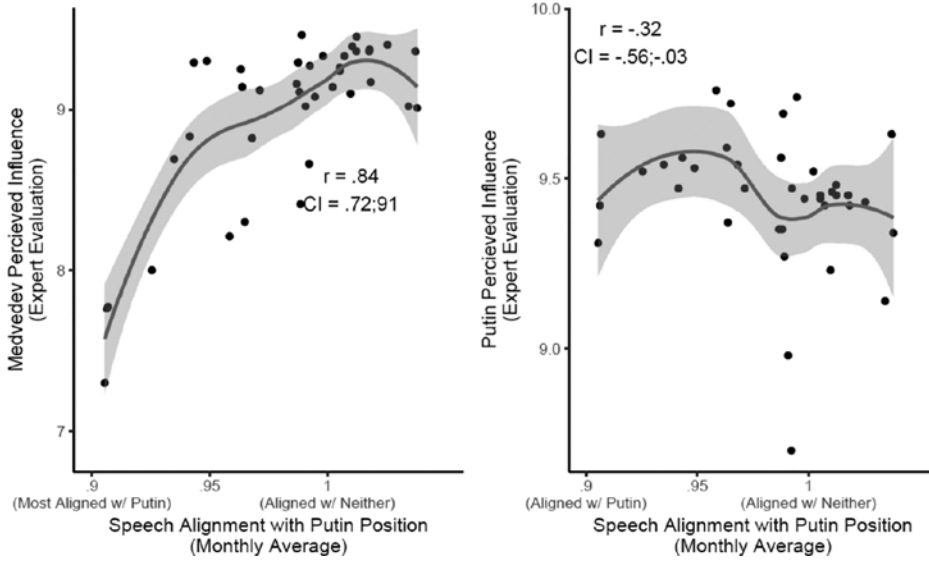

to the original Wordscores model, and solves some of the problems identified in Lowe (2008).

A second issue that has drawn some attention is how to transform the raw scores obtained by the procedure described above to the same scale used to score the reference texts. In their original article LBG assume that the raw scores for the reference texts have the correct mean but that the variance is incorrect. Lowe (2008) argues that this assumption might lead to biased scores because of the shrinkage discussed above. Martin and Vanberg (2008) criticize the original transformation, arguing that there the original transformation is dependent on the choice of reference text, leading to the uncomfortable position that any desired result could be obtained provided that the right combination of reference texts are chosen. Consequently,

they propose a transformation of the raw scores which builds on the relative distance ratios using two anchoring texts which serve as the unit in relation to which all other positions are expressed. Lowe (2008) argues that researchers are then confronted with a choice when deciding which transformation to use. The original LBG transformation is dependent on the reference texts and is indifferent to the virgin texts; the opposite is true of the Martin–Vanberg transformation.

## UNSUPERVISED TECHNIQUES: WORDFISH

Wordfish (introduced in Slapin and Proksch, 2008) is an unsupervised machine learning algorithm, which is based on a Poisson item

**Figure 27.2 Perception and governor speeches**

Note: The figure shows the correlations between expert perception of Medvedev’s and Putin’s power, respectively, and the Wordscores estimate of the average governor’s alignment with Putin. The solid lines are Loess smoothers, and the shaded regions are 95% pointwise confidence intervals.

response theory (IRT) model (Lowe, 2015). Being unsupervised, it simultaneously estimates policy positions and learns the policy space using only the texts provided, with no external information in the form of virgin texts or anchoring (Grimmer and Stewart, 2013). While this is a strength in many aspects, it requires strong modeling assumptions and presents challenges, particularly in regard to validation of the particular policy scales and the dimension as such (Grimmer and Stewart, 2013; Lowe and Benoit, 2013). In this section, we briefly introduce the statistical model underlying Wordfish, its assumptions and they can be broken, and how a Wordfish model can be estimated and interpreted.

**The Wordfish Model and Assumptions**

The Wordfish estimator assumes the data generating process to be as follows:

$$y_{ij} \sim \text{Poisson}(\lambda_{ij})$$

$$\lambda_{ij} = \exp(\alpha_i + \psi_j + \beta_j * \omega_i)$$

Where  $y$  is the count of word  $j$  in the position document of actor  $i$ .  $y$  is assumed to be drawn from a Poisson distribution and connected through its mean,  $\lambda$ , to the systematic component, where  $\omega$  is the estimated position of document  $i$ .  $\psi$  is a word fixed effect, which signifies the frequency of word  $j$ , when a document expresses a center position on the estimated scale (the difficulty parameter in IRT language).  $\beta$ , a word’s weight in estimating positions, is an estimate of how sensitive the use of a word is to the political position. In IRT it is called the discrimination parameter, because it measures how the latent position parameter changes in response to word frequencies. It is parallel to a variable’s loading in factor analysis (Jackman, 2001).  $\omega$  is the position of actor  $i$  as estimated through its position document. Finally, this leaves  $\alpha$ , a set of document fixed effects. ‘While

estimation was originally done by iterating over conditional maximum likelihoods, equivalent – but faster – implementations relying on expectation maximization have since been suggested’ (Lauderdale and Herzog, 2016).<sup>5</sup>

Wordfish requires a number of the previously introduced assumptions about the underlying spatial model. However, dimensionality in particular is key to the Wordfish model, and it uses a different statistical operationalization than Wordscores.

### *The statistical model*

Wordfish operates under the assumption that the generation of words in a text – conditional on the model – follows a Poisson process. This has consequences for estimation of both the latent position parameter and the uncertainty of all quantities in the model. First, regarding parameter estimation, it translates into an assumption about the functional form of the relation between word frequency and the latent parameter being log-linear. The model specification introduced above implies assuming monotonicity and that the weight of each word must be the same in any subgroup with the same latent parameter. The former would be violated in situations where word weights do not always increase or decrease with the latent parameter. The latter violation occurs if two groups with the same policy position use the same word differently.

Second, assuming a Poisson process implies that the variance of the rate of the word count is equal to its expected rate. This assumption will be broken in the presence of both under- and overdispersion as well as structural zeros (when there is zero probability of a word occurring in a text). This induces well-known problems of underestimation of the uncertainty in Poisson models for count data (King, 1998), which translate directly into the Wordfish setting (Lowe and Benoit, 2013). In practice, violations of the distributional assumption will also lead to poor coverage (Lowe and Benoit, 2011).

### *(Uni)dimensionality of the policy space*

While all scaling techniques require assumptions about dimensionality, the unsupervised ones – like Wordfish – are particularly vulnerable, because they learn about the policy space without input from the researcher.<sup>6</sup> If a researcher misspecifies dimensionality, she risks estimating a policy dimension which is either meaningless or not the one she is interested in. There are a number of reasons why this is a risk. When the generative model specifies a unidimensional policy space, when it really is multidimensional or when the word weights are misspecified, we risk misspecifying the policy dimension. But even if all modeling assumptions hold, the dimension identified by Wordfish might simply be wrong. First, word use in texts addressing the same concerns are likely to be highly correlated. Wordfish will recognize differences in word use between two texts as indicative of their different political positions, but in reality these differences could be due to the topics addressed by the authors (Lowe and Benoit, 2013). A notable such case is in situations where texts use completely incomparable language or do not address similar topics at all. In these situations they cannot be scaled together, and if they are, it will often result in the main policy dimension being misspecified. Finally, the Wordfish estimator’s likelihood function is prone to have many local minima, and estimation can easily get stuck in an uninteresting one. This problem could be compounded if there is not enough data for the curvature of the likelihood to be estimated correctly. In this situation, the algorithm might capture noise and a meaningless policy dimension.

### *Using Wordfish*

To illustrate the use of Wordfish, we investigate its performance in estimating the policy positions of European interest groups on

three specific issues. Here, we draw on data from Egerod (2016). We use texts from the European Commission's online consultations regarding *Reinforcing Sanctioning Regimes in the Financial Services Sector*, *A New European Regime for Venture Capital* and *Review of the Investor Compensation Scheme Directive*. We will refer to them simply as Sanctions, Venture Capital and ICSD, respectively. For the present purposes, we include only a subset of the interest group responses. Below, when we examine the consequences of violated assumptions, we include all groups. Alongside the interest group position papers, we include the Commission's original Green Paper, which outlines the issues within each consultation, and the final policy proposal.

The main fracture between the interested parties in all three consultations was whether the EU should impose *more* or *fewer* rules. Therefore, we can think of the underlying spatial model as one in which actors are placed along a continuum ranging from wanting more to fewer supranational rules. This is the underlying political space in which we wish to place actors. To gauge Wordfish performance, we compare its estimates to hand-coded positions, which aim directly at capturing this space. See Egerod (2016) for more information on the hand-coding.

To prepare documents for Wordfish scaling, we reduce words to their stem and remove stopwords, numbers and punctuation. Figure 27.3 shows the positions estimated through Wordfish, and how they correlate with the hand-coded positions for documents in each of the three online consultations we investigate here. The two correlate highly in all three cases, although by far most strongly in the case of National Sanctions and clearly the least in the Venture Capital case. To save space, we do not discuss the reasons for discrepancies between automated and human scaling which are present in all three cases.

