Of these, the question of how much data is needed to train an algorithm is a common sticking point for researchers. The most common response is ‘as much as possible’; Hopkins and King (2010) offer 500 as a rule of thumb. While algorithms have been shown to have a learning curve which eventually flattens out, leading to diminishing returns from the creation of additional labelled data (Figuroa et al., 2012), the complexity of text classification and the resource constraints faced by most researchers make it unlikely that they will reach this point, so as a general rule more labelled data is better. In more practical terms, we can think of the volume of labelled data required as a function of the number of inputs (i.e. the size of the vocabulary being used in the texts) and the number of outputs (the number of categories to classify). A text corpus which addresses a wide range of different issues will require more labelled data than a more narrowly focused corpus; for example, a set of social media posts addressing a specific policy initiative will have a smaller lexicon of relevant vocabulary than a set of posts about a candidate in a major election, as the latter will likely include posts discussing a range of different issues and policies. As such, more labelled data would be required for the latter data set, even if the actual sizes of the two corpora

were the same. The choice of algorithm is also relevant to this question; as a general rule, aggregate algorithms require less labelled data than classification algorithms.

The other main challenge to keep in mind when dealing with building an appropriate and reliable set of labelled data relates to the sampling of documents. Classification methods implicitly assume that the labelled set is a random sample from the population of documents to be coded, in terms of the opinions expressed (but see below the discussion about aggregate algorithms) as well as, crucially, the language employed. This is because supervised learning methods use the relationships between categories and features in the labelled set to classify the remaining documents. Such algorithms are flexible enough to classify any kind of data that can be broken down into ‘tokens’ (features), but simply cannot classify the sentiment of any feature which was not encountered in the labelled data. As such, if an important word or other such feature (like an emoji or a hashtag) was not included in the texts classified by human coders, the trained algorithm will miss its relevance to the sentiment of the texts it classifies. This presents particular difficulty when all the data are not available at the time of coding of the labelled set, for example in situations where all the data have not yet been digitised or, as is often the case with sentiment analysis on social media, where data will continue to be produced in the future. This causes situations where the difference in the language between the labelled set and the unlabelled set grows over time, such as when new words and phrases, or new meanings of existing words and phrases, appear in the latter set but not in the former set. For example, a politician may introduce a new slogan during a speech which was not part of the common lexicon at the outset of a campaign period, or a common word may take on a new meaning through association with a scandal or a major policy. Alternatively, the inverse may occur, and words, phrases and their meanings may exist in the labelled set

but not in the unlabelled data. This is most common in long-term analyses; for example, in the years after the fall of the Berlin Wall, terminology related to the Cold War largely disappeared from political rhetoric. Some of these challenges may be partially addressed with the use of distributed word embeddings, a technique which has become popular in natural language processing and computational linguistics (Goldberg, 2016; Pennington et al., 2014; see also Chapters 26 and 55 of this *Handbook*). Word embeddings represent words in a continuous vector space in which words with similar meanings are mapped closer to each other. Using a set of word embeddings appropriate to the texts being analysed can allow new words encountered in the unlabelled texts to be classified according to their similarity to words that were present in the labelled texts (Rudkowsky et al., 2018). This does not, however, account for the arising of new meanings for words, such as the naming of new scandals – word embeddings produced from early 1970s texts would correctly identify ‘Watergate’ as being close in meaning to the word ‘hotel’, but would need to be regenerated from new texts to identify its new meaning closer to ‘scandal’ and its consequent importance to political sentiment.

Once the sample has been classified, the subsequent process is broadly the same regardless of which kind of algorithm is used. As a result, researchers often train multiple algorithms and test to see which approach, and which algorithm, is more effective for their specific case. This testing is performed by repeatedly splitting the labelled sample data into ‘training’ and ‘test’ sets, training the algorithm on the former and then testing it on the held-out data in the latter – a process known as cross-validation. The algorithm which performs most effectively and consistently in these tests is then used to classify the entirely unseen texts in unlabelled data set.

For the purposes of explaining classification and aggregate algorithms, let us assume that we have a labelled corpus (classified

by human coders) of  $N$  distinct texts, sampled from the overall corpus (which we label  $C$ ) we wish to classify. Let us denote by  $D = \{D0, D1, D2, \dots, DM\}$  the set of  $M + 1$  possible *categories* (that is, sentiments) expressed in the texts.  $D0$  denotes the likely most prevalent category in the data – generally, ‘off-topic’ texts or those which express opinions/sentiments not relevant with respect to the analysis, that is, the *noise* in this framework. Noise is commonly present in any corpus of texts crawled from social media and the internet in general and should be taken into account when we evaluate a classification method (a point to which we will return below).

Suppose that after pre-processing the text (removing irrelevant words and features, stemming or lemmatising as appropriate, and so on) we are left with  $L$  features (word stems, or tokens). The document-term matrix  $S$  representing our corpus then has  $N$  rows and  $L$  columns, with each document  $j$  being represented by a vector  $S_j$  of length  $L$ . The value of each element of the vector  $S_j$  may either be the frequency with which that feature appeared in document  $j$ , or a binary value – 1 if the feature appeared at all, 0 if it did not. This latter representation is commonly used for short documents such as social media posts, since the frequency of a given word is most likely to be 0 or 1 anyway; for longer documents the range of word frequencies is much greater and of more importance. If the lengths of the documents being studied differ significantly (which is usually not the case for social media posts) it is also necessary to account for this in their vector space representation, for example by weighting the vocabulary frequency inversely to the length of the document. Note that the overall document-term matrix ( $S$ ) is often quite a large data set but very sparse, in that it contains a large number of zero values since each document only contains a small subset of the overall lexicon of the corpus  $L$ .

Regardless of the subsequent approach taken to sentiment analysis, this document-term

matrix  $S$  will be the basic data set used. To ensure the robustness of the entire estimation strategy, cross-validation is performed. This process entails dividing the labelled data into a number of equal-length, randomised segments (usually between 5 and 10) and using each segment in turn to train the algorithm being tested. Each of these trained algorithms is then tested against the remainder of the labelled data, which is called the ‘held-out’ data – so for example, if the labelled data is divided into five segments, the algorithm being evaluated would be trained five times, each time on 20% of the data, and tested each time against the remaining, or held-out, 80% of the data. If an algorithm performs well on each step of cross-validation (for example in terms of its accuracy, that is, the proportion of correctly classified documents)<sup>2</sup> it can be expected to perform reliably on entirely unseen data as well (that is,  $C-N$ ); conversely, an algorithm which fails on a given cross-validation step may be poorly suited to a specific permutation of features that arises in the data.

### *Classification algorithms*

There is a very wide variety of different classification algorithms, ranging from those which will be familiar to most researchers with a background in statistics, such as Naïve Bayes, through to complex and computationally intensive algorithms such as Neural Networks and Random Forests (see Dreiseitl and Ohno-Machado, 2002 for details of many of these models). The differences between classification algorithms are the subject of very extensive literature in statistics and computer science which is beyond the scope of this chapter – an in-depth overview of the field as a whole is provided in Aggarwal (2014). For the purposes of the political science researcher attempting to perform sentiment analysis, the key thing to note is that the training process for any one of these models takes the same input (a training subset of the term-document matrix  $S$  described above) and gives the same output,

a model (or function) which predicts the category  $D_j$  to which a given document  $j$  belongs given that its features are represented by the vector  $S_j$ . This model can be represented as  $P(D|S)$  – for a given document  $j$  and set of categories  $M$ , it will find the value of  $m$ , that is, the classification, which maximises the model  $P(D_{m=0,1,\dots,M} | S_j)$ . Expressing this as a matrix model, the classification algorithm is  $P(D) = P(D|S) P(S)$  – where  $P(D)$  is a vector of length  $M+1$ ,  $P(D|S)$  is a matrix of conditional probabilities and  $P(S)$  is a vector representing the distribution of text vectors across the corpus of texts. This means that regardless of the broad differences in how the algorithms function internally, it is possible to train them using the same data, directly compare their results, and select the one which is most effective for your specific data and usage case. In fact, popular machine learning packages such as Python’s *scikit-learn* (Pedregosa et al., 2011) provide pipeline structures which are designed to automate this entire process of training, testing and comparing algorithms.

Once trained, classification algorithms can be used to predict the sentiment classification of an entirely unseen text. This approach has some significant advantages over the dictionary-based approach. It is by nature domain-specific; the algorithms base their predictions on words or patterns which were relevant to the classification categories in the training set and can often identify the sentiment of a phrase which would be entirely missed by a dictionary approach. A good example is political catchphrases – in the 2016 US presidential election, the phrase ‘lock her up’ was strongly associated with negative sentiment towards Hillary Clinton, while ‘build the wall’ was associated with positive sentiment towards Donald Trump. An effective classification algorithm trained on tweets related to the election would correctly identify the relevance of those terms, while a sentiment dictionary approach would treat both phrases plausibly as being neutral. Classification algorithms are also language-independent;

while some languages require more complex pre-processing steps before the algorithms can be applied, the algorithms themselves do not know or care which language the words (or ‘tokens’) are in, making this approach perfectly effective even in ‘resource-scarce’ languages which lack high-quality sentiment dictionaries.<sup>3</sup>

Nevertheless, classification algorithms are by no means perfect. This is in part due to the properties of the sentiment analysis task itself: not only is language intrinsically stochastic, but there is also a subjective element to the sentiment classification of many edge cases and disagreement even between human coders is normal. Moreover, classification algorithms generally rely on the Bag of Words approach and are unaware of sentence structure; this provides for fast and effective classification but fails on certain edge cases (for example, the Bag of Words representation of the sentence ‘I’m voting for Clinton because Trump is the most corrupt candidate ever’ is exactly the same as the representation for ‘I’m voting for Trump because Clinton is the most corrupt candidate ever’, so a classifier would be unable to distinguish between these polar opposite sentiments). As such, no classifier should be expected to achieve or even approach 100% accuracy in testing against held-out data – in fact, approaching 100% accuracy is likely a sign that the algorithm has been overfitted to the training data and will not be effective at classifying unseen data.

A further problem with classification algorithms can arise when a single category is predominant in the data. This means that during the training process the algorithm ‘learns’ that the vast majority of feature vector configurations are associated with this dominant category  $D_0$ ; only a small subset of specific vectors express any other category  $D_j$ . As a result, for a large proportion of input vectors  $S_j$  the output of  $P(D_i|S_j)$  will be zero, or extremely low, for all categories other than the dominant one ( $i=0$ ). The trained model will therefore tend to overestimate this

category vastly over-represented compared to others when classifying unseen texts. This effect is especially strong when the dominant category is a ‘Off-Topic’ category (a catch-all featuring all documents which did not include a topic or sentiment of interest to the study) as is commonly the case with social media data. This category will contain all of the ‘noise’ that is present in data collected from social media; only a specific subset of input vectors will correspond to the other categories being trained, with every other possible vector (a much larger domain) being implicitly ‘noise’. Depending on the objectives of the researcher, this over-estimation of a dominant category can sometimes be unproblematic – but where the objective is to find the overall distribution of sentiment within a data set, this systematic overestimation can result in significant bias. In the next section we will discuss a new class of algorithms which have been developed also to deal with this bias.