We can use the word weights, or  $\beta$  parameters (i.e. the word discrimination parameter),

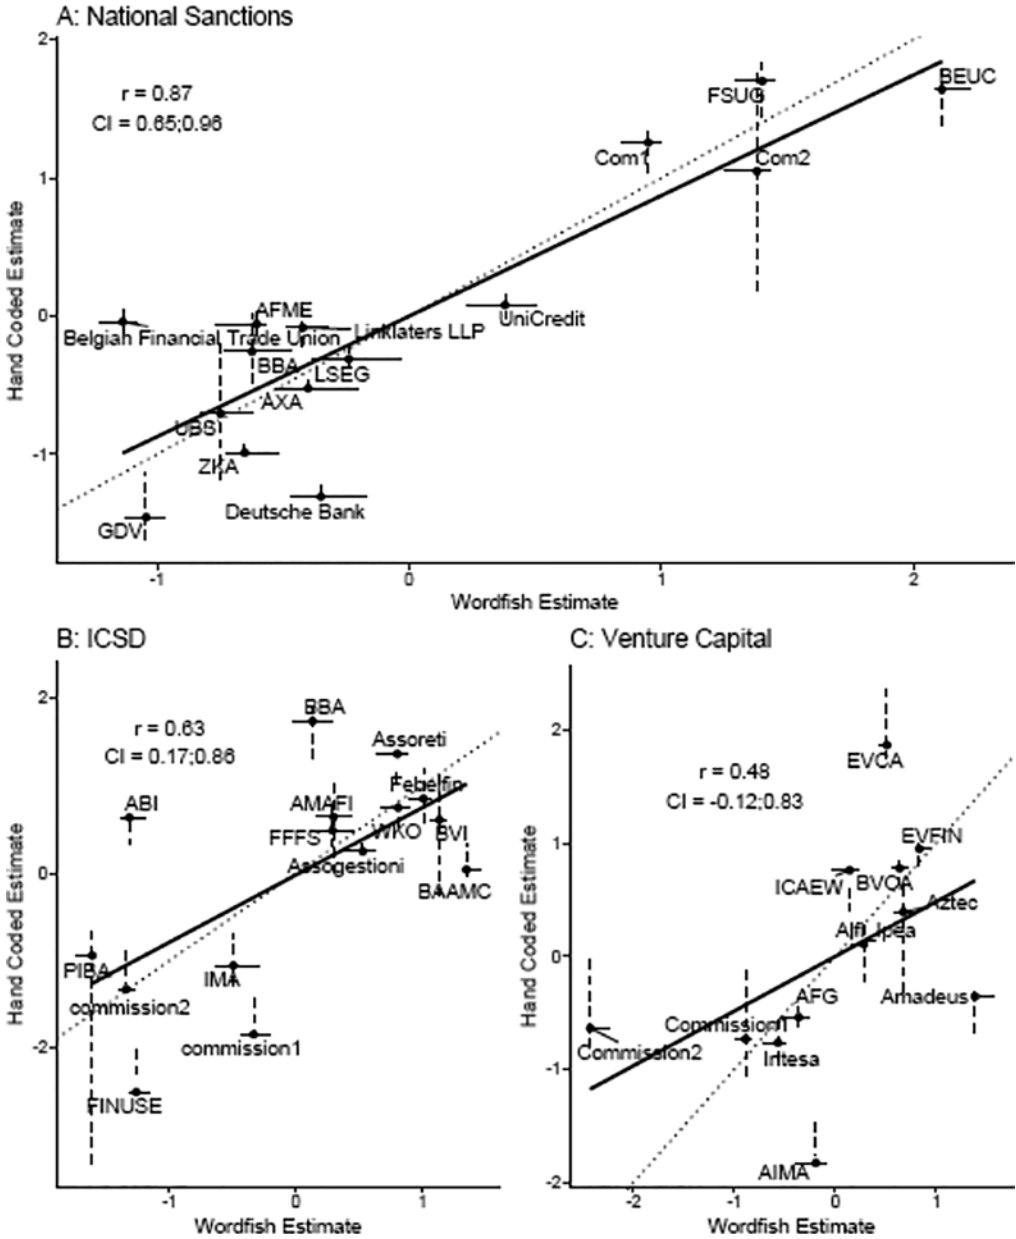

to analyse the substantive content of the dimension recovered by Wordfish. This can potentially be used to explain why the two sets of scales diverge for some documents. Figure 27.4 shows the 21 words with the, respectively, highest and lowest weights for each consultation.

We can take the National Sanctions consultation as an example of how to diagnose divergence between human and machine based scales. There, we can observe that 'labour', 'clause' and 'employ' all have very negative weights – far out in the tail of the full distribution of word weights. This can help us explain why the Belgian union of employees in the financial sector is estimated to be a stronger advocate for fewer EU rules. A thorough reading of the union's position document reveals that, while it is relatively positive overall, it expends many words on strongly arguing against employees of financial institutions being liable to prosecution when laws are broken. This seems to be the aspect Wordfish has caught.

### **Extensions to Wordfish**

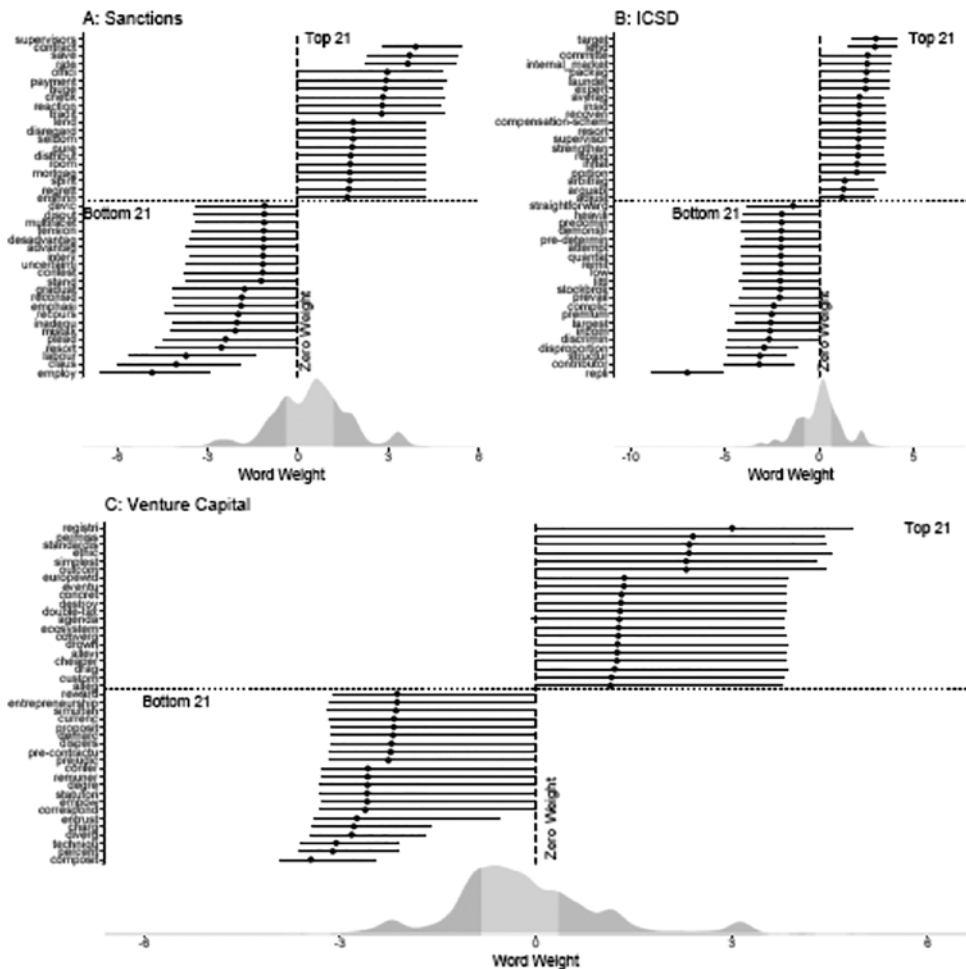

While Wordfish builds on item response theory, it is closely related to correspondence analysis (like Wordscores) (Lowe, 2008). Therefore, correspondence analysis will often provide similar position scales at a lower computational cost. In an early implementation of the Poisson scaling model, Monroe and Maeda (2004) use a Bayesian setup to estimate a two-dimensional model. This is one way of dealing with some dimensionality issues. Slapin and Proksch (2008) have done so by manually separating out the parts of a text that are most closely aligned with predefined dimensions.

Besides these issues of dimensionality, there are a number of relevant extensions to the Wordfish model itself. Lowe and Benoit (2013) introduced the use of asymptotic standard errors, instead of the very computationally intensive Poisson bootstrapped

**Figure 27.3 Validating Wordfish estimates against a human benchmark**

Note: Horizontal lines around points are 95% parametric Poisson bootstrapped confidence intervals (CIs) around the Wordfish estimate. Vertical dashed lines are 95 percent CIs from non-parametric bootstraps of the hand-coded scales. 500 resamples used. The solid line is the best linear fit; the dotted diagonal line shows what a perfect fit would look like.

**Figure 27.4 Which words define the policy space?**

Note: Points show the point estimate for each word weight. Lines are 95 percent CIs based on 500 resamples from a conditional Poisson distribution. Density plots show the marginal distribution of word weights in the full corpora. Dark shaded areas are below the 25th and 75th percentiles, respectively.

standard errors used in Slapin and Proksch (2008). The Lowe and Benoit (2013) implementation also allows for varying levels of dispersion. Both the analytical and the original technique, however, rely heavily on the model being correctly specified. As a way of obtaining uncertainty estimates with weaker assumptions, Lowe and Benoit (2013) also introduced a non-parametric bootstrap procedure. The `quanteda` package in R supplies functionality for random sampling of

words, which can be used to implement the bootstrap with relative ease. Lauderdale and Herzog (2016) deal with problems of comparability between corpora by using `Wordfish` to estimate issue specific positions, which they aggregate using Bayesian linear factor analysis to get estimates of overall ideology from text data.

Finally, Lo et al. (2016) exploit the fact that as the rate of failure converges to the limit, a Poisson distribution can be reparameterized

as a negative binomial one. This allows them to incorporate a document level dispersion parameter, which can be interpreted as the clarity associated with a document's stated position.

## WHEN ASSUMPTIONS ARE BROKEN

Assumptions about the generative model and the use of prior information vary between models. Thus, when one model is obviously misspecified and performs poorly, a researcher can choose another, more suitable one. However, it is not well understood how to handle violations of assumptions that are common across models, or how to proceed when no algorithm performs satisfactorily. In this section, we will investigate the consequences of violations of two basic assumptions that all common scaling techniques rely on: the comparability of language use and the length of the texts.<sup>7</sup>

We use real-world texts and simulate changes to the corpora to quantify the effect of marginal changes to document length and word use. This allows us to inspect what happens when core assumptions are broken in realistic but controlled settings.

### *Language Differences*

When we previously illustrated the use of Wordfish by using position documents from interest groups in EU consultations, we only relied on a subset of the actual position papers, consisting of 14, 13 and 15 documents, respectively, in the National Sanctions, Venture Capital and ICSD consultations. In reality, however, each corpus consists of 42, 44 and 57 documents from a very wide range of different actors, ranging from individuals, through government branches and NGOs, to different kinds of corporations and capital funds. These three corpora present an extremely hard test for both the Wordscores

and Wordfish algorithms, in particular regarding dimensionality and the comparability of the authors' use of words.

To gauge the impact of language differences, we ran both scaling techniques several times on different subsets of consultation documents. We began by running them on all documents in each consultation, then we randomly removed five to eight documents. In each consultation, we chose not to remove the type of actor which was most active in the consultation, which ensures that the included documents become more comparable with each iteration. In the case of Sanctions, we only removed non-corporations. In Venture Capital, we removed documents from actors that were not venture capital funds. In the case of the ICSD, we removed all documents other than those from national employer associations. After numerous iterations, this left only one or few types of organization and the Commission. The strength of this framework lies in its approximation of counterfactual scenarios – as documents are removed in a semi-random way, and the consultations otherwise remain the same, we hope to estimate the causal impact of altering the composition of the different corpora. Additionally, the dimensionality of the policy space is close to pre-defined by the Commission in its original policy paper, since it directs interested parties to comment on specific topics.

To save space, we do not show the performance of scalers within each iteration. However, we do find that both Wordfish and Wordscores are highly sensitive to the subset of documents being used, and that both perform best in the smallest, most homogeneous sets of texts. To quantify the degree to which these improvements are driven by decreased differences in word use, we use the correlation between the recovered scales and hand-coded positions as the dependent variable in two linear regressions – one for each algorithm. We measure differences in language with two proxies: the average correlation in word use and the number of unique words

in each iteration. Because other quantities change besides similarity of the documents, we include as controls the number of positions to be estimated, the average document length, an inverted Herfindahl-Hirschman index capturing how many different types of interest group were included in the estimation and fixed effects for consultations. The results for our variables of interest are presented in Figure 27.5.

As we can see, the improvements in algorithm performance follow predictable patterns. For both algorithms, the correlation between the human benchmark and the computer-based scales decreases by almost .1 for each percentage point the number of unique words increases. Note that because we control for average document length, the increase in the number of unique words captured here is for an unchanged document length. For Wordfish, performance improves by more than .1 every time the average correlation of word use in the corpus increases by .1. This effect is smaller for Wordscores, where the improvement in performance is .02. While the latter estimate is not statistically significant, it is still a strong correlation.

This illustrates that as word use in documents becomes more dissimilar, automatic scaling becomes less feasible. The fact that Wordscores is less vulnerable to differences in word use correlations illustrates a key difference between the two algorithms. Wordfish relies heavily on documents addressing the same concerns using the same words. If they do not, the algorithm is likely to pick up differences in the topics the authors address, not in their political positions. For Wordscores, performance relies more on the reference texts being representative of the broader universe of texts in the corpus. As long as that is the case, differences in word frequencies matter less (although they are not irrelevant), but as they become less representative (e.g. because the number of unique words increase), the performance of Wordscores decreases markedly.

### ***Document Length and Informativeness***

To get at the effect of document length on the performance of scalers, we use a text corpus where we know that Wordscores and Wordfish provide good estimates of policy positions – the Lowe and Benoit (2013) data on parliamentary speeches during the debate on the 2010 budget in the Irish Dáil. This data also includes estimates of the position of each speech based on human judgment. We simulate changes in document length by randomly reducing the number of times an actor articulates each word in the corpus by between 0 and 3. We reduce the word frequencies in the corpus in this way 100 times, estimating both Wordscores and Wordfish models in each iteration. To measure the performance of the algorithms, we predict the expert coded benchmark using scales recovered from each algorithm and compute the root mean squared error (RMSE). Because reductions in word frequencies are random, we can get estimates of uncertainty through randomization inference repeating the entire process 100 times. The results are presented in Figure 27.6.

The results show that the performance of Wordfish and Wordscores decreases dramatically as the average document length decreases from the baseline of approximately 3,900. To begin with, scales from both models predict the positions of speeches with a relatively small RMSE of between .3 and .4 – corresponding to approximately one-third of the standard deviation. The error increases quickly and stabilizes at about 80% of a standard deviation for Wordfish, when it hits an average document length of 1,800 words. For Wordscores, the RMSE stabilizes at approximately 75 percent of a standard deviation, when the average document length is around 700.<sup>8</sup> With an error of that size, the recovered scales are close to useless.

As in the previous simulation, the use of reference texts to guide the estimates of the Wordscores model proves an important

Figure 27.5 How the performance of scaling algorithms vary with the comparability of texts

**Figure 27.6 Document length and performance of scaling models**

Note: In each iteration, we reduce the frequency with which each actor uses a word by a random integer between 0 and 3. We run 100 iterations, and rerun the algorithm 100 times to get uncertainty. Shaded lines represent the root mean squared error in each iteration, the solid line shows the average across different random removals. The shaded area is the 95% confidence interval.

feature. As the average document length decreases below 600 words, Wordscores' performance actually starts to improve again. This happens because the word usage in the reference texts becomes more representative as the length of the left-out texts decreases. While this obviously hinges on a good choice of reference texts, it suggests that the performance of the Wordscores model is a non-monotonic function of document length. With the right reference texts, the algorithm may perform equally well in small and large corpora. The obvious caveat is, of course, that because the texts are very short in the final 20 iterations of each chain, the uncertainty around the average root mean squared error is relatively high.

### ***Guidelines for Constructing Your Corpus***

With the results from these two simulation studies, we can provide some tentative guidelines for researchers. While it is difficult to give precise advice beyond the particular cases we have investigated here, the results show that the performance of the two scaling techniques is strongly influenced by observable characteristics of the documents being scaled. While we probably cannot infer precise thresholds from these cases to the universe of potential texts to be scaled, it does tell us what we should be aware of when we construct those corpora.

In our cases, scaling documents when the average correlation between word frequencies is below .6 to .7 resulted in poor performance. Additionally, increasing the number of unique words beyond 2,000 without also increasing document length resulted in the recovery of biased positions. Regarding the length of the included documents, we found that scaling corpora with fewer than approximately 1,800 words in the average text is infeasible using both algorithms. For Wordscores, however, corpora consisting of very short texts (below 400 words on average)

can be scaled if the reference documents provide good coverage of the virgin texts.

The analyses also provide some insight into how these problems can potentially be handled. First, when there are many unique words relative to the average document length, it will often make sense to trim away very infrequent words, as this removes noise in the Wordfish estimation and improves the representativeness of the reference texts for the Wordscores algorithm.

Second, if texts are simply incomparable, it can make sense to redefine the population of interest to a more coherent group of texts, if it is possible given the particular research question. If estimation is done over time, it would make sense to split the sample up and run the algorithm within more narrow time periods. If the positions of many different types of groups are to be recovered, one can focus on the most relevant one and only include that one in the estimation.

Finally, if the average document is very short, and there is no way to increase the amount of data available for estimation, Wordscores seems to be able to recover good, but noisy, positions – under the important condition that the reference texts are representative of the remaining corpus.

### **WHAT IS THE ROAD AHEAD?**

In this chapter, we have laid out the conceptual foundations for scaling policy positions from hand-coded texts as well as automated content analysis. We argued that a spatial model of how policy positions relate to language use is a necessary condition for scaling texts, and that the choice of statistical model should follow from this conceptualization. Based on this framework for understanding text scaling, we outlined the necessary and sufficient assumptions for estimating positions from political texts. This highlights how important conceptualization and the accompanying statistical

assumptions are – which, yet again, shows that automated scaling can never replace human judgment, only augment it (Grimmer and Stewart, 2013).

We then introduced commonly used techniques for scaling text through supervised as well as unsupervised machine learning (the Wordscores and Wordfish estimators, respectively). Based on the conceptual framework outlined at the beginning of the chapter, we discussed the assumptions embedded in these techniques, and how they could be broken. We illustrated the use of these three scaling models with diverse corpora of political text.