### *Aggregate algorithms*

While classification algorithms aim to predict the sentiment of every individual piece of text in a data set, it is often the case that a researcher is looking for the distribution of sentiment within a corpus of texts and does not actually require an item-level classification. As a result, researchers end up aggregating the item-level classifications, which means that some of the trade-offs that are made by classifiers in the name of providing a single classification for every item – such as the issue of over-estimation of a dominant category, as discussed above – are actually unnecessary and may be needlessly reducing the accuracy of the prediction on the overall distribution. For example, a method that classifies 60% of documents correctly into one of eight categories might be judged successful and useful for classification. However, because the individual category percentages still might be off by as much as 40 percentage points, the same classifier may be useless for some social science purposes

(if individual-level errors do not cancel each other out). Recognising this problem has led to the development of a new set of algorithms which treat the text corpus in an aggregate manner from the outset – they do not provide classifications for individual texts at any point in the process, instead producing results showing the distribution of sentiments within the overall corpus. The first of these algorithms to be released was ReadMe (Hopkins and King, 2010), which has since been joined by iSA (Ceron et al., 2016); while these algorithms have different strengths, they use similar inputs and produce similar outputs, making it possible to train and test them against one another in a similar manner to the algorithm selection process used for classification algorithms.

These aggregate approaches are less flexible than classification approaches, since they cannot be applied to any research that actually requires the classification of individual texts at any point – but in return they offer two major advantages. First, because they are not constrained by the need to produce a classification for every text, they can treat classifications as probabilities rather than binary predictions – so instead of decisively coming down on the side of a text being either ‘positive’ or ‘negative’ (or whatever categories are being used) when it actually shows some features of multiple categories, the algorithm can in essence treat it as being partially positive and partially negative when calculating its impact on the sentiment distribution of the entire corpus. This kind of approach, moreover, can deal well with situations in which the relative frequency of categories in the training set is very unevenly distributed – such as in the above mentioned case of a category containing off-topic ‘noise’ being statistically dominant within the data set – or where the distribution in the training set is quite different from the frequency in the unseen data set.

Expressed in statistical terms, aggregate algorithms follow from the insight of Hopkins and King (2010) that the estimation process used by classification algorithms and

shown in the prior section –  $P(D) = P(D|S)P(S)$  – can be reversed; they propose a solution as follows:

$$P(D) = [P(S|D)^T P(S|D)]^{-1} P(S|D)^T P(S)$$

In essence, this formula uses an inverse matrix to allow the estimation not of  $P(D|S)$  (the probability of category  $D$  given vector  $S$ ), but of  $P(S|D)$  – the probability of vector  $S$  given category  $D$ . Given sufficient coded texts for each category  $D$ , it is actually possible to estimate this significantly more accurately than  $P(D|S)$  – the trade-off being that we must estimate it across the entire text corpus, not on a per-document basis.

The secondary benefit of these algorithms is related to the required properties of the labelled set of documents. First, it is often possible to achieve good results with a smaller set of labelled data than is required to train an accurate classification algorithm. Moreover, aggregate algorithms do not require that the labelled set should be a representative sample of the full population of texts; the only demand for selection of labelled data is that the language used in the labelled documents to express some given concept must be the same as in the whole population of texts, and that the labelled data must include sufficient examples of each individual category to be classified as to permit generalisation.

While aggregate algorithms are not perfectly suited to all kinds of analysis, their specific strengths make them particularly attractive not only for analyses that rely entirely on aggregate data, but also for real-time applications (where it is likely not possible to generate large amounts of training data on the fly) and for projects that lack the resources to undertake human coding of a large sample of the data.

## SENTIMENTS ON SOCIAL MEDIA

One of the most common applications of sentiment analysis in recent years has been in

uncovering the sentiments being expressed about topics on social media. While the field of sentiment analysis itself far predates social media (or indeed widespread internet usage), the volumes of text data produced on social media are often orders of magnitude greater than any prior data source in the political or social science fields. Combined with the unprecedented level of access to the preferences and views of a large section of the public represented by social media posts, this has made the ability to programmatically calculate sentiment across large datasets extremely important.<sup>4</sup>

Using social media data for sentiment analysis introduces a number of opportunities and challenges for researchers (some of them already discussed in the previous pages). In essence, social media data is generally made up of a large number of short texts, which makes it ideal for this kind of analysis. When applying sentiment analysis to longer texts such as newspaper articles or political speeches, it is necessary to decide what the actual unit of analysis will be – an entire document, a paragraph or an individual sentence. While some social media platforms do permit the posting of long texts, posts are generally short enough to settle on the individual post as a unit of analysis – especially on Twitter, a platform whose open nature makes it especially useful to researchers and whose strict character limit makes it easy to treat every post as a distinct unit for analysis.

### ***The Pre-Processing Stage***

Social media posts are often written and presented in a very different style to formal texts such as newspaper articles or speeches, however. Slang, abbreviations and shorthand are common (especially on Twitter, whose tight character limits encourage brevity). Along with platform-specific text features like @usernames and #hashtags, posts may also include images, web links and emoji (pictographs). In some regions, users commonly

construct faces from punctuation marks and other characters to express emotions using ‘smileys’ or ‘kaomoji’. These text features create special challenges for researchers, not least because many kinds of text analysis software can’t handle them – it’s not uncommon for punctuation marks to be removed in pre-processing (which therefore removes smileys and kaomoji) and for emoji either to be ignored or to result in software errors. Handling of web links can also create problems; software often splits links up into multiple tokens (e.g. changing ‘http://www.google.com’ into ‘http’, ‘www’, ‘google’ and ‘com’) and the high incidence of tokens like ‘http’ and ‘www’ (which appear in every URL) can result in feeding bad data to the sentiment analysis process. It is therefore important for researchers to pre-process social media data (texts) in a way that is sensitive to these specific text features; in particular, approaches which dispose of emoji or smileys should be avoided, since these features often have a very direct impact on the sentimental content of a text. A single emoji at the end of a sentence can entirely change the sentimental tone of that sentence, so any sentiment analysis approach which ignores emoji is excluding important data from the outset.<sup>5</sup>

### ***The Data Access Riddle***

A further problem with social media data relates to the relevance and reliability of the data itself. Gathering representative data from social media given the limitations placed by factors such as API limits (programmatic limitations on the amount of data that can be downloaded in a given time period) and account privacy settings is a major challenge that is beyond the scope of this chapter, but researchers wishing to perform sentiment analysis on social media data need to make themselves aware of these issues and develop a strategy to tackle them. More specifically related to sentiment

analysis is the problem of keyword specificity – the keywords used to gather and filter social media data must be chosen very carefully in order to ensure that the data is actually relevant to the topic being studied. There are several problems which can emerge in this regard, the simplest of which is the use of a keyword which actually has different meanings in different cultural or geographic contexts. For example, in a project on the Kenyan elections which one of the authors participated in, the name of a presidential candidate, ‘Uhuru’, was used as a search keyword on Twitter; it only emerged in later analysis that this word is also used in a completely different way by some right-wing groups in the United States, resulting in a large amount of irrelevant data being downloaded. Without removing these irrelevant results from the data by some means, sentiment analysis would have given skewed results due to calculating sentiment for posts that actually had nothing to do with the election we were studying. This problem can be tackled in several different ways: limiting the posts gathered to a specific country or language can often be effective, but if this is impossible, adding the already discussed ‘off-topic’ classification to a supervised learning approach can allow human coders to effectively train the algorithm to recognise these irrelevant posts. A more complex problem arises when posts include multiple keywords which are being studied; for example, a post might mention the names of both candidates in an election, making it difficult to judge which candidate the sentiment classification actually relates to. One approach which can be effective in solving this problem is training a supervised learning algorithm to identify not just overall sentiment, but sentiment related to specific topics – so for example, in analysing a corpus of tweets related to the 2016 election, an algorithm might be trained to identify ‘Trump-Positive’, ‘Trump-Negative’, ‘Clinton-Positive’, ‘Clinton-Negative’ and ‘Off-Topic’ classifications (‘Neutral’ might

also be an option) instead of a simple polar ‘Positive’ or ‘Negative’ classification.

### ***Non-European Languages***

Related to the challenges and opportunities with respect to social media data is a further set of challenges which arise from working with data in non-European languages. In particular, different languages often require different pre-processing before being converted into a Bag of Words or a document–term matrix, a tabular view with the corpus’ vocabulary on one axis and the documents themselves on another, allowing each document to be represented as a sparse vector of vocabulary frequencies. East Asian languages such as Chinese and Japanese, for example, do not use spaces to separate their words and therefore require a more complex ‘tokenisation’ step for dividing up sentences into their component vocabulary. There is also a variety of different approaches to simplifying the vocabulary whose usage differs depending on the language being analysed: ‘stemming’ (which converts all conjugated words into their dictionary form) and ‘lemmatisation’ (which reduces words back to a more basic semantic meaning, so for example the words ‘preside’, ‘president’ and ‘presidential’ might all be converted into ‘presid’) require different approaches in different languages, and may not be applicable to some languages at all.

A further complication arises from the lack of high-quality resources for sentiment analysis in some languages. As already noted, this is especially problematic for dictionary- or lexicon-based approaches; while there are a wealth of different sentiment dictionaries and algorithms available for English, some languages may have none at all, or may only have poor-quality or incomplete dictionaries. In these cases, supervised learning approaches are essential; the great advantage of supervised learning (both classifier and aggregate approaches) is that the algorithms

are entirely language-agnostic. In fact, many of these algorithms are also used to classify data that isn't even text, such as sounds or images – as long as the features encountered in the unlabelled data to be classified also appeared in the labelled documents, it doesn't matter at all what those features actually are. Supervised learning algorithms will classify a document–term matrix of Japanese words just as easily as one made up of English words and will not care if some of those 'words' are actually other text features like emoji, smileys or hashtags.

## A WORKED EXAMPLE

We will conclude with a practical example of the different techniques we have outlined above, showing the differences between the methods and their outcomes and pointing out potential pitfalls researchers may encounter with different sets of data. For the purposes of this example, we will use the Stanford Large Movie Review Dataset (Maas et al., 2011) – a data set which includes 50,000 movie reviews drawn from the IMDb website and classified as 'positive' and 'negative' according to the score the user gave the film, with reviews scored 1 to 4 considered 'negative' and those scored 7 to 10 considered 'positive'. Since these are user-submitted reviews, they include many of the same features we would expect from social media texts – misspellings, slang and grammatical mistakes are commonplace, which can pose problems for some sentiment analysis approaches. For the purposes of this example we randomly sampled 5,000 reviews to treat as labelled data, with the remaining 45,000 being treated fictionally as unlabelled data and used to test the accuracy of the various approaches.

For this worked example, we will use Python with a number of popular and readily available scientific packages. A full version of the script, with additional information and

details of the packages and techniques used, is available in the online Appendix.<sup>6</sup>

## *Loading and Pre-Processing*

We first load the data into the script – in this case, the data set is distributed as a large folder of text files, one review per file, but it is also common to need to import data from CSV files, Excel files or databases. Regardless of the source, it is often easiest to convert the data into a list of text strings. For training purposes, we also need the classifications of the test data, which should also be stored in a list (in the same order as the documents to which the classifications belong).

The pre-processing which needs to be carried out on the text differs according to the text source and the language being analysed, but this case is typical – we remove HTML tags from the text, convert it all to lowercase and strip out all punctuation. For longer texts, it may be preferable to divide the text into sentences so that a sentence-by-sentence sentiment analysis can be carried out; for these short texts, we ignore sentence boundaries and other punctuation.

## *Dictionary/Lexicon Sentiment Analysis*

To demonstrate the performance of dictionary analysis approaches on these texts, we can use two of the built-in dictionaries in the NLTK (Natural Language ToolKit) package for Python – the Liu & Hu Sentiment Lexicon and the VADER Sentiment Scoring tool. The Liu & Hu lexicon is the simplest approach – for this we simply divide up each review into its component words (a process known as 'tokenisation') and check each word to see if it is listed as having a positive or negative polarity in the lexicon. Documents with more positive than negative words are treated as 'positive' and vice versa; documents

whose negative and positive words cancel one another out (or which have no such words) are ‘neutral’. Since this approach requires no ‘training’, we could employ the dictionary to directly label all the 50,000 reviews in our corpus. However, to allow a direct comparison of dictionary sentiment analysis with the supervised approaches employed below, we have instead estimated the scores for the 45,000 ‘unlabelled’ reviews. Despite the simplicity of the approach, it managed to correctly score 69.6% of the reviews in this corpus – detailed results can be seen in Table 29.1.

The second approach we use is the VADER Sentiment Analysis algorithm. This is a more context-sensitive approach to sentiment scoring and gives a ‘polarity score’ for each document – a score scaled between  $-1$  (completely negative) and  $+1$  (completely positive). This can be useful in some situations and VADER can often correctly identify the sentiment of edge cases which more simple lexicon approaches miss. However, on this set of test documents VADER yields largely similar results to the simpler Liu & Hu lexicon, with 69.6% of reviews correctly classified – largely due to a very high rate of negative reviews being incorrectly classified as positive. The algorithm was much more successful at classifying positive reviews, achieving 85.2% accuracy on these.

Note that both of these approaches are only applicable to the English language – for any other language, a different lexicon would need to be used (or created).

## Preparing a Document–Term Matrix

Most approaches to sentiment analysis rely on the previously mentioned Bag of Words approach, which represents each document as a collection of words – ignoring their position and relationship to other words. While this loses significant amounts of information, it has proved very effective for a range of text mining applications. For a simple approach like the Liu & Hu lexicon analysis shown above, it’s sufficient simply to divide the sentence up into its component words, but more complex approaches such as classification algorithms require a development of a *vector space model* – which converts each document into a vector recording the presence or frequency of each vocabulary word. This representation of a corpus is known as a *document–term matrix*, with each row being a document, and each column a vocabulary word. This matrix can grow extremely large since the range of vocabulary in a corpus is often in the order of thousands of words. Two key approaches are used to manage this; first, the vocabulary list is trimmed by excluding very common and uncommon words (which are of little use for distinguishing documents from one another) and by stemming or lemmatisation – processes which reduce words down to shorter ‘stems’ representing their core meaning. It is often possible to reduce a corpus’ vocabulary list to a few hundred words in this way. Second, the document–term matrix is stored as a ‘sparse matrix’ – an approach allowing

**Table 29.1 Results for Liu & Hu sentiment lexicon**

	<i>Actual-Negative</i>	<i>Actual-Positive</i>
<i>Predicted-Negative</i>	14597	4475
<i>Predicted-Neutral</i>	1662	1300
<i>Predicted-Positive</i>	6234	16732

**Table 29.2 Results for VADER sentiment analysis**

	<i>Actual-Negative</i>	<i>Actual-Positive</i>
<i>Predicted-Negative</i>	12142	3329
<i>Predicted-Neutral</i>	20	9
<i>Predicted-Positive</i>	10331	19169

computers to store large matrices where most values are zero in a fraction of the space normally required.

To construct a document–term matrix, we need to specify a tokeniser (a software function which splits sentences into component words, then applies stemming, lemmatisation and other such processes). In English and other European languages this step is relatively simple due to the spaces between words; in languages such as Japanese or Chinese, an additional piece of software is required to detect the word boundaries and carry out tokenisation. For Chinese, the Stanford Segmenter is a popular tool, while analysing Japanese is usually carried out using MeCab or Janome. Other languages, such as Korean, also require this step. A mistake in this tokenisation process can result in ‘junk data’ in the document–term matrix, so it’s important to pick appropriate tools for the language you are working with.

Next, the tokeniser is used to train a ‘vectoriser’ which will analyse the corpus to find which vocabulary terms are relevant; after this ‘fitting’ process, it can be used to generate a document–term matrix for the entire corpus, or a vector for a single unseen piece of text which will be compatible with the vectors in the document–term matrix (that is, each position on the vector will represent the same vocabulary term as it would in a row of the matrix).

## Classification Algorithms

The process of training and testing a classification model involves ‘fitting’ the model to a set of training data and then scoring its performance at predicting the classifications of a set of test data. This process is carried out using multiple different models in order to select the most effective one for a specific set of data. Using the movie review data set, we tested a selection of classification models using a ‘labelled’ set of 5,000 randomly selected reviews. To ensure the robustness of this process, *cross-validation* is used, wherein the data is divided into multiple ‘folds’ and the model is repeatedly trained and tested on different folds of data. In this example, the cross-validation process uses three folds (five to ten folds are also commonly used; the more labelled data you have, the more folds you can effectively use in this process), so the 5,000 labelled set is randomly divided into three subsets. We reserve one subset (the test set) and train the model on all other subsets (the training set). We then test the model on the reserved subset and record the prediction error, before repeating this process until each of the three subsets has served as the test set. We finally compute the average of the three recorded errors. This is called the cross-validation error and serves as a performance metric for the model. The results for the models tested can be seen in Table 29.3.

**Table 29.3 Initial results for classification algorithms**

<i>Model Name</i>	<i>Average Accuracy</i>	<i>Cross-validation Error</i>
Multinomial Naïve Bayes	0.822	+/- 0.030
Bernoulli Naïve Bayes	0.808	+/- 0.015
Support Vector Classifier	0.813	+/- 0.014
Linear Support Vector Classifier	0.501	+/- 0.000
Stochastic Gradient Descent	0.800	+/- 0.028
Random Forest (10 trees)	0.730	+/- 0.019
Neural Network (Multi-Layer Perceptron)	0.811	+/- 0.021

There is no one-size-fits-all classification algorithm; in this specific instance, the linear support vector classifier performed worst, with the random forest also achieving only marginally better scores than the dictionary-based approaches outlined above. For other data, however, these algorithms may outperform the others; it is important to test a variety of algorithms to see which is best suited to the specific combination of data and classifications being used. In this instance, the Multinomial Naïve Bayes classifier proved the most effective, with 82.2% accuracy on the held-out data set.

This is not the end of the process of training an effective classification model, however. Most algorithms also have a range of ‘hyper-parameters’ – assumptions and modifiers which can be set to different values prior to training – that can significantly impact performance. Finding the right set of hyper-parameters for a certain task is also largely a case of trial and error. However, several different packages, both in Python and R, provide ways to automate this task; this is known as a ‘grid search’, allowing researchers to exhaustively search through every combination of a set of hyper-parameters to find the best performing model. This process can take a lot of time – often in the order of several hours for algorithms with complex sets of parameters – but often yields better performance than the default parameter set. For example, in our case we were able to locate a set of parameters for the support vector classifier model which boosted its performance to 82.3% – a full percentage point higher than the algorithm’s performance in our initial test. This model would likely be considered sufficiently accurate and reliable for use in a research project. In the present example, it is possible to test that accuracy by scoring the trained algorithm’s performance on the ‘unlabelled’ set of 45,000 reviews; for the final trained algorithm (the support vector classifier with the best hyper-parameters chosen through the grid search procedure), those results are shown in Table 29.4. The

**Table 29.4 Results for final classification algorithm**

	<i>Actual-Negative</i>	<i>Actual-Positive</i>
<i>Predicted-Negative</i>	18261	3464
<i>Predicted-Positive</i>	4232	19043

algorithm achieved 82.9% accuracy overall, 84.6% on the positive reviews and 81.2% on the negative reviews (more detailed scoring, including the precision, recall and f1-score metrics mentioned above, can be found in the online Appendix). Note that in a real research situation you would have to trust the accuracy of your trained algorithm at this point, since the rest of your data really would be unlabelled.

One additional possibility which we have not explored in this worked example is combining different algorithms to achieve better accuracy than a single algorithm would manage on its own. This is called an ‘ensemble’ approach and comes in two basic forms. The first, ‘model averaging’, involves training multiple different algorithms and then combining the results of those which showed acceptable performance on the test set, either by blending their predictions or by running them independently and allowing them to ‘vote’ on the classification of the text. The second, ‘model stacking’, was introduced by Wolpert (1992) and involves feeding the predictions from an ensemble of algorithms into another algorithm as parameters for a final prediction. Further details of these two approaches can be found in Sardinha (2017).

### **Aggregate Algorithms**

Although aggregate algorithms function very differently from classification algorithms in many regards, they take exactly the same input – the document–term matrix – so we can re-use the matrix from the previous step.

For this example we are using the Python version of iSA, PyiSA – at the time of writing there is no Python implementation of the other major aggregate algorithm, ReadMe, but this example could be recreated in R to test ReadMe’s performance.

The procedure followed by iSA is very similar to the one used by the classification models shown above. First, we use the labelled documents to train the algorithm. Then the algorithm will predict the classification of the unlabelled documents. Unlike the classification models, however, iSA returns an estimate of the distribution of each classification within the overall corpus and also estimates its own standard errors. If you wished, it would also be possible to run a cross-validation of the iSA algorithm by checking the consistency of results from different sub-folds of the labelled data – we have not done so in this instance, but the procedure would be functionally the same as for a classification algorithm.

In our test on the movie reviews, iSA estimated that 51.4% of the reviews were negative (std. error 0.01) and 48.6% were positive (std. error 0.01) – very close to the actual 50:50 distribution within the overall corpus. While the classification algorithms also came close to estimating the correct distribution, this was largely due to the balance of mis-classifications (positives labelled as negative, and vice versa) being evenly distributed. If the sentiments were not evenly divided in the corpus, or if there were additional categories (e.g. a ‘neutral’ or ‘off-topic’ category), as already noted above, this could have produced significant skew in the results of the classification algorithms, which the aggregate algorithms would have handled more robustly. Furthermore, the aggregate algorithms are better able to cope with smaller amounts of labelled training data, while the performance of classification algorithms can drop off quickly when the amount of training data is reduced. For example, if we reduce the amount of labelled data in the above example to 1,000

reviews (a reasonably realistic number for many research projects), the accuracy of the best classification algorithm we could train fell to 77.5% – a drop of more than 6% – while iSA’s estimation remains extremely accurate; in fact, its accuracy improved despite the smaller amount of training data, in this case estimating the split in the corpus at 50.1% to 49.9%.

## Notes

- 1 Sentiment analysis is just one type of analysis a dictionary method can perform. The general concept of dictionaries makes them relatively easy and cheap to apply across a variety of problems, including the identification of words that separate categories (for example policy categories) and measuring the frequency of those words in different texts. See Laver and Garry (2000) for an approach in this regard.
- 2 To assess model performance, beyond accuracy, other commonly used statistics are recall (a measure of what proportion of actual instances of a given category the algorithm correctly identified) and precision (a measure of how many of the times the algorithm identified a category were actually correct, as against how many times were false positives). The f1 score is another commonly used measurement that combines both recall and precision on a per-category basis.
- 3 For a supervised learning approach applied to Arabic language, see for example Ceron et al. (2019) or Cunliffe and Curini (2018); an example in the Japanese language can be found in Fahey et al. (2018).
- 4 For a recent review of works within the social science field that apply such approach, see Ceron et al. (2017).
- 5 The pre-processing stage of the analysis (that is, the series of decisions a researcher makes on which types of word or features of a text to include or exclude from analysis and how to treat those text features, for example whether to apply stemming and lemmatisation) can have large consequences for the quality of the results of any automated text analysis. See Haselmayer and Jenny (2017) for a study that shows how pre-processing decisions impact on sentiment analysis.

# Big Relational Data: Network-Analytic Measurement

Ernesto Calvo, Joan C. Timoneda and  
Tiago Ventura

## INTRODUCTION

In less than a decade, we entered an era of massive datasets reporting inter-connected observations. Social media data provides one of the most visible examples, but it represents just the tip of the data iceberg. Wireless phone networks, live transit data, e-cities and e-government data, citation networks, web page hyperlinks, congressional collaboration events, scientific mentorship dyads, are all part of vast, clean and accessible sources of information currently at our disposal. The flood of data is so extensive that empirically minded scholars have become hoarders of unused datasets stored in their computers.