We then proceeded to investigate what happens when two important assumptions are broken. By simulating random changes in two corpora of real-world text, we illustrated the consequences of estimating positions from texts that (a) use their words too differently, and (b) are too short. The results suggested that the performance of Wordscores is affected less by changing these factors as long as the reference texts are representative, and yielded some tentative guidelines about how to construct a corpus. The key takeaway is that performance varies systematically and according to observable features of a corpus. While the thresholds uncovered in the specific corpora investigated here may not hold in any given other setting, the findings can still inform researchers when they construct a corpus. The results illustrate how we can use observable features of a corpus to judge its suitability for scaling – we do not always have to rely on abstract argumentation.

In concluding, we will briefly discuss two potential venues for future research into text scaling which we think may be fruitful: (a) potential ways of improving our scaling models and (b) how we can think about measurement error when we incorporate scaled positions in econometric models. One goal of this diversity was to illustrate how broadly the spatial model of politics can be construed.

### ***Improving Scaling Models: Dealing with Comparability and Conditional Independence***

Throughout this chapter, we have repeatedly discussed two assumptions about the textual context: (1) conditional independence of word (or n-gram) frequencies, and (2) similarity in the way authors ascribe meaning to words (i.e. stability of the vocabulary). We believe that important new work on word and text embeddedness (Mikolov et al., 2013; Ng, 2017) may offer ways to deal with this within existing scaling frameworks. We will briefly discuss two such possibilities.

#### ***Conditional independence of words***

While most scaling techniques perform relatively well, in spite of relying on the simplifying ‘bag of words’ assumption, there is little doubt that it can hurt algorithm performance – and sometimes severely. Throughout the text, we have emphasized that using the frequencies of single words – while the political science standard – is not the only feasible level of analysis. Any n-gram could conceivably be used. This, however, could induce more noise than looking at single words. One way to think about the utility of word embeddings for scaling techniques is that they offer a statistical model for learning about word context – and, among other things, ways to construct n-grams in a principled manner. The iconic word2vec (Mikolov et al., 2013; Ng, 2017) technique, for instance, either uses the context of any given word to predict it, or uses that word to predict its own context. Either provides a set of probabilities that words co-occur, which in turn gives a foundation for finding the optimal n-gram, which could make the conditional independence assumption more valid.

#### ***Grouping most similar documents***

A well-known fact – which we substantiated through simulations – is that dissimilarity in word use and the ways in which meaning is

ascribed to individual words can severely harm the performance of scalars. Embedding texts in their contexts might help in this. If we think about dissimilarity of documents as a confounding factor, learning the context of documents may offer a way of modeling it directly. Seeing as position scales will be severely confounded with the most prevalent topics when documents are dissimilar enough, one way of doing this would be by using topic modeling to learn about the topics in documents before scaling, and then conditioning on them during the estimation of document positions. Only comparing documents that concern similar topics during estimation could be one way of estimating the policy positions of highly dissimilar actors on the same latent scale.

### ***Improving the Use of Scales: Systematic Measurement Error in Political Positions***

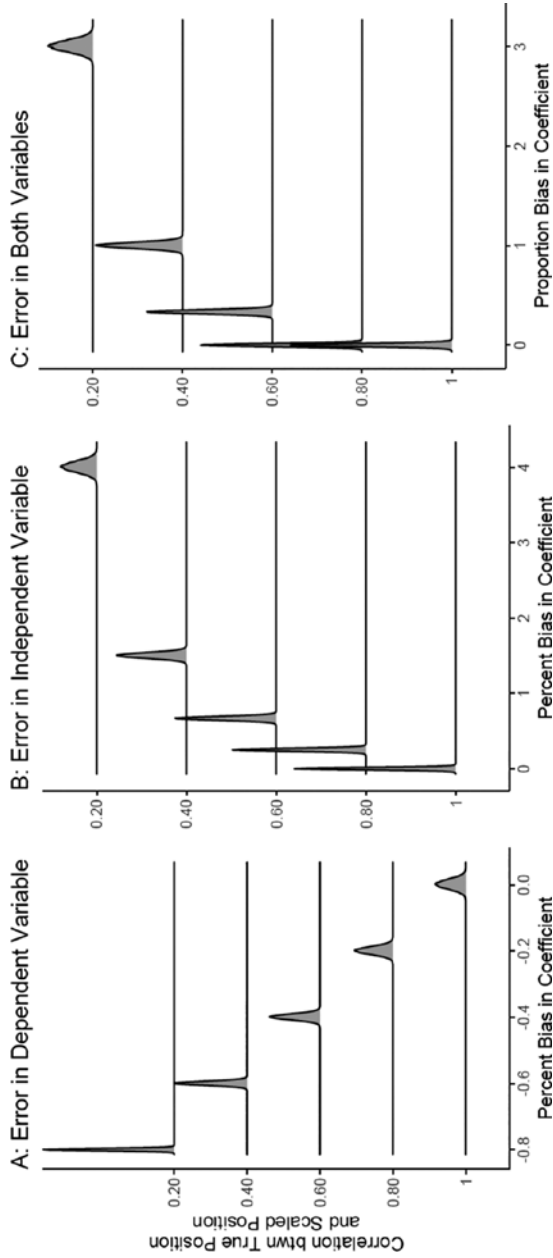

No matter how much we improve our models or how complex they become, they will always be erroneous approximations of real-world text generation. While it is relatively straightforward to deal with the special cases, when our models perform either dismally or in a superb manner, we need more research on how to handle the intermediate cases, where a model provides estimates that correlate with true positions but far from perfectly. This is especially pertinent when we use those position scales in econometric models seeking to estimate their correlates or use them to explain other political phenomena. The default solutions seem to be to either disregard the measurement error (or assume that it is random), or to disregard any results based on these imperfect scales – neither of which are satisfactory. Because position scales in any given case will be flawed, they will correlate imperfectly with the true positions of a set of actors. Thus, by definition, measurement error in the estimated scales cannot be random. But on the other hand, it

seems foolish to discard estimates that, while wrong, provide some useful information.

While a complete treatment of problems with measurement error is beyond the scope of this chapter, we will briefly illustrate how we can think about problems arising when including erroneous scaling estimates in econometric models. To do so, we conduct a number of Monte Carlo simulations. We use variations of a simple setup: we include a variable measured with some systematic error as either dependent, independent or both variables in a linear regression. We vary the measurement error in increments of 0.2, so the observed scales correlate with the true position estimates with  $r \in \{1; .8; .6; .4; .2\}$ . To keep things simple, we assume that all remaining Gauss-Markov assumptions are met. We run the three models in 10,000 random samples each including 1,000 observations. Figure 27.7 shows the distributions of bias arising from each scenario.

Because the setup does not necessarily generalize, the most important thing to note is the direction of bias: systematic error in the dependent variable biases the regression estimate downward, while the opposite holds when the independent variable is measured with error. There is reason to believe that the errors to some extent cancel out when both variables are measured erroneously. This conclusion, however, rests on the assumption that errors in variables on either side of the equation induce an equal amount of bias in the estimation. In this particular setup, that only seems to be the case when the independent variable correlates by more than .6 with the true concept. For lower correlations, bias induced by systematic measurement error on the right hand side is much larger in this scenario.

This provides an initial illustration of how measurement error in position scales may affect results downstream when they are included in econometric models. While the scenarios are general, the exercise shows that researchers should think hard about how measurement error in their scales may impact

**Figure 27.7 Error in scales and bias in econometric models**

Note: Each distribution shows the percentage difference between estimated coefficient and the true effect as measurement error varies. Each distribution is made up of 10,000 iterations of an ordinary least squares (OLS) regression, each with a sample size of 1,000 observations.

later stages of their research – not just ignore or discard them – and that more research into the topic might be needed.

## Notes

- 1 We thank Lucas Leemann as well as the editors Luigi Curini and Robert Franzese, who provided very valuable feedback on earlier versions of this chapter.
- 2 This is the so-called proximity based model of space. While a *directional* model obviously is possible as well, none of the currently implemented models use it (Armstrong et al., 2014).
- 3 While this is typically what we model, it is not the only conceivable form.
- 4 Additionally, in the statistical model for Wordscores proposed by Lowe (2008), where words differ in informativeness, text and word positions should be closely spaced relative to each word's discriminatory power (informativeness).
- 5 This is where the informativeness of the text corpus is particularly important: for estimation to be done, there has to be enough data for the curvature of the log likelihood to be approximately quadratic (Lowe and Benoit, 2013).
- 6 When using supervised techniques like Wordscores, the researcher to some extent defines the policy space herself through her choice of reference texts. This still entails an assumption about unidimensionality, which is obviously likely to be wrong, but if the reference texts are chosen well enough, the estimator is unlikely to estimate a policy space that is very different from the one the researcher is interested in.
- 7 E.g. Lowe and Benoit (2011) investigate what happens when distributional assumptions are broken.
- 8 It should be noted that the speed with which the error increases is in part driven by the fact that more words are deleted within each iteration in the beginning, because there simply is more content to delete.

# Classification and Clustering

Sarah B. Bouchat

Text serves as a critical source of political data – comprising everything from official statements to news coverage, social media responses and legal documents – that is also increasingly accessible via large-scale digitization and open-source analytical tools. Perhaps even more critically for political science, classifying and characterizing these complex data facilitates inferences about policies, norms, strategic communication and the ideological landscape. Much like typological research that has a long lineage in the social sciences, classification using text data allows us to make fundamental claims about the nature of discourse and communication in politics that generalize across space and over time.

This chapter examines both supervised and unsupervised learning techniques for classification and clustering as they apply to text data, detailing both the history and available methodologies developed in information retrieval, natural language processing and computational linguistics, as well as the

extant applications of these approaches to questions in political science.

The remainder of the chapter proceeds as follows. First, it describes the goals of text classification and its theoretical underpinnings, including what distinguishes supervised and unsupervised alternatives. The second section offers a brief history of the development of these methods, including their origins and uses in cognate disciplines. The following sections explain how to implement text classification using both supervised and unsupervised approaches, including Naïve Bayes and Latent Dirichlet Allocation.

These sections also provide examples of work within political science and international relations that applies these methodologies, using these works to highlight the significant opportunities that exist for text-as-data within political science, but also to examine the drawbacks and limitations of classification approaches. The final section expands upon these insights to describe the practical issues that researchers might

confront in using text classification methodologies, including what problems are most and least suitable for these types of methods and the research design considerations they require. The chapter concludes with suggestions for further development in classification methodologies that would benefit political scientists.

## WHAT IS TEXT CLASSIFICATION?

A variety of classification techniques exist within the machine learning literature that apply to a broad set of data types, where boundaries that discriminate between distinct classes within the data may be linear or non-linear. A regression-based understanding of this type of classification specifies a separate *discriminant function* for each class, into which data are then sorted according to which class maximizes this function. While students of statistical and machine learning approaches to data classification more generally will be familiar with logistic regression or linear discriminant analysis approaches, this chapter highlights methods that are particularly common for analyzing text data.

Broadly speaking, and as is true for other types of data, text classification aims to map a set of inputs (e.g., documents) to a predicted class as the output. The utility of these approaches for textual data is directly related to the high dimensionality of text: automated approaches allow for dimensionality reduction in ways that manual coding and analysis do not. As with other types of data, text classification using supervised learning requires a defined set of classes  $\mathbf{C}$  into which text can be classified:  $\mathbf{C} = c_1, c_2, c_3, \dots, c_j$ . Suppose that text is organized coherently into documents  $d_i \in \mathbf{D}$ . The classification learning procedure then wants to determine  $f(d_i) \in \mathbf{C}$ ; that is, it learns  $f$ , the *classification function*. In order to do this, a researcher requires a training set of documents selected from

the corpus  $\mathbf{D}$  that already have labels in  $\mathbf{C}$ . The remainder of this portion of the chapter explains how each of the previously mentioned classification approaches applies specifically to text data.

For research tasks in which the underlying set of categories is not known or assumed, unsupervised approaches using clustering are appropriate. These approaches seek to ‘classify’ documents or components of text into classes that share some characteristics, where ‘discovering’ these classes and the features on which they rely is part of the research process. Grimmer and Stewart (2013) provide an extensive overview of the varying types of classification approaches for unknown categories, including both fully automated and computer-assisted clustering techniques.

## THE EVOLUTION OF TEXT CLASSIFICATION METHODS

Prior to the advent – and increasing popularity – of automated text classification, manual approaches dominated, particularly for social and political science projects. Many research projects utilizing qualitative text analyses used the presence or absence of keywords to determine whether a given text matched a category of interest. This manual undertaking can now be automated via supervised machine learning, where dictionary methods measure relative frequencies of a set of words to classify documents into categories. Automation further facilitates even more complex analyses that take into consideration more features of text.

Supervised classification approaches in particular can be thought of as strategies to improve the efficiency and accuracy of tasks that have been undertaken in content analysis of political texts for decades. While automation indeed promises to diminish the significant time and human resource expenditure necessary to perform some of these analyses, classification approaches are not without

their own set of assumptions, challenges and modeling constraints.

One popular example of text classification is spam filtering in email. Spam filters learn, via initialized settings as well as user-tagged examples, what types of senders, words, links and other characteristics are most indicative that an email is spam. While generating an initial set of indicators for spam emails may seem simple and obvious (e.g., misspellings, mysterious senders, Nigerian princes), generating a list of characteristics that is reliable or exhaustive, and which is highly accurate across accounts, languages or time, suggests just one of the main challenges of supervised learning tasks: specifying categories and characteristics. Search engine indices, another application of text classification, also confront this challenge of applying a constrained set of categories to an increasingly large number of highly complex pages that change over time. As daunting as these tasks may appear in applications that many people utilize on a daily basis, the underlying challenge applies to classification tasks in social and political science as well.

Mosteller and Wallace (1963) demonstrate the applicability of this type of text classification to questions in political science. Mosteller and Wallace undertake an authorship attribution task to attempt to identify the authors of the anonymously written *Federalist Papers*, using a Bayesian approach (a predecessor to Naïve Bayes) to distinguish papers most likely written by Hamilton from those most likely authored by Madison. This approach also generalizes to other authorship attribution problems focused on differences in writing style, including identifying the author's gender or demographic characteristics. Sentiment analysis, discussed in depth elsewhere in this *Handbook*, is another common example of classification: identifying words that appear in text and counting and categorizing them according to their tone, mood or emotional content.

A key component of the successful implementation of classification in a case like

Mosteller and Wallace's, however, is the presence of text with known category labels. For Mosteller and Wallace, these were texts known to be authored by Hamilton and Madison, to which unattributed *Federalist Papers* could be compared. While automation may speed the sorting of documents into classes, generating labels for texts and applying these labels to an initial 'training' set of documents presents both theoretical concerns and practical limitations when creating hand-coded labeled corpora for analysis (Manning et al., 2009). In addition to resource-intensiveness, issues with inter-coder reliability in applying known class labels can threaten the consistency and quality of results in text classification projects.

The development of crowdsourcing platforms to distribute the task of labeling training data, or algorithms such as *ReadMe* (Hopkins and King, 2010) that can efficiently predict classes with fewer training observations, have facilitated more text classification projects in political science than resources would previously allow. Yet these gains in efficiency do not resolve the primarily theoretical problem of defining and delineating categories to structure supervised learning.

Unsupervised approaches, in turn, face different assumptions and raise additional challenges despite the appearance of being less model-reliant. For topic modeling projects, for example, while an unsupervised approach allows for the discovery of new classes and latent organization within and among texts, it remains the job of the researcher to interpret the topics identified in the modeling procedure and the words that characterize them. Making these automatically generated topics legible and ensuring their relationship to the initial research question is related to parameter choices made at the outset of the modeling process, but is not obviated by them. The next section discusses these design considerations and challenges for both supervised and unsupervised approaches in greater depth.

## DESIGN AND PROCEDURE

This section describes the design and implementation of text classification projects from the initial step of identifying documents and labeling training data through to the analysis of the test set and validation of the results. While the process used to collect and extract the text data will influence the ultimate quality of the analysis, the steps for collecting and processing text data are covered extensively elsewhere and therefore omitted from this discussion. Rather, this section begins with a discussion of how to define and design a text analysis project with classification in mind.

A key, often undiscussed, assumption that inheres to text classification projects is the coherence of the corpus under examination. Supervised approaches may not adequately distinguish among texts that fit the underlying assumptions of the categorization and those that do not, while unsupervised approaches will merely ‘discover’ structural qualities of the text (e.g., shifts across time or subject matter) that might have been apparent prior to the analysis or that may be of less interest. That is, using automated text analysis procedures does not absolve the researcher of responsibility for ensuring that the texts under examination are related to the research question and have theoretical consistency. For example, texts may be selected for inclusion in a corpus on the basis of keyword searches, themselves a form of classification that can produce errors, omit relevant documents and include irrelevant ones (Hillard et al., 2008). Even having identified and justified the integrity of a particular corpus, the unit of analysis will also influence the nature and quality of classification results. Throughout this chapter, the unit of analysis for classification is referred to as the ‘document’, but classification can be conducted at lower units of analysis as well (e.g., sections, paragraphs, sentences, words).

While not discussed in depth here, a prerequisite for classifying text data is formatting the data to be machine readable and structured according to the features most

appropriate for analysis, where terms (words) are the most commonly selected feature of interest. Most applications of text classification use a *bag-of-words* approach, meaning that words are treated as units without respect to their order. Each document, then, appears in the dataset as a vector of counts for each word present, eventually comprising a *document–term matrix*. Words may also be weighted according to how rare or frequent they are in the corpus via a *tf–idf* (term frequency–inverse document frequency) matrix (Manning et al., 2008).

Once the researcher has constructed their corpus and divided it into appropriate units of analysis, procedures diverge depending on whether the ultimate objective is a supervised or unsupervised task. For a supervised task, data should be divided into training and test sets. The classification algorithm will eventually ‘learn’ about appropriate categories and classes via the training data, and then apply these insights to classify the text data. Practically speaking, separating data into training and test sets is typically achieved via random partitions. At one extreme, where no training data are available, or the dataset does not allow for separation into training and test sets, relying on a priori manual coding rules is necessary; while the dictionary-based classification can be automated, the project is greatly simplified (e.g., only documents containing the word ‘Republican’ will be classed as ‘conservative’).

How much data are allocated to each set will depend in part on the project objective, the size and diversity of the corpus and the complexity of the problem. If a category does not occur, or occurs extremely rarely, in the training set, there is insufficient opportunity to ‘learn’ about this category and its properties, which will in turn interfere with the process of classifying test-set documents into this category correctly. When attempting to detect small changes or rare categories, therefore, increasing the probability that they are observed in the training set often means increasing the size of the training set relative

to the test set. The feasibility of achieving an optimal training/test split for a given research question will in part depend on the size of the corpus; that is, some research questions emphasizing particularly complex or difficult-to-detect classes, which in turn require larger training sets, may be best served by selecting a large corpus at the outset and allowing flexibility in achieving the appropriate training/test split. Hopkins and King (2010) provide additional guidance on selecting the size of training and test sets.