Big relational data (BRD) represents a challenge to scholars trained in social network analysis, a field that developed most of its techniques to describe small and sparsely featured datasets. As is the case for their smaller counterparts, BRD observations are not independent and identically distributed draws from a population. Paraphrasing

Tobler's first law of geography, everything is related to everything else, but connected things are more related to each other than unconnected ones. As we move from small and shallow relational datasets to large and full featured ones, storing and representation, processing time, parallelization, data dependency, model specification, and model estimation need to be considered together. In this chapter, we discuss theoretical, empirical and practical problems that emerge from the study of large networks, where models for data dependency need to overcome significant conceptual and computational constraints.

As we grapple with the technical issues described above, readers also need to consider what type of information is important to retrieve from their large networks. This chapter introduces readers to a variety of strategies to describe and study big relational data (BRD). This includes feature description, influence and propagation, network dimensionality and reduction, as well as a

description of simple alternatives to estimate inferential statistics that address network dependency in large datasets. The chapter prioritizes practical solutions for inference and a theoretically informed discussion of network dependency, in a field that is rapidly evolving and poised to see significant change and growth in the coming years.

The field of computational social science for social networks is undergoing a massive technical and conceptual revolution, from new algorithms and statistical strategies to specialized software and hardware. These new advances are certainly exciting. However, with constant change comes increased academic uncertainty. As concepts, theories, software and techniques undergo rapid change, academic consensus and accepted standards fail to develop.

Such a rate of innovation makes it difficult to present techniques that will survive the test of time. Every month, new versions of R, Python, igraph, SNA and hundreds of related packages are made available to researchers. At a dizzying pace, dozens of new functions and algorithms are proposed and packaged for academic consumption every month. In this chapter, consequently, we provide a conceptual roadmap for the future using today's technologies. While it is inevitable that the current techniques will be superseded by new advances, the conceptual and empirical problems will likely persist.

Each of the sections in this chapter provides solutions to specific problems that often hamper the study of large networks. We begin with practical advice to create objects that make smart use of limited memory and computational capacity. We then present solutions to improve visualization and description of network topologies when researchers work with anything less than a supercomputer, and provide a few suggestions for if and when supercomputers are an available resource.

We provide practical examples using Twitter data, which has become one of the most prevalent sources of ready-to-go

network data for the study of political communication.

The order of presentation is as follows. First, we present readers with some basic principles that will make data collection and processing more efficient. Memory and processing power are important, scarce resources when dealing with large networks. Therefore, we describe some challenges in data processing and variable selection and discuss some strategies to facilitate network reduction and reproducible datasets. Second, we discuss the efficient manipulation of nodes and edges, as well as functions that describe the topology of large networks. As networks are increasing in size, we will provide alternatives to computationally expensive structural terms such as triangles, stars and geodesic forms. Third, we discuss how to model social influence, network activation and propagation using less computationally demanding algorithms. Finally, we discuss simple solutions to model data dependency in large networks.

## STORING AND DESCRIBING LARGE NETWORKS

### *First Rule: Be Efficient!*

When dealing with networks of hundreds of thousands of nodes and millions of edges, inefficiencies scale at a dizzying pace. Consider a moderately sized network of 100,000 nodes. An undirected affiliation matrix for this network will take a huge amount of space,  $100,000 * 100,000 = 1e + 10$  numbers – that is, 10 billion numbers. An affiliation matrix for a network of 120,000 nodes would add another 5 billion to your memory demands. Therefore, every piece of inefficient code will bring your machine to a grinding halt, and even your department's supercomputer will likely exit with an unceremonious 'insufficient memory allocation' message. Therefore, consider simple functions to run your analyses and store in memory only the variables that you will use.

### **Second Rule: Write Simple Functions to Collect Your Variables of Interest**

One of the most common data formats to store complex relational data is JavaScript Object Notation, known by its acronym JSON. The JSON format allows complex hierarchical information to be presented in a string of characters. Every tweet delivered by Twitter's API, for example, needs to include very different types of information, such as the unique id of the tweet, the unique id of the user, nested information about the user (Twitter bio or self-description, color selected for the wall, number of followers, etc.), and nested information about the tweet (time of the tweet, hyperlinks, etc.). While the JSON format is very efficient in storing the relevant information for every tweet, it also duplicates the variable names and stores dozens of variables that we would never use for our analyses. R packages such as *quanteda*, *twitteR* and *streamR* provide off-the-shelf functions that process a subset of important variables that many researchers use. However, this still includes many variables that we may not need, representing millions of observations that occupy valuable memory space. Further, these functions often store many intermediate objects as they process the data, making it likely that the computer system will run into memory allocation problems much sooner. Reading JSON files and parsing the needed variables using your own function will save significant memory space and time.

### **Third Rule: If Possible, Use Optimized Functions in Stable Package Distributions**

Some packages, such as *igraph* (Csárdi and Nepusz, 2006), have extremely efficient functions to deal with massive networks, subject only to RAM and CPU limitations of the system. But even extremely good packages

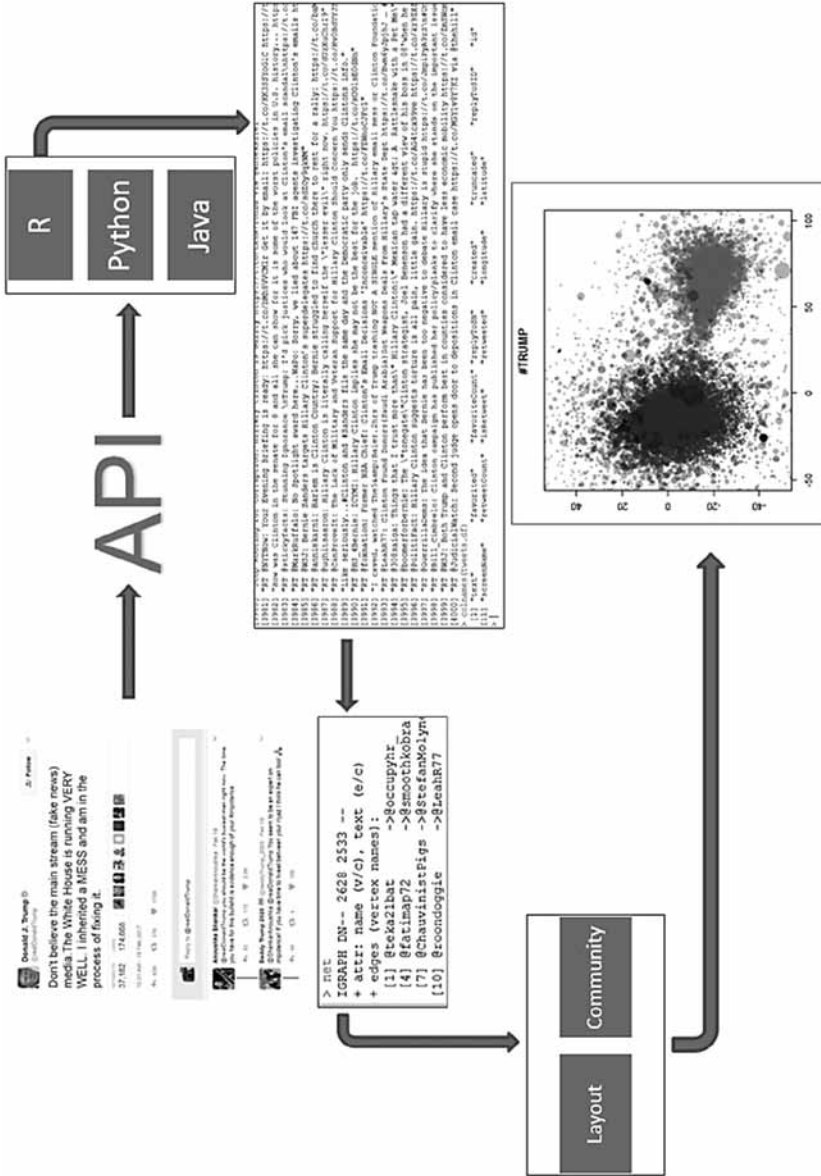

often add wrappers around functions which can increase time and reduce memory. For example, consider `get.adjedgelist()`, one of the most important and useful functions, which retrieves the adjacency matrix for edges in *igraph*. The function that does the heavy lifting is extraordinarily fast and can be easily executed directly using:

```
.Call('R_igraph_get_adjedgelist', net, 1,
      PACKAGE = "igraph")
```

The wrapper in `get.adjedgelist()`, however, adds other functionalities such as the edges' names, with internal calls that slow down the system as networks' size increases. Whenever possible, lose the wrapper and just use the function that executes the required process.

### **Accessing, Selecting and Parsing Data for Big Networks**

We now exemplify a typical data processing exercise using Twitter files. Figure 30.1 describes the usual steps that most researchers follow, reading the JSON file into memory and creating network objects that include a variety of descriptive information, such as the in-degree and out-degree of each node, the nodes' latent locations (layout) and the nodes' membership within subnetworks (community detection). In graph theory, the degree of a node represents the number of edges connected to this node; in the case of directed graphs, where the edges have a direction associated with them, the number of edges coming to the node is called in-degree whereas the number of edges coming out is called out-degree. Twitter networks are obviously directed graphs, since the action of the direction of the connection on Twitter matters. For example, the action user  $v_1$  retweets user  $v_2$  is different from the action user  $v_2$  retweets user  $v_1$ . Nodes with high in-degree are labeled authorities in the network, while nodes with high out-degree are called hubs.

**Figure 30.1 API interface and pre-processing of large Twitter network**

Note: We use one of the dedicated APIs to download JSON files with tweets that include the character 'kavana', on the morning of 9/19/2018. We parse the JSON file to select 25 variables of interest, including the user names ('hub' and 'authority' for each tweet). We estimate a location for each node using the Fruchterman-Reingold layout and identify communities using the walk-trap community detection algorithm in igraph.

Twitter data can be accessed using one of Twitter's dedicated APIs, the forward or 'live' stream and the backward or 'search' stream. The forward API captures tweets in real time on a topic set by the researcher using one or multiple keywords. These tweets are downloaded as they are published by Twitter users. Note that the live stream is throttled once the topic of interest surpasses 1% of total global traffic on Twitter, which can be solved by gaining access to Twitter's Firehose. The search API provides a sample of tweets on a given topic published up to a week before the query. The sample is curated to mix both popular and most recent tweets containing a given keyword. Access to tweets older than one week comes at a cost.<sup>1</sup>

Packages have been developed in languages such as R and Python to access Twitter's APIs. TwittR and streamR in R as well as twarc in Python are prominent examples. All of these solutions store information in a JSON (JavaScript Object Notation) file, which can then be parsed to extract the information required by the researcher.

### ***Parsing JSON Files***

The JSON format organizes information in strings of characters that are easy to parse. They are particularly useful for objects with dynamic and open-ended data structures such as large nested lists and arrays. Consider that one tweet produces over 200 different variables with information about the tweet and the user who wrote it. Functions such as `searchTwitter()`, from the package `TwittR()`, provide only 16 of the most frequently used features in Twitter data, while the function `filterStream()` from the package `streamR()` returns 42 variables. Both programs provide simple functions to transform the downloaded JSON file into a ready to use dataset in R. In Python, the package `twarc` downloads a complete JSON file which can then be processed in R, Java or Python. Downloading and parsing the full JSON file

is always better if a different set of variables is needed for our research or if memory constraints make the use of off-the-shelf functions unfeasible. Code to parse a JSON file is available from the authors' websites.

To improve memory management, it is convenient to create functions that, after uploading JSON files into the system, select a few important variables and collect them into a dataframe. Rather than iterating with a *for* loop, some of the base functions such as `apply`, `lapply`, `sapply`, as well as the map functions from the `purrr` R package will significantly improve computation time as the size of the dataset increases.

### ***Creating a Large Network***

Once the JSON file has been uploaded and variables have been selected into a dataframe, we can create our network using relational aspects of the data such as retweets or replies, which connect user *j* and user *i*. Other variables may also be loaded to the nodes – characteristics intrinsic to each user – and to the edges – characteristics of the relationship between users.

### ***Fourth Rule: When Creating Your Network, Add Your Important Variables at Once!***

As we will show, networks need to be trimmed, pruned, sliced and transformed in multiple ways. You do not want to merge new variables later in the process once a large number of edges and nodes have been selected out and it has become hard or impossible to apply the same selection rules to new variables. In R, packages such as `igraph` and `Network` create efficient objects that can store variables of length (nodes) or length (edges). When a large network object is created, therefore, add all variables of interest to the nodes:

```
V(net)$friends = kavana.df$friends # (igraph)
net %v% friends
  = kavana.df$friends # (network)
```

as well as to the edges:

```
E(net)$text = kavana.df$text #(igraph)
net %e% text = kavana.df$text #(network)
```

A common way to build a network from Twitter data is by analyzing the retweeting behavior of users. In doing so, we act on the assumption that a retweet is a sign of affinity, where users that retweet some users rather than others are closer to the former and more distant from the latter. We may use this information to identify, for instance, more important or influential users, that is, users that are more frequently retweeted (e.g. users with higher in-degree) or users with a larger number of ‘followers’. Later in the chapter, we provide some modeling strategies to understand retweeting behavior of users.

## THINNING LARGE NETWORKS

### *Fifth Rule: The Whole Data is Not Always Better!*

There is little doubt that networks can be visually stunning. Figure 30.3, for example, uses the Fruchterman–Reingold layout and the walk.trap community detection algorithm to describe the relationships between 8,835 retweets about Donald Trump by 7,911 users on the morning of October 8, 2018. The original network (upper plot, Figure 30.3) includes a very significant number of smaller subnetworks in its periphery. As readers may notice, these smaller sets of users are not connected to the primary cluster and, consequently, cannot be placed on the same latent space; nor are they connected to a particular community of the main cluster. Visually, it

will be tempting for readers to perceive these unconnected nodes as if their location in the graph and community membership was meaningful. However, there are no paths that connect nodes in the main cluster to any of those subnetworks.

As networks are loaded, researchers will often have to make decisions regarding the network objects that deserve their attention. This could require working with the primary connected cluster (middle plot), which considers only the largest cluster of connected users (e.g. users with paths to all other users). Oftentimes, filtering for the primary connected cluster will also eliminate isolates that are not truly ‘talking’ about the same events.

Another important question is whether single occurrences by a user (a single connecting edge from one user to one other user in the network) adds relevant visual information. The middle plot in Figure 30.3, which only includes the main connected cluster, still includes a large number of users that participated only once in the network, extending a single link to one other node. Their contribution is already captured by the in-degree of the receiving node, visualized by larger circles. Therefore, it is often a good idea to filter single occurrence nodes and retain in the network object only those users that either have an out-degree larger than 1,  $degree(net_{ij}, mode="out") > 1$ , or an in-degree equal or larger than 1,  $degree(net_{ij}, mode="in") > 1$ . The third and final plot in Figure 30.3 describes a filtered network that eliminates unconnected users as well as users of  $out - degree == 1$ , who would be given an arbitrary location in the network.

## NETWORK TOPOLOGY

Different from spatial models in geography, which locate points in a sphere according to projections that respect the original

```

twList <- function(tw=tw) {
  test <- tryCatch(fromJSON(tw), error=function(e) NULL)
  out <- c(test$id_str, test$text, test$user$screen_name,
  ifelse(is.null(test$user$verified)==TRUE, "", test$user$verified),
  out)}
  library("rjson")
  my.file <- "trump.json"
  my.tweets <- readLines(my.file)
  att <- sapply(my.tweets, function(x) twList(x), simplify=TRUE,
  USE.NAMES = FALSE)
  trump.df <- t(att)

```

**Figure 30.2** Sample code to create a dataframe with selected variables

distances between points, network visualizations are not constrained by a ‘true underlying grid’. Data reduction techniques that locate nodes and edges on the space, *layouts*, are selected by researchers because they summarize and communicate information that is deemed relevant.

### ***Sixth Rule: Know What Information You Wish to Transmit to Your Readers!***

Consider the same dataset used in Figure 30.3, but subject to a variety of algorithms that recover locations for all nodes and edges. Each algorithm represents a compromise between pure data reduction techniques (e.g. multidimensional scaling layout in the left-middle row of Figure 30.4) and pure visual discrimination (e.g. the Random layout in the right-middle row of Figure 30.4).

Force-directed algorithms, such as the Fruchterman–Reingold plot in the upper-left corner of Figure 30.4, are a compromise between the pure data reduction retrieved from the adjacency matrix and visual

discrimination among nodes. In the case of the Fruchterman–Reingold plot, discrimination between nodes in close proximity is carried out through *springs* that separate nodes over short distances. This short distance repulsive force is absent in multidimensional scaling. Therefore, better visualization by the Fruchterman–Reingold algorithm will also add information that is not in the adjacency matrix.

Researchers should select algorithms for network description (e.g. both visualization and data reduction) which provide readers with the appropriate information. Researchers need to report both the advantages of the selected layout and the data implications. The selection of a layout, therefore, should make explicit the type of information that researchers wish to communicate to readers. Let us describe some of the most common layouts used for network visualization.

### ***Fruchterman–Reingold***

The Fruchterman–Reingold layout is a force-directed graph drawing algorithm that

**Figure 30.3 Twitter 'Trump' network (1)**

*Note:* The top plot presents all nodes and edges in the data, with node size according to the in-degree of each node. The middle plot retains the primary connected cluster, with unconnected sub-clusters eliminated. The lower plot retains the primary connected cluster and eliminates nodes with out-degree = 1. The information of the eliminated nodes is preserved in the size of the node (e.g. the in-degree in each node)

groups together nodes that share more connections with each other. The length of the edges is minimized, and nodes repulse each other as if electrically charged when they come into contact. When in equilibrium, the process creates a map of the network in which communities with strong ties are easily detected, as they are separated from each other by force. By altering the size of the nodes in accordance with some measure of importance within the subnetwork, we can also broadly assess the hierarchy of the network and the presence of authorities. As a disadvantage, the Fruchterman–Reingold algorithm is particularly slow in networks with more than 1,000 nodes. Precisely because of the force that underpins the graphing technique, nodes with weak connections to other actors in the network will be pushed out toward the periphery (Fruchterman and Reingold, 1991; Kobourov, 2013).

### **Davidson–Harel**

Davidson and Harel's algorithm is based on simulated annealing, a technique used to cool liquid that leaves a crystallized structure by reducing energy slowly. The top-right plot in Figure 30.2 shows precisely this: it's as if the nodes and edges of the network had been slowly set in one non-random but cohesive structure. Notice that communities can be detected by the color of the nodes, and it is therefore not random. Contrast this with the plot immediately below the Davidson–Harel graph, which is indeed random. Both nodes and edges are distributed evenly in the random plot, while nodes and edges are concentrated in communities in Davidson–Harel. It minimizes edge crossings and ensures vertices are not too close to non-adjacent edges. These communities, however, are much less clear to the naked eye than they are, for instance, in the Fruchterman–Reingold layout. As a note of caution, Davidson and Harel themselves admitted that

the layout algorithm underperforms in networks with more than 60 nodes (Gibson et al., 2013).

### ***Multidimensional Scaling***

Multidimensional scaling is a visual representation of networks in which nodes that are more similar to each other are placed closer together. Distances among objects are estimated using a data reduction technique and placed on a map, which can have two or more dimensions. The final orientation of the axes is arbitrary, prioritizing the accurate estimation of relative distance. As opposed to factor analysis, multidimensional scaling is a non-linear dimension reduction technique. As with Fruchterman–Reingold, multidimensional scaling identifies communities well, as it groups together nodes that are similar to each other and separates them from those that are not. But since both procedures use entirely different algorithms to place objects in space, the way they communicate information varies slightly (Gibson et al., 2013; Buja et al., 2008).

### ***Kamada–Kawai***

The Kamada–Kawai model produces a force-directed layout based on a logic of stress minimization. As opposed to Fruchterman–Reingold, it does not ensure that nodes are not too close to each other. Rather, it seeks to reach an equilibrium in which the geometric differences between points closely resemble those in the graph. The Kamada–Kawai algorithm is computationally expensive and may struggle to detect communities as precisely as Fruchterman–Reingold. This is because, in the latter, nodes repel each other such that vertices that are far away from each other in theory are further apart in the graph. Kamada–Kawai, on the other hand, represents a more direct mapping of the

theoretical distance between nodes in a graph layout (Kobourov, 2013).

### ***Large Graph Layout (LGL)***

The large graph layout (LGL) was developed to visualize large networks of hundreds of thousands of nodes and more than a million edges, which is particularly difficult to do with the layouts described above. A force-directed algorithm, the LGL begins by identifying different clusters within the network, that is, it separates the overall network into highly connected clusters. It then lays out each connected set separately in space before bringing the entire network together into the same coordinate system. For smaller networks such as the one used as an example here, the LGL does not appear to make a difference. Indeed, the bottom-right plot in Figure 30.2 provides a less clear visual representation of the two different communities in the network than do the Kamada–Kawai, multidimensional scaling and Fruchterman–Reingold algorithms. However, in a large network, the LGL would provide a more meaningful layout of the network (Adai et al., 2004). Table 30.1 summarizes the different layouts we introduced here.

## **COMMUNITY DETECTION**

Beyond estimating the location of users in a network (layout), we may be interested in identifying groups of nodes that interact more frequently with each other (e.g. regions of the network with nodes that are more densely connected). In Figure 30.4, the  $[x,y]$  coordinates of the nodes (different layouts) summarize information about the latent location of nodes, but such proximity provides little information about the probability that these nodes will be more likely to interact with each other than with the rest of the nodes in the network.

**Table 30.1 Summary of layouts for network visualization**

<i>Layouts</i>	<i>Summary</i>	<i>Keywords</i>
<i>Fruchterman–Reingold</i>	A graph drawing algorithm that separates communities by force. It ensures that nodes are never too close to each other	force-directed, spring forces, minimum separation
<i>Davidson–Harel</i>	Network energy is reduced slowly and minimizes edge crossings. Vertices not too close to non adjacent edges	simulated annealing, slow energy reduction
<i>Multidimensional scaling</i>	Nodes similar to each other are placed closer together. Nonlinear dimension reduction technique. Works with multiple dimensions	multiple dimensions, data reduction
<i>Kamada–Kawai</i>	Force-directed layout based on stress minimization. It represents a more direct mapping of the theoretical distance between nodes in a graph layout	stress minimization, theoretical distance
<i>Large graph layout (LGL)</i>	Used for large networks. It breaks down clusters first, then connects them back into one single coordinate space	large networks, force-directed

### ***Girvan–Newman***

One way to detect communities is by using the Girvan–Newman algorithm. It progressively removes edges from the network starting with those that most likely link different communities. It first calculates the ‘edge betweenness’ of every edge in the network, assessing the number of shortest paths of which it is part. The higher the edge betweenness, the more often a given edge is likely to connect various communities. Clearly separate communities emerge after these edges are removed. However, betweenness is recalculated after removing the edge with the highest score, which makes the procedure intensive and often error prone (Girvan and Newman, 2002).

### ***Fast and Greedy***

The fast and greedy algorithm provides a fast calculation of modularity in larger networks,

using a bottom-up approach. Each vertex is initially independent, and the algorithm progressively merges nodes in such a way that it produces the largest locally optimal increase in modularity in each step. These communities are then aggregated and the hierarchy of the network is revealed from the bottom-up. This is a fast method partly because there are no parameters to estimate, but it requires a certain sample size to work properly (Clauset et al., 2004).