## SUPERVISED METHODS

For supervised problems, the researcher is aiming to classify documents into a set of known or assumed categories based upon rules or information that can be learned from the training set. This requires *labels* in the training set from which to infer categories in the test set. Once labels are applied to the training set and a supervised learning method generalizes from this training set to the test set, only validation of the model remains. While data in some sorts of tasks, such as author-attribution problems, are conveniently pre-labeled, most often this step of the research requires human effort, whether via experts, trained research assistants or crowdsourcing on platforms like Amazon's Mechanical Turk.

Manually generating this initial set of labels can prove arduous and time-consuming, but is also fraught with concerns about consistency and accuracy. King et al. (2017) highlight this problem with respect to human keyword selection: when attempting to identify and recall keywords for search and collection tasks, humans are extremely unreliable and inconsistent. That is, while labeling training data often requires the use of human coders to sort texts into desired categories, human coding lacks consistency and reliability both within and across individuals, above and beyond the time and expense required to complete the task.

Conditional on having identified a set of classes into which documents will fit, and defined labels for a training set of those documents, several possible supervised learning approaches exist to conduct text classification, including Naïve Bayes, Support Vector Machines (SVMs), k-Nearest Neighbors and logistic regression approaches.

Once texts are correctly processed and formatted for analysis, several classification techniques are available. Naïve Bayes is an appropriate tool for classification of high-dimensional feature spaces, of which text is a classic example (Hastie et al., 2009: 210). Naïve Bayes applies Bayes' Rule to a given document  $d_i$  for a given class  $c$ :  $P(c|d_i) = \frac{P(c) \prod_j P(d_{ij}|c)}{\sum_{c'} P(c') \prod_j P(d_{ij}|c')}$ . That is, Naïve Bayes determines the class into which a given document most likely fits given the features of the document. Notably, Naïve Bayes treats these features as though order does not matter (a typical bag-of-words condition) and as though they are independent given the class (conditional independence). The latter assumption about feature independence conditioned on class is what makes Naïve Bayes 'naïve': this is a *strong* assumption that is necessarily inaccurate for text data, where the existence of some features will highly correlate with the existence of others. That is, using words as features, documents are predicted to belong to a class according to whether some words are present while other words are not, but words often co-occur with a regular frequency, which can complicate the classification process.

To provide an intuition for Naïve Bayes, suppose you want to classify newspaper articles according to whether they cover a 'political' subject or not. You encounter the following example phrases in your training set:

<i>Phrase</i>	<i>Class</i>
'The end of election season'	Political
'A new storefront'	Not political
'Closing the polls'	Political
'Parades drew crowds'	Not political
'A close contest'	?

Using Naïve Bayes, you want to estimate  $\Pr(\text{Political} \mid \text{'A close contest'})$ , using features such as relative word frequency (i.e., how often

does that phrase appear in articles known to be political versus not?). Constructing the desired probability via Bayes' Rule, you would have:

$$\Pr(\text{Political} \mid \text{'A Close Contest'}) = \frac{\Pr(\text{A close contest} \mid \text{Political}) \times \Pr(\text{Political})}{\Pr(\text{A close contest})}$$

Note that the divisor serves as a scaling constant across both classes of interest. This exact phrase may not appear in the training set, however. Phrases are larger components of text than individual words, and are therefore less probable than the words that

comprise them. To overcome this challenge, the bag-of-words assumption then is useful – rather than calculating the probability of the phrase, we can calculate the joint probability of these component words due to their assumed independence:

$$\Pr(\text{'A close contest'}) = \Pr(a) \times \Pr(\text{close}) \times \Pr(\text{contest})$$

Useful though it may be, this assumption is necessarily strong: words tend to co-occur regularly, rather than appearing with independent frequency. Furthermore, the model incorporates Laplace smoothing of final estimates to compensate for the non-appearance of certain terms in the training data.

Because it primarily emphasizes counting features, Naïve Bayes has persisted as a fast, reliable and less memory-intensive approach that works well even with relatively little training data (although it suffers from bias, as per Ng and Jordan, 2002), and significantly better with a very large amount of data. Likewise, it works well with many, equally weighted features, while irrelevant features will cancel out, and does not tend toward overfitting on smaller datasets as other approaches do.

For medium-sized datasets, where Naïve Bayes suffers most from high bias, Support Vector Machines (SVMs) provide a viable alternative. SVMs find the optimal separating hyperplane between data points by maximizing distance (the 'margin') between a given hyperplane and the points nearest to the decision boundary that would be most challenging to classify; that is, it is one example of a *maximal margin classifier*. Because full separability among latent classes may not exist, this margin is 'soft', which gives rise to the support vector. SVMs

generalize to sets of classes greater than two as well, either via using a multinomial loss function or by reducing the problem to a two-class solution (comparing one-to-one or one-to-all).

k-Nearest Neighbors (KNN) approaches similarly use observations within the training set and locate other observations in their 'neighborhood' to predict outcome values in a regression framework. That is, the regression identifies the  $k$  training observations that exist closest (in Euclidean distance) to a given point of interest  $x_0$  (a 'neighborhood'  $N_0$ ), and then estimates  $f(x_0)$  using the average of those training responses:

$$f(x_0) = \frac{1}{|N_0|} \sum_{x_i \in N_0} y_i$$

Implementing kNN requires selecting an optimal value of  $k$ , where that optimal value depends on a researcher's assessment of the bias–variance tradeoff. Small values of  $k$  will generate low bias, high variance responses; larger values generate 'smoother' outcomes (high bias, low variance).

## UNSUPERVISED METHODS

Supervised classification methods assume defined types or categories into which

documents fit. Within the realm of computer science or information retrieval, supervised approaches are therefore definitionally ‘classification’, since the typology into which documents are sorted already exists, and the procedure for correctly identifying documents that belong to these prescribed categories is the central focus. In political and social science applications, however, ‘classification’ is a broader theoretical project, part of the overarching objective to generalize and infer information from the data at hand. To that end, even projects where categories and major characteristics are unknown can be thought of as ‘classification’ projects.

For this type of goal, when the research design seeks to discover the set of categories among the texts in a corpus, unsupervised methods such as clustering and topic modeling are appropriate. Unsupervised approaches can both generate categories from the features of text and assign (classify) texts according to those categories. While a variety of techniques and variations or refinements of general algorithms exist to conduct unsupervised learning about text categories, this section primarily focuses on two commonly used options: k-Means and Latent Dirichlet Allocation (LDA).

For unsupervised problems, no pre-set categories exist into which documents must be classified. Rather, ‘classification’ occurs via the discovery of underlying characteristics and categories within text. With high-dimensional and complex data like text, identifying all possible partitions of the text is neither feasible nor useful for answering social science questions. Rather, unsupervised approaches ideally allow researchers to uncover characteristics and categories that have theoretical significance and perhaps substantive importance.

Directly generalizing from the supervised case in which a researcher seeks to classify documents according to their known set of categories (e.g., according to partisan identification or authorship), an analogous

unsupervised task supposes that documents or sets of text belong to a single category or class, but does not impose a label on that class a priori. For the k-Means algorithm, this assumption means that the model seeks to minimize the difference between documents that define a cluster, where that difference is measured as their squared Euclidean distance in vector space. Once the researcher selects a number of clusters  $k$ , the k-Means algorithm produces a set of partitions for the documents in the corpus that minimize the distance between documents within each cluster from the cluster centroid. That is, it seeks to minimize within-cluster variation across all possible clusters.

Yet because k-Means relies on an approximation for optimization, it is subject to convergence problems and dependence on initialization values. For social science questions, furthermore, k-Means has additional pitfalls in its ability to adapt to the inclusion of new data or to appropriately evaluate true ‘outlier’ observations: new data may disrupt the pattern giving rise to the original partition, and determining which classification to ‘prefer’ is a matter of theory rather than one of model output, while ‘outlier’ observations are likewise coerced into inclusion in clusters as part of the distance minimization procedure. In addition, the selection of  $k$  is based on a metric of diminishing marginal returns for additional clustering – once the total within-cluster sum of squared distance decreases past a certain threshold, a larger  $k$  no longer decreases within-cluster variation. While practical, this parameterization may seem deeply atheoretical for certain social science projects.

Likewise, k-Means operates from an assumption that each document must belong to a category and that categories do not overlap. Mixed membership models such as *topic models* instead emphasize categories at the level of the word that can then generalize to the level of the document. The most common type of topic modeling, Latent Dirichlet Allocation, begins from the assumption that

each document is a mixture of topics; that is, topics are multinomial random variables defining a mixture model from which words are sampled (Blei et al., 2003). Documents, then, are a probability distribution over topics (Blei, 2012). In this sense, a whole document may be ‘classified’ into a given topic, but more accurately portions of documents are classified into topics across the entire corpus.

Colloquially, the notion that unsupervised methods are superior, in that they are not ‘model dependent’ like supervised approaches, is prevalent. Yet, far from achieving superiority or more ‘objectivity’, unsupervised approaches present their own set of challenges, namely in validation and researcher discretion. In addition to topic models producing unstable results across iterations (Wilkerson and Casas, 2017), validation of unsupervised models can prove difficult since labels and categories were not chosen prior to analysis. Several possible methods of validation are possible. Human coders can identify words that distinguish topics and conduct manual labeling to check the output of the automated model, but this is often intractable or counter to the purpose of an unsupervised method. Experimental validation can vary word or topic inclusion in the model to assess variation in results, or metrics such as exclusivity (words having a high probability in one topic have low probabilities in others), entropy (difference between topics) and cohesion (the affinity of particular words with a given topic versus others, such as with pointwise mutual information) may be used. Grimmer and Stewart (2013: 287) distinguish between semantic validity (coherent representation of concepts within topics) and predictive validity (validity in comparison to external circumstances or shocks). Which approach is most suitable for validation is not clear *ex ante*, and current validation procedures are often designed as bespoke solutions for a particular research problem rather than as tried and tested methods that generalize for unsupervised approaches.