### ***Louvaine***

A similar method to the fast and greedy algorithm is the Louvaine method for community detection, although it is computationally more intensive and slower. As opposed to the Girvan–Newman algorithm, the Louvaine method is a bottom-up approach that first estimates the smallest possible subnetworks by optimizing modularity. After each step,

communities are collapsed into one node, and again the process is repeated. All nodes are allocated in this way until no increases in modularity are possible. Once this process is over, the algorithm builds the network again, with clearly separate communities (Blondel et al., 2008).

### **Random Walk**

The logic of the random walk approach to community detection is that most random walks will stay within the community, as there are few edges that lead to other communities. You can select the number of steps for the random walk and the algorithm will then generate communities using a similar bottom-up approach as in fast and greedy. What random walks lose in speed, they usually gain in the accuracy of the results (Pons and Latapy, 2006; Yang et al., 2016). In Table 30.2, we summarize this discussion about distinct

algorithms for community detections in network analysis.

Once nodes are given a location in the space (layouts) and a group membership (community detection), it is often unnecessary to visualize the edges. This is particularly true once networks grow in size and plotting the edge information would just add visual noise. As networks increase in size, hundreds of thousands of edges will become just a color background, with little information value.

### **Seventh Rule: As Networks Increase in Size, Lose the Edges!**

Of course, we are not suggesting that the information of the edges should be eliminated – far from it. It is just not necessary to plot those edges when the relevant information can be described by adjusting the properties of the nodes. We will exemplify this suggestion in the next section, as we plot

**Table 30.2 Summary of the algorithms for community detection in the network**

<i>Method</i>	<i>Summary</i>	<i>Keywords</i>
<i>Girvan–Newman</i>	A top-down approach that removes those edges that have the highest levels of edge-betweenness first. Computationally more intensive as betweenness is calculated after every step	top-down, edge betweenness
<i>Fast and Greedy</i>	A bottom-up approach to identify communities quickly. Modularity is optimized locally at each step, generating communities. These are then aggregated into a hierarchical network	bottom-up, local optimization
<i>Louvaine</i>	Similar to fast and greedy, slightly slower. Communities are collapsed into nodes after each estimation until no increases in modularity can be achieved	modularity optimization, bottom-up
<i>Random Walk</i>	Most random walks will stay within the community, and fewer will lead to other communities. The algorithm uses this insight to build communities from the bottom up	bottom-up

different hashtags that *activate* content of the Kavanaugh network of tweets in September of 2018.

## INFLUENCE AND PROPAGATION

Large networks differ from small networks not only because there are a very large number of nodes but also because these nodes are arranged in network topologies that are locally distinct. For example, consider the small but complex network in Figure 30.5, which has three different but connected local topologies. There are three edges that connect the different regions, allowing information to flow from one part of the network to the others. Those three edges have high edge betweenness, which bridges the content that circulates between each set of communities.

Influence and propagation, the capacity to elicit responses from nearby nodes and the capacity to activate content in a network

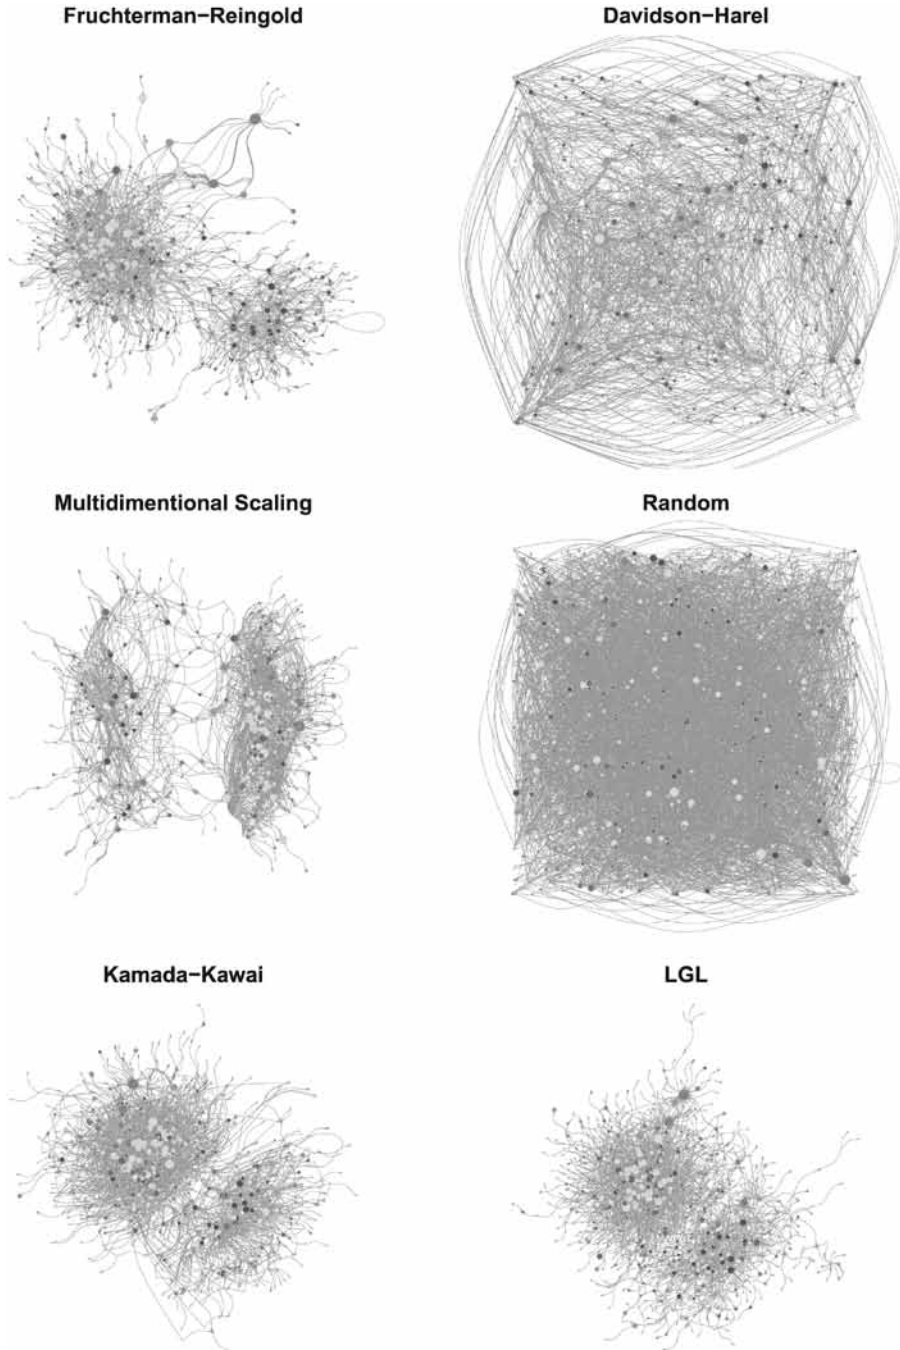

have become an important area of research as we move from small and sparsely featured networks to large and complex ones. Indeed, Table 30.3 describes some of the techniques available to assess the influence of nodes in such social networks.

Figure 30.5 describes the flow of information over multiple rounds in this network, allowing in-degree information to propagate to contiguous nodes until node information is equalized (entropy). In each round, nodes read the average in-degree of the contiguous nodes, allowing for information to converge. After 25 rounds, the in-degree information has equalized and all nodes converge to the average in-degree scores of the network.

However, as shown in Figure 30.5, information propagates rapidly in the fully connected community (top) and slowly in the ring community (lower right). In complex networks, information propagates at different rates in regions of the network, depending on how groups of nodes are connected to each other. Therefore, influence (e.g. the capacity to affect the behavior of contiguous nodes)

**Table 30.3 Influence and propagation**

Source	Definition	Keywords
<i>Rashotte</i>	a phenomenon caused by interaction among individuals that changes their thoughts, sentiments, and behavior	changes in behavior, interaction among actors
<i>Watts and Dodds</i>	influence defined as individual/s who appear in a given percentile $q$ of the influence distribution $p(n)$	top $q\%$ , Poisson distribution
<i>Cha et al.</i>	influence based on three types of actions: following, retweets and dialog	actions
<i>Bakshy et al.</i>	the influence of a given post is calculated first; then a model is fitted that predicts influence incorporating individual attributes and past cascades	reposting, cascading
<i>Tang et al.</i>	the extent to which individuals change their behavior based on their relationships with other people, organizations and society	changes in behavior, perceived relationships

**Figure 30.4 Twitter 'Trump' network (2)**

*Note:* The six different layouts are created applying different algorithms to the network. Different from Euclidean geography in transportation networks, there is no 'right' layout. The different layouts represent compromises between visualization and proximity. Data reduction techniques, such as multidimensional scaling, respect latent distance in the data at the expense of visualization. Force-directed algorithms respect relative proximity and improve visualization by adding short-distance distortion.

and propagation (e.g. the capacity to activate content that reaches contiguous nodes) varies locally in complex networks. As networks increase in size, summary information such as the density, the average degree, the centrality or the overall betweenness scores become less informative.

### ***Eighth Rule: Go Local! Understand Activation Events in Your Network***

Consider the activation of different hashtags in the Kavanaugh network in Figure 30.6. For these plots, we still use the Fruchterman–Reingold algorithm that locates users in the primary connected cluster as well as the random walk algorithm for community detection. Colors for the communities were edited, with blue for those that oppose the nomination of Kavanaugh and red for those that support nomination. Inspection of the largest authorities in each community (e.g. users with the highest in-degree) show that political figures from the Democratic party are prevalent in the opposition community and that President Trump and Republican representatives are prevalent among those that seek confirmation.

As shown in Figure 30.6, very different hashtags were activated by users in each

community. To explore the activation of different contents in the Kavanaugh network, we collect all the hashtags embedded in tweets of the Kavanaugh network, with tweets searched by the string of characters ‘kavanaugh’ on the morning of September 19, 2018. The upper-left plot describes the full distribution of nodes, with users opposing confirmation in blue and those supporting confirmation in red. Then, we use the edge-contiguity matrix to create a node attribute that counts the number of edges for each node that include our selection of hashtags.

Rather than coloring millions of edges, we modify the size of the nodes to reflect the log-counts of the hashtags, plotting thousands of nodes rather than millions of edges while preserving the information.

The information depicted in the different figures showed that supporters of Kavanaugh’s confirmation were more likely to use #MeToo hashtags than those opposing nomination. Instead of shying away from the issue, supporters of Kavanaugh used hashtags such as #MeTooHucksters to argue that #MeToo accusations were just an attempt to derail confirmation.

As shown in Figure 30.6, modeling how content is activated in different regions of the network is considerably more informative

**Figure 30.5** A complex network with three local topologies: (a) a ring subnetwork, (b) a fully connect subnetwork and (c) a follow the leader subnetwork. Information propagates at different rates within and across networks. In fully connected networks, information moves effortless to all nodes. Meanwhile, information takes several rounds to reach removed nodes in the ring subnetwork

than reporting just the frequency of content on the average node.

## STATISTICAL DEPENDENCY

Activation and propagation are two different, although interrelated, phenomena. In the case of activation, we model how different regions of the network communicate different information. In the case of propagation, however, we hope to understand how nodes influence each other locally – that is, to model the extent to which the probability of observing a local event is affected by contiguous nodes.

When working with big relational data, tools to model network dependency may be computationally untractable (Schmid and Desmarais, 2017). In their recent article, Schmid and Desmarais note that exponential random graph models (ERGMs) may be computationally prohibitive once they reach 1,000 nodes, a modest network size for today's standards. Instead, they argue, for networks of those sizes, maximum pseudolikelihood estimation (MPLE) may be an alternative. However, even MPLE, or simpler structures such as triangles, stars or geodesic forms in an entire network, will be outside MPLE reach when we deal with the smaller 'Trump' network described earlier.

In this final section, we discuss some simple solutions to model data spatial dependency in large networks. We begin with the *Path Weighted Local Regression Model* (hereafter *PWR*). This model extends the *geographically weighted regression (GWR) model* (Fotheringham et al., 2002), allowing researchers to model spatial dependency and heterogeneous effects of big relational networks using a less demanding computational strategy. We then briefly discuss an autoregressive network model that uses the first order contiguous nodes to control for network dependency. Both strategies are computationally cheap, can be easily parallelized

and will see modest increases in computation time as the size of the network grows large.

### *The Path Weighted Local Regression*

PWR is an alternative to model spatial dependency and non-stationary, heterogeneous effects of covariates across large connected networks. Inspired by the geographically weighted regression model of Fotheringham et al. (2002), Lloyd (2010) and Darmofal (2008), the PWR strategy describes the effect of unobserved factors across closely connected nodes.<sup>2</sup> The model takes as input the distance weights matrix of a network and gives more weight to nodes that have shorter paths between them. As a network variation on LOESS (Jacoby, 2000; Keele, 2008), the model is estimated locally, with  $i$  values for each local  $\beta$ , with weighted paths to all nodes in a network.

Consider a linear model on the data of a fully connected network where the dependent (node) variable  $y_i$  is explained by a set of observed covariates  $x_N$  and unobserved parameters  $\beta_N$ :

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \dots + \beta_n x_{in} + \varepsilon_i \quad (1)$$

Using ordinary least squares (OLS) we minimize the sum of square residuals and solve for the  $\hat{\beta}$  parameters, so that:

$$MSE(\beta) = \frac{1}{N} \sum_{i=1}^N (y_i - x_i \beta)^2 \quad (2)$$

$$\hat{\beta} = (X'X)^{-1} X'y \quad (3)$$

For any given node, however, we may consider that observations that are more closely connected (lower path distances) will have a larger effect on the dependent variable than observations that are further away. Therefore, for each node in the network we may estimate a separate weighted linear regression model:

$$wMSE(\beta, w_1, \dots, w_N) = \frac{1}{N} \sum_{i=1}^N w_i (y_i - x_i \beta)^2 \quad (4)$$

And solve for the local parameter:

$$\hat{\beta} = (X'WX)^{-1} X'Wy \quad (5)$$

Similar to the standard geographically weighted regression, we are estimating separate models for each node in the network, with observations that are further removed from a node weighing less than those observations that are closer. That is, all PWR estimates are local and the output of the model returns coefficients for each covariate at each node  $i$  in location  $[x, y]$ .

Model results provide a full distribution of  $\hat{\beta}$  parameters for all nodes in the network, which can then be post-processed and visualized. Heterogeneous effects of the independent variables by node location, consequently, allow researchers to understand differences in content propagation at different regions of the network.

In contrast with GWR in spatial models, path distances in networks are shorter, with a relatively small set of discrete values that connect all nodes. Therefore, bandwidths across different networks will have greater similarity compared to bandwidths in GWR. For our implementation of the PWR, we consider the minimum number of paths connecting each pair of nodes, creating a distance weights matrix. In dense areas of a network, therefore, there will be a larger sample of minimum paths connecting all nodes. By contrast, in sparsely connected regions of a network the opposite holds.

More important, shorter paths in densely packed communities will display lower variation across nodes as information will travel fast, while longer distances across communities will result in higher parameter discrimination. That is, more dense networks will reduce local effects, as the distance across all pairs of nodes will be smaller. Meanwhile, local effects will be more distinct in sparse networks, where path distances across nodes are on average larger.

Similar to GWR, building the weights matrix requires that researchers decide the relative contribution of nodes through a decay function. Several alternatives are available, with the Gaussian weighting function being the most common choice in existing literature (Fotheringham et al., 2002; Darmofal, 2015). The Gaussian discount function takes the form:

$$w_{ij} = \exp \left( \frac{-I}{2 \frac{P_{ij}^2}{b}} \right)$$

In the previous equation,  $P_{ij}$  describes the minimum number of paths connecting node  $i$  to node  $j$ , and  $b$  is the bandwidth for the path-decay of the weighting function. A larger bandwidth results in estimates that are more distinctively local. By contrast, a smaller bandwidth results in estimates that are roughly similar across nodes. As in other local polynomial models, there is a trade-off between bias and variance in the choice of the PWR bandwidth. To approximate an optimal bandwidth, one strategy is the leave-one-out cross-validation selection (Fotheringham et al., 2002):

$$CV = \sum_{i=1}^N (y_i - \hat{y}_{i \neq i})^2$$

The cross-validation procedure uses a leave-one-out process in which each local estimation of the observation  $i$ , where the local parameter is centered, receives weight equal to zero. Then, the score takes the square difference of the  $y_i$  and the prediction of the model for the observation where the weight was set to zero. We provide an analytical solution to find the point where the optimal value of the score CV is minimized. Working on big relational data, one can approximate the value by taking a sample of the nodes. The same procedure is suggested in applications of geographical weighted regression (Fotheringham et al., 2002).

### ***A Note on Parallelization***

One of the advantages of the path weighted regression model is that it can be easily parallelized. The technique is running separate regressions for each node, weighing more heavily those vertices that are closer to each other. The model can independently fit as many linear regressions as there are nodes in the network. Since calculations are computed using the same bandwidth on a steady weights matrix, regressions can be run in parallel rather than sequentially, which translates into lower computation times and more efficient use of computing power. The extent of these savings will depend on the number of cores available and the clock speed of each core, virtual or real. In a supercomputer cluster, one can expect much greater gains in efficiency and speed. This is particularly important in large networks, which are computationally demanding.

As important, the weight matrix in a PWR model does not increase exponentially, as the addition of new nodes does not translate into a more than proportional increase in the number of weights. As a result, computation does not become exponentially more difficult when a network size increases. Because more nodes only increase estimation demands linearly, larger networks can be modeled without sacrificing time or computational resources. Thus, combined with parallelization, PWR is a fast and efficient modeling strategy for large networks.

### **APPLICATION: TWITTER NETWORK ANALYSIS OF THE KAVANAUGH CASE**

To provide an example of the PWR, we analyze the Twitter repercussions of Donald Trump's nomination of Brett Kavanaugh to the US Supreme Court. After his nomination to the Senate in September of 2018, allegations of sexual harassment by the nominee were disclosed in the press and in Senate

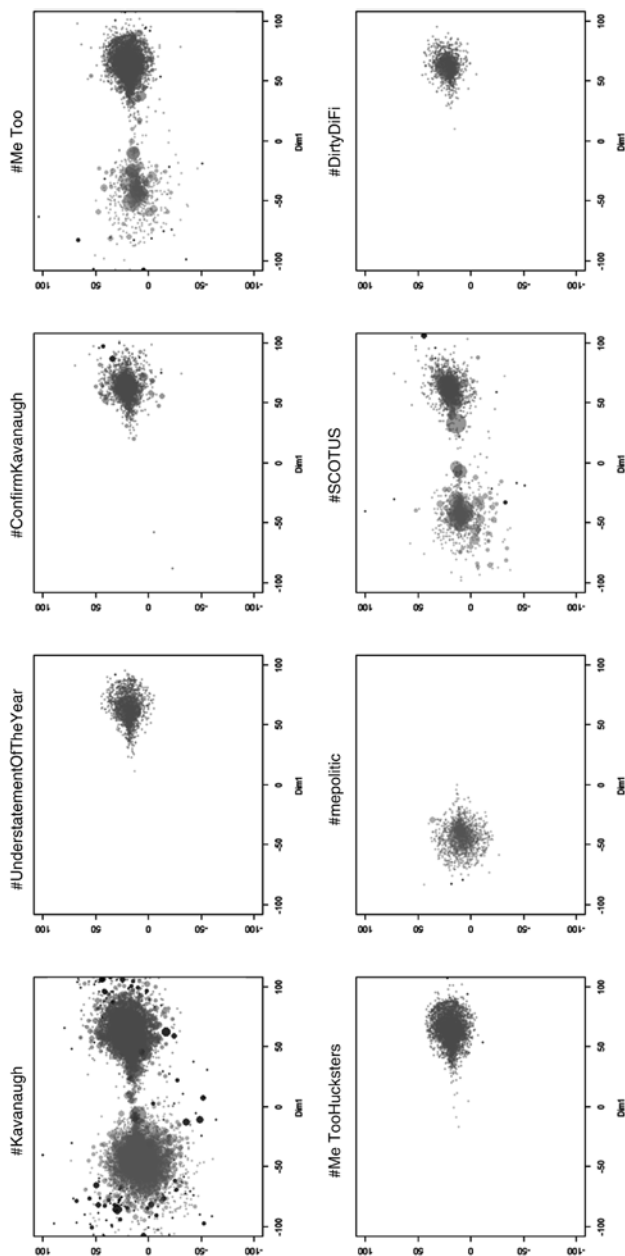

hearings. While Kavanaugh denied all charges, discussions in social media follow deeply polarized fault lines.

Between 8am and 12pm on September 19, 2018, we tapped into Twitter's stream API to collect publications that included the string of characters '*Kavanaugh*'. To provide a visual representation of the data, we estimated a Fruchterman–Reingold layout on the Kavanaugh network, retrieving the [x,y] coordinates for each user described in Figure 30.7. We also ran the walk.trap algorithm in *igraph 1.0* and retrieved an index community value for each node (Csárdi and Nepusz, 2006). The walk.trap algorithm (Pons and Latapy, 2006) sorted nodes in two large communities, which we identified by their highest in-degree users as aligned with opposition to Kavanaugh's nomination (39,631 users) or support of the nomination (54,174 users). The remaining 1,268 accounts were sorted into 532 smaller communities weakly connected to the two larger communities. Figure 30.7 provides a general visualization of the #Kavanaugh network.

We then ran our PWR model on the #Kavanaugh network, regressing each node's *average time to retweet* in seconds on the nodes in-degree. The model seeks to explain the speed of retweets of users that have a larger group of retweets (high in-degree), to model the propagation of information in different regions of a network. The PWR model allows us to explain heterogeneous effects of in-degree on content propagation at the center or periphery of each community, with time to retweet as a valuable measure of content propagation (Aruguete and Calvo, 2018).

### ***Estimation***

We first retrieved an optimal bandwidth for the weight matrix of path distances. To this end, we selected 250 random samples of 100 nodes, using the mean of these distributions to estimate the full cross-validation model. Figure 30.8 plots the sampling distribution of the bandwidth, which returns an optimal

**Figure 30.6** Activation of eight different hashtags during the Kavanaugh Confirmation Hearings, September 19, 2018

*Note:* The network has 95,073 nodes and 771,665 edges. Therefore, plotting all edges of the Kavanaugh network would be computationally expensive and produce very heavy graphs. However, we can simply adjust the size of the nodes to be proportional to the number of edges that include each hashtag. Therefore, all the relevant information can be presented to readers without plotting hundreds of thousands of edges.

bandwidth of 1.217 to be used on the complete dataset. It is worth noticing that smaller bandwidths will increase local effects while larger bandwidths will provide local estimates that are closer to the overall network mean. Finally, we parallelize estimation as suggested in the previous section.

Figure 30.9 presents the distribution of local  $\beta$  coefficients for the PWR model. We color the nodes by quartile to facilitate visualization. The size of the nodes describes the users' in-degree. The upper plot presents local intercepts while the lower plot presents the slopes of the model for each node. Interpretation of the results is straightforward, with more negative slope coefficients describing slower time to retweet as the in-degree goes up. The fact that authorities (i.e. users with higher in-degree) would

take a longer time to retweet information is expected for two distinct reasons. First, high in-degree authorities will be more risk averse regarding sharing content that may reflect poorly on them. Second, bots, trolls and other managed response systems tend to have a smaller numbers of followers and are set to quickly share content from priority accounts.