## APPLICATIONS OF SUPERVISED METHODS

Supervised methods have been used for a range of political science questions and applications, for projects ranging from political economy to international relations. Within these varying applications, furthermore, authors select the type of supervised approach most appropriate to the topic. O’Halloran et al. (2016), for example, utilize Naïve Bayes to evaluate financial regulatory laws from the United States, assessing the extent to which legislation reflects ‘agency discretion’ since 1950. For their research, Naïve Bayes performs better than focusing only on manually coded text features or a set of computer-generated features when attempting to classify documents according to a ‘score’ for the amount of delegation they prescribe (O’Halloran et al., 2016: 106). This research on financial regulation is just one instance in which automated classification demonstrates improvements over a research design relying solely on human analysis.

D’Orazio et al. further note that while researchers may want to gather information on a specific topic, *how* exactly to identify what information is relevant and to organize these data for analysis is not clear (D’Orazio et al., 2014). While the authors address document classification in political science broadly as a technique with a variety of applications, they particularly emphasize the value of SVMs as a linear classification approach that does not require as much labeled training data but nevertheless handles sparse text data well. The paper introduces a two-step SVM approach that facilitates classifying 1.74 million news documents from the Correlates of War Militarized Interstate Dispute (MID) data. While D’Orazio et al. highlight the challenges that other types of classification (e.g., Naïve Bayes or k-Nearest Neighbors) would pose for their data, other applications to questions of political interest seek to evaluate appropriateness or combine approaches for greater accuracy and

flexibility. Mickevicius et al. (2015), for example, test both SVM and kNN in classifying the topics of Lithuanian parliamentary votes to evaluate which approach is most efficient, concluding that SVM is most accurate in their desired application. Similarly, Collingwood and Wilkerson (2011) assess how much labeled training data is necessary for a variety of approaches, including SVM and Naïve Bayes, noting that particularly for SVM, machine classification is on par with trained human classification even with only 15% of data labeled.

Another classic example of classification in political science pertains to party or ideological classification, often from Congressional speech or legislation (e.g., Yu et al., 2008). Diermeier et al. (2011) use SVMs to identify words most indicative of conservative versus liberal policy positions using legislative speeches from the US Senate. That more ‘cultural’ terms, rather than economic ones, provide the most leverage in distinguishing between political ideologies runs counter to expectations, and demonstrates the value of directly engaging with and classifying textual references in an automated fashion. Human coders with prior training in political science theory might have been primed to think economic language was most distinct or important and classified accordingly, while even an automated approach predicated on knowing the ideological position of some senators in the sample was able to uncover ‘culture’ words as a useful measure of distinction. This type of task, predicting party affiliation or ideological leaning based on speech, is particularly prevalent among political science applications. Evans et al. (2007) likewise utilize several modeling techniques, including Naïve Bayes, to classify amicus curiae briefs from the affirmative action cases in *Bakke* (1978) and *Bollinger* (2003). Classification research seeking to identify ideological dimensions now also leverages new data sources, such as Facebook pages and posts (see, e.g., Chiu and Hsu, 2018), and can extend beyond these typical dimensions

like partisanship to apply to other areas, like re-constructing China’s censorship architecture via observed banned terms and websites (King et al., 2013).

As these examples illustrate, the potential applications for supervised text classification in political science are many and varied, but authors have the responsibility to adjudicate between existing classification algorithms and approaches to determine which is most suitable given the size and nature of their text data. In addition, while manual label generation for supervised methods remains costly, recent efforts to automate procedures for providing labels for text documents could significantly improve the uptake and efficiency of supervised approaches. Hopkins et al. (2010) introduced the *ReadMe* software, which takes text documents and a classification scheme selected by the user as inputs to produce a proportion of documents aligning with those categories. Likewise, *RTextTools* combines all preprocessing and classification steps, as well as assessments of algorithm accuracy and ensemble results, into a single package (Jurka et al., 2013). Miller et al. (n.p., 2018), for example, draw on a variety of active learning approaches to overcome the issue of sampling unlabeled data for the purposes of text classification. Creative combinations of approaches and applications to new data – see, e.g., Ku and Leroy (2014) on classifying crime reports using a combined ‘decision support system’ with aspects of Naïve Bayes and logistic regression, or Sapiro-Gheiler (n.p., 2018) comparing results across Naïve Bayes, SVM, lasso and decision trees when evaluating Congressional speech data – suggest that supervised text classification has many promising future directions.

## APPLICATIONS OF UNSUPERVISED METHODS

The increasing popularity of text-as-data methods in political science has led to an

explosion of research, particularly in topic modeling. Wilkerson and Casas (2017), for example, evaluate the topics that arose in 10,000 short floor speeches within the US Congress in 2013–14. LDA enables the authors to evaluate which topics emerge most frequently, and whether partisan affiliation impacts which topics are spoken about. Mueller and Rauh (2018) also use LDA to assess topics within newspaper text, which then serve as a basis for predicting conflict in a panel regression setting. The authors leverage evolution and change in topics within text, as well as their relative stability over time given the nature of newspaper coverage, to tackle the notoriously difficult task of predicting variation in conflict onset.

In a classic example of topic modeling for political texts, Quinn et al. (2010) emphasize temporal variation in topic analysis for political texts, specifically political speeches that have a single (but unknown) topic. Again, the distinctions which the authors highlight in their data (e.g., that speeches focus on a particular topic but that distinguishing and identifying topics presents a challenge) relative to computer science applications of dynamic topics indicates that political science has much to contribute in the evolution of text classification methods for questions and subjects that might otherwise be overlooked.

## COMPLICATIONS AND EXTENSIONS

The starkest limitation of supervised classification methods is the requirement that categories be pre-defined. This theoretical limitation then directly relates to the practical challenge of acquiring labeled data on which to train a classification algorithm. The arduousness of labeling training data for supervised approaches should not, however, be interpreted to suggest that unsupervised methods have greater utility or more efficiency or are more ‘objective’ by dint of omitting larger scale manual coding. Rather,

supervised and unsupervised approaches may be used in tandem for similar projects and research questions, but should also each be evaluated on their merits for a particular application according to their strengths and pitfalls. The advent of automated methods for text classification opens up a vast array of possibilities for research questions in every subfield of political science that seek to utilize increasingly large and complex text datasets.

As Hopkins and King (2010) note, however, methods adapted from computer science do not necessarily satisfy the research aims of social science, and should be adopted and adapted with care. Rather than an emphasis on classifying particular documents, they argue, social scientists aim to generalize: a task to which supervised classification methods are not particularly well suited. The development of text classification, categorization and clustering techniques by social scientists is therefore critical to the existence of models and approaches that better account for the objective of inference, rather than prediction.

For many social science questions, for example, metadata about the source, speaker, date or other characteristics of the documents in a corpus can provide useful insights and condition the presence and prevalence of topics or categories in text. This observation prompted the introduction of structural topic models (STM) by Roberts et al. (2016), where topics are conditioned on document-level covariates. Roberts et al. (2014) apply this method to open-ended survey responses, bridging a gap in literatures between machine learning methods for text analysis and causal identification – a goal of particular interest to social and political scientists. As with topic modeling using LDA, STM requires the researcher to select an appropriate number of topics for their corpus, and while the output has greater structure than with LDA, interpretation of topic prevalence and content is still at the researcher’s discretion. While this is only one example, STM represents the

promise and possibility of not only applying text classification techniques from other fields to the questions and problems that are most pressing in political science, but also innovating on these tools to better serve social science research aims.

# Sentiment Analysis and Social Media

Luigi Curini and Robert A. Fahey

## **'HOW DOES IT MAKE YOU FEEL?'**

Sentiment analysis, sometimes also called tone analysis (Grimmer and Stewart, 2013) or opinion mining (Dave et al., 2003), is a set of methods designed to answer the same deceptively simple question – how do people feel about a given subject? More precisely, given a specific topic (which might be a product in the case of a marketing analysis, or a politician, party or policy in the case of a political analysis), do the authors of a certain set of texts express positive or negative feelings with regard to that topic?

This is the kind of task which humans generally find intuitive and simple, but which transpires to be exceptionally complex and difficult for computers to perform. A class instructor reading over their end of term feedback forms will quickly form a sense of whether students enjoyed the course or not. A computer performing text analysis on the same data, however, faces a number of daunting problems. A text analysis algorithm will

lack context, so students' references to specific topics or events during the semester will be rendered meaningless. It may find some of the casual or idiomatic language students use difficult to parse or recognise (in this, at least, many instructors may sympathise). Moreover, given the inherently stochastic nature of text and working from such a limited set of data – just a few dozen pieces of text – it may be unable to establish any consistent framework for what a 'positive' or 'negative' piece of feedback actually looks like.

In spite of this difficulty, sentiment analysis has become an essential tool in many fields across the social sciences. Like many other text analysis techniques, its great strength lies in its ability to handle large volumes of data. While a human being may make a more reliable and nuanced judgement of sentiment on a single piece of text, or a small number of texts, it is impossible for a human to read and analyse the volume of texts generated by, for example, product reviews on a major website, or the customer feedback form for

a popular product. The problem of volume is compounded further when social media is the focus of study; a major event can generate millions of posts per minute on a site like Twitter and even a relatively obscure topic may leave researchers with hundreds of thousands, if not millions, of posts to analyse. Effective application of sentiment analysis to social media has created remarkable new possibilities for political and social researchers – for example, real-time sentiment analysis of Twitter data has allowed researchers to see how audiences are reacting moment-to-moment to election broadcasts and candidate debates (Wang et al., 2012; Smailović et al., 2015).

This chapter will introduce a range of different approaches which are used for sentiment analysis, broadly categorising them according to the form of methodology employed and discussing the benefits and limitations of each approach. There is no single ‘best in breed’ approach to sentiment analysis and a researcher’s choice of technique will depend heavily on the kind of texts they wish to analyse and the resources – in terms of both time and technical skill – at their disposal.

## APPROACHES TO SENTIMENT ANALYSIS

Sentiment analysis approaches can broadly be divided into two major categories – dictionary techniques and supervised learning techniques. Dictionary techniques, as the name suggests, involve constructing a dictionary of sentiment-scored terms and applying it to a text using an algorithm which uses the dictionary scores to calculate the sentiment of the overall text. These approaches range from relatively naïve sentiment scoring of individual words through to more complex techniques, for example taking into account the surrounding context of a word in determining its scoring and weight. Supervised

learning techniques, on the other hand, rely on the creation of a labelled set of data – usually by getting human coders to classify the sentiments of a sub-sample of the data to be analysed. This human-coded data is then used to train an algorithm which will classify the remainder of the (unlabelled) data. While many supervised learning approaches to sentiment analysis, described below as ‘classification methods’, are effectively special cases of the broader text classification methodologies outlined in Chapter 28 of this *Handbook*, another group of approaches – which we refer to herein as ‘aggregate methods’ – do not try to assign a specific classification to every piece of text in a corpus, instead aiming to probabilistically estimate the distribution of sentiment across the corpus as a whole. These aggregate methods are especially well suited to corpora with very large numbers of very short texts – for example, Twitter posts – where individual messages might not contain enough information for standard classification approaches to make a reliable determination about sentiment.

### **Dictionary Approaches**

Dictionary, or lexicon-based, approaches to sentiment analysis rely, at the most basic level, on identifying specific words as being positive or negative and calculating the sentiment of a text based on those scores.<sup>1</sup> The most challenging aspect of this approach is compiling the sentiment dictionary itself; many different ways of tackling this problem have been developed, such as crowdsourcing lexicon entries through services such as Mechanical Turk (Haselmayer and Jenny, 2017); using a thesaurus to iteratively ‘snowball’ out from an initial set of human-chosen positive and negative seed words; estimating positive and negative weights for new words based on the frequency of their co-occurrence with known words in a large text corpus; or using pointwise information to calculate the probability of given words appearing in

positively or negatively coded documents. This process is generally complex and resource-intensive, and generally beyond the scope of a political science research project; while there may be circumstances in which a political science researcher decides to compile their own sentiment dictionary (either selecting terms by hand, an example of which can be seen in Rooduijn and Pauwels' (2011) work on identifying populism in text, or by refining existing lists of words to make the sentiment scoring more relevant to a specific field, such as in Loughran and McDonald (2011)), it is much more common to use an existing dictionary that has been compiled and tested by researchers in the fields of natural language processing or computational linguistics.

The availability of pre-compiled sentiment dictionaries – such as the MPQA Subjectivity Lexicon (Wilson et al., 2005), the Hu & Liu Opinion Lexicon (Hu and Liu, 2004), SentiWordNet (Baccianella et al., 2010), AFINN (Nielsen, 2011) or EmoLex (Mohammad and Turney, 2013) – makes dictionary-based sentiment analysis an attractive option for researchers simply due to its simplicity. In fact, popular text analysis software packages such as R's *tidytext* (Silge and Robinson, 2017) or Python's NLTK (Bird et al., 2009) come with a variety of sentiment dictionaries pre-installed, making it very easy for researchers to try out dictionary approaches on their text data. The major advantages of dictionary-based sentiment analysis approaches lie in their speed and simplicity, allowing researchers to rapidly assess the sentiment expressed in very large datasets with minimal use of resources. While this makes these approaches attractive for certain applications, especially where real-time analysis is required, significant concerns over the accuracy of these methods limit their potential in political science research.

The major weakness of these pre-compiled dictionaries is that they are by nature very generalised and lack the domain-specific

features which might be required for sentiment analysis of a topic that has specific associated vocabulary and language features. On a broad level, this means that some dictionaries are not appropriate for classifying certain types of text – a dictionary trained using a corpus of formal language (such as the text content of Wikipedia or a large corpus of newspaper articles) would perform poorly in classifying the sentiment in a casual, slang-heavy corpus of social media posts, and vice versa. To address this problem, domain-specific pre-compiled sentiment dictionaries have been created: AFINN and the VADER Sentiment Lexicon (Gilbert and Hutto, 2014) are designed for the kind of text commonly found in social media posts, while other dictionaries encompass vocabulary related to a specific topic (for example, the Loughran & McDonald sentiment lexicon for financial texts: Loughran and McDonald, 2011). These dictionaries go some way towards making lexicon-based approaches viable for a wider range of applications, but fundamental problems remain. Dictionaries are static, while language is ever-evolving – especially in the political domain, where words and phrases can take on new meanings or implications very rapidly during the course of an electoral campaign or political news cycle.

A further challenge for dictionary approaches relates to how the scoring of the lexical dictionary is applied to the text. In the simplest possible model, the positive and negative sentiment scores for each word in the text are added together to yield a final score. While this approach is intuitive, its drawbacks are easy to see. Consider the following sentence from a review of a movie:

*The movie has a fantastic cast, an interesting concept and amazing special effects – but it is utterly boring.*

A naïve calculation based on a sentiment dictionary would almost certainly find that this sentence was positive due to the presence of a large number of positive words ('fantastic', 'interesting', 'amazing', 'special') and

only one negative word ('boring') – yet to a human reader it's very obvious that the overall tone of the sentence is in fact negative. In order to improve on the accuracy of this kind of approach, algorithms have been developed which take into account additional features of the text. Where the naïve dictionary approach is a pure 'Bag of Words' approach, which is common to many text analysis methodologies and treats a document purely as a collection of words, ignoring the order of those words or the relationships between them, more advanced algorithms draw instead on the field of Natural Language Processing (NLP). A simple but effective example is the VADER algorithm, which incorporates a number of features that improve the accuracy of dictionary-based classification – for example, it understands various forms of negation (so 'not good' and 'this wasn't good' would both be treated as negative despite 'good' being a positive word), contrastive conjunctions such as 'but' or 'however', words which alter the intensity of a sentiment (like 'utterly' in the example sentence above) and the presence of emoji in social media posts. These improvements make VADER and similar algorithms more effective than naïve dictionary-based sentiment scoring without increasing the complexity for researchers using the tool. Even more advanced ways of applying sentiment dictionaries continue to be developed by NLP researchers, but often introduce a degree of technical complexity or resource-intensive computation which puts them beyond the reach of most researchers seeking to implement a practical sentiment analysis: the Stanford Sentiment Treebank (Socher et al., 2013), for example, achieved an improvement in classification accuracy over other approaches by using an artificial neural network to process sentence structure, but this introduces a computational and technical overhead which is likely to be impractical for most researchers.

The domain-specificity of sentiment dictionaries means that a given dictionary can

only be used effectively to classify sentiments in text that follows broadly the same linguistic styles and standards as the corpus used to create that dictionary. As a consequence, while a large number of sentiment dictionaries exist for English, and dictionaries have also been created for other major languages, there are a significant number of languages for which few, if any, high quality sentiment dictionaries exist (Mohammad, 2016). This significantly restricts the potential for using sentiment dictionary approaches in analysis of text in minority languages, or in cross-linguistic analyses; while attempts to apply English-language sentiment dictionaries to other languages using machine translation tools have been made, there is little evidence to support the effectiveness of such an approach. Nonetheless, sentiment dictionaries remain a useful set of techniques for use in exploratory analysis of data, or for providing supporting evidence in research where sentiment analysis is not the primary analytic tool being employed.

### ***Supervised Learning Approaches***

Unlike dictionary-based approaches, which make *a priori* assumptions about the positive or negative meanings of specific words in a lexicon, supervised learning approaches begin with a blank slate each time, making no assumptions about the sentiment or meaning of any word in the corpus. Instead, a subset of the corpus is classified by human coders and this labelled set is used to train a machine learning algorithm, which will then estimate the sentiment of the rest of the corpus based on the patterns and correspondences found in the labelled set. One set of algorithms, the classification algorithms, attempt to accurately classify the sentiment of each individual unit of text in the corpus (in this regard resembling the dictionary approach described above); another, the aggregate algorithms (sometimes called proportional classification algorithms:

Wiedemann, 2018), focus instead on accurately estimating the distribution of sentiment across the entire corpus.

The drawback of such approaches is immediately obvious – you cannot proceed without first creating labelled data. While a pre-compiled sentiment dictionary allows you to instantly start exploring the sentiments in a corpus of text data, supervised learning approaches require that you first classify a sample of the data by hand. This brings with it the usual problems associated with human content coding – the need to train coders, to verify the consistency of their work using inter-coder reliability measures and to decide on an appropriate sampling approach and sample size to classify.