The intercept of the model described in the upper plot of Figure 30.9 shows that the average time to respond by users that are located at the center of each community is slower than the average time of the second periphery. More interesting, the slope estimates displayed in the lower plot show that the effect of in-degree on time to retweet is larger at the center of each community. That is, as in-degree increases, the decline in time to retweet is considerably larger for core nodes

**Figure 30.7 Primary connected network of #Kavanaugh**

*Note:* Blue dots describe users opposing the confirmation of Kavanaugh. Red dots describe users that support confirmation. Layout of users estimated using the Fruchterman-Reingold algorithm in *igraph*.

*Source:* Community detection using walk.trap algorithm in *igraph* (Csárdi and Nepusz, 2006).

**Figure 30.8** Sampling distribution of the bandwidth selection procedure (250 samples with 100 observations each)

in the pro- and anti-Kavanaugh networks than in their peripheries. By contrast, nodes in the periphery of each community are quick to propagate content even when their in-degree increases. The lack of effect of in-degree on content propagation on the second periphery of both communities lends considerable support for the presence of bots and computer managed accounts.

The heterogeneous effects of in-degree on content propagation are large and substantively interesting. As in-degree increases, the model shows, as expected, that nodes will take longer to share messages from other users. Users at the center of each community have a stronger decay function, while, for loosely connected nodes on the periphery, being an authority matters less for quickly propagating news.

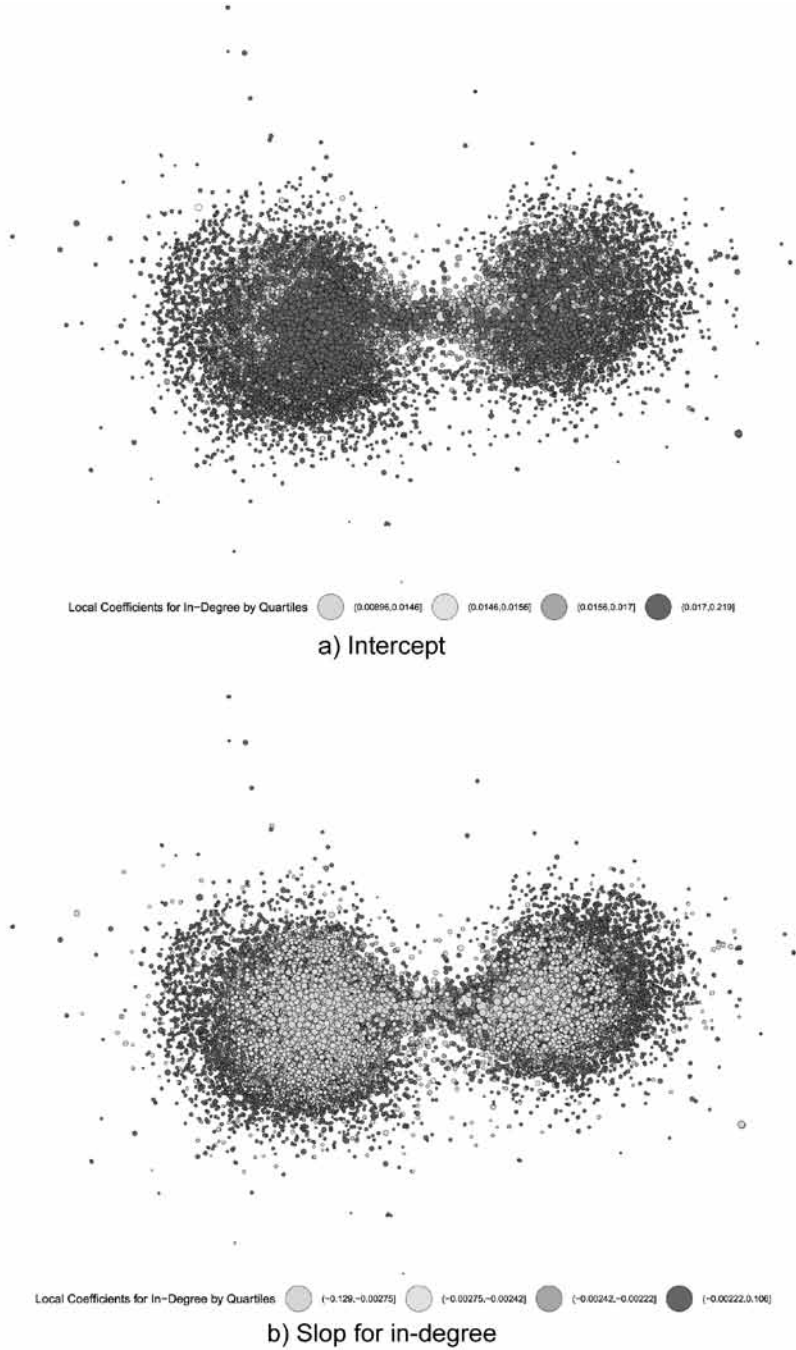

One caveat is important here. As one can see by the size of the nodes in Figure 30.9, authorities tend to be at the center of each community. Therefore, the average in-degree of the nodes is higher in the more populated areas of the network. With that feature in

mind, the PWR model allows us to assume that the effects of popularity exhibit increasing returns on the rate of content activation. One additional retweet of a user on the periphery of the network who rarely receives attention has a negligible effect on one's speed of content activation; the same increase in popularity has more substantial adverse effects in the speed of propagation on authorities located at the center of the network.

## CONCLUSION

As data availability increases, finding novel strategies to model big relational data has become a more pressing issue. In this chapter, we have emphasized the importance of efficient data management skills and the need for statistical models that are computationally efficient.

In the past decade, statistical advances in studying small and relatively homogenous social networks have been remarkable.

**Figure 30.9 PWR results in the network format. The model runs locally the impact of in-degree on time to retweet**

However, powerful new techniques such as exponential random graph models become technically challenging or altogether unfeasible as network size increases. Future methodological contributions to the study of social networks need to provide computationally feasible models for large heterogeneous networks.

The path weighted regression model is but one statistical alternative to extract meaningful information from very large social networks. Adaptation of standard error correction and auto-regressive models that can address network dependency seems to also be a valuable venue for computationally feasible estimation of inferential models for large networks.

## Notes

- 1 Twitter modified the way its APIs operate in August 2018, but the methodology explained here continues to be useful at the time of writing.
- 2 We direct the reader to some applications of GWR in the literature here (Darmofal, 2008; Cho and Gimpel, 2009; Calvo and Escolar, 2003).

# Quantitative-Empirical Methods

*This page intentionally left blank*

# Econometric Modeling: From Measurement, Prediction, and Causal Inference to Causal-Response Estimation

Robert Franzese

One can identify four modes, or purposes, of empirical analyses of positive<sup>1</sup> political science and international relations: *measurement* and description, *testing* (of causal theory or ‘effects’), *prediction* or forecasting, and *estimation* (of causal models and causal responses or effects).<sup>2</sup> These alternative aims or ends one might have in empirical analyses will place emphasis on different methodological challenges and properties over others and so demand different methodological approaches and tools. Econometric modeling<sup>3</sup> is an approach and set of tools that can be useful toward all four ends, but it plays an especially crucial role in the last: causal-response estimation. *Causal responses*, as opposed to *treatment ‘effects’*, refer to how some outcomes of interest (dependent variables) respond to inputs of interest (independent variables or treatments). As such, causal responses are inclusive of the contextual conditioning and effect heterogeneity, of the temporal, spatial, and spatiotemporal dynamics, and of the causal-simultaneity feedback

that *treatment ‘effects’* purposefully exclude (in order to cleanly identify tests for causal-effect *existence*), and these heterogeneities, dynamics, and feedbacks cannot be estimated without modeling of the theoretical and substantive structure. Indeed, the specification and estimation of the empirical model, far from being an unfortunate unavoidable limitation, is, from that perspective and for those aims, the very goal of the exercise. The purpose of the analysis and the aim of the theoretically structured model is for its estimates to provide a ‘useful empirical summary’ of the actual substantive processes under study.

*Measurement* follows (as directly as possible) on *operationalization* – the translation from theoretical concepts,  $X$  and  $Y$ , to observable empirical indicators of those concepts (see Munck et al., Chapter 19, this *Handbook*) – to assign quantitative values gauging the extent or presence of those indicators in some unit of observation. As an end-goal of empirical analysis, measurement is distinct from the other modes in its purely descriptive aims:

scholars might conduct empirical analyses to offer measures of –i.e., to describe empirically– democracy (e.g., Coppedge et al., 2008; Treier and Jackman, 2008), the ideological placement of parties (Poole, 2019), and socioeconomic cleavage-structures (Selway, 2011), to name just three. Measurement is also distinct in being a fundamental prerequisite of any of the other modes of empirical analysis: causal inference, causal estimation, or prediction/forecasting. Econometric modeling is central to some measurement analyses (for examples, see Fariss et al., Chapter 20, this *Handbook*; Leemann and Wasserfallen, Chapter 21, this *Handbook*; and Treier, Chapter 48, this *Handbook*), but the focus of this overview remains the distinction between causal-effect *testing* and causal-effect *estimation* and the essential role of econometric modeling in the latter.

Regarding testing of causal theory and ‘effects’, the aim of the analysis is to evaluate empirically some causal-theoretical claim, i.e., to assess *whether* some posited causal relationship or causal effect *exists* empirically. Because the analyst’s central purpose is to *test* a particular theory, ideally as little as possible from beyond that theory will be brought into the empirical assessment, so as to isolate the ‘empirical existence proof’ of the hypothesized causal effect. An empirical implication is derived from the theoretical argument that some  $X \Rightarrow Y$ , and the empirical analysis aims to evaluate this argument, this causal proposition, this hypothesis; in other words, the researcher wants to verify empirically that  $dx \rightarrow dy$ ,<sup>4</sup> which entails (a) demonstrating that  $dx$  associates with  $dy$  empirically and (b) substantiating that the causal arrow goes from  $X$  to  $Y$  in the expressed direction. Notice that the adverb *empirically* applies only to component (a), empirical association of  $x$  and  $y$ ; it intentionally does not apply to establishing causality because *causality* is a theoretical and not an empirical concept. Thus, the validity of ‘empirical tests of causal “effects”’ rests on the strength of the empirical association and, separately, on the strength of the arguments establishing that

the causal arrow generating that empirical association goes in the theorized direction from  $X$  to  $Y$ . That is why the gold-standard ideal for *causal inference*<sup>5</sup> (see Bowers and Leavitt, Chapter 41, this *Handbook*) is the randomized controlled trial (RCT).

The potential-outcomes framework (POF)<sup>6</sup> proposes as the estimand for causal inference, i.e., for testing the existence of a causal effect of  $X$  on  $Y$ :

$$\text{Causal Effect} = Y_{it}(X = 1) - Y_{it}(X = 0) \quad (1)$$

The *fundamental problem of causal inference* arises immediately: for a single observation on unit  $i$  at time  $t$ , denoted subscript  $it$ , the treatment or causal impetus,  $X$ , either is present ( $X = 1$ ) or is not ( $X = 0$ ). The counterfactual cannot be observed. Empirical designs for causal inference typically then proceed to establish conditions under which the difference in the empirical sample-means of  $y$  under  $x = 1$  vs under  $x = 0$  can be taken as an estimate of (1).<sup>7</sup> In the POF, this involves designing an analysis in which the comparison treatment ( $X = 1$ ) and control ( $X = 0$ ) groups are identical in all ways except treatment status ( $x$  value) and, potentially, the outcome ( $y$  value). The association of  $x$  and  $y$ ,  $dx \rightarrow dy$ , is measured or estimated, and it can be understood as indicating the causal relationship  $dx \Rightarrow dy$  if two alternative causal-relationship possibilities can be ruled out as having instead generated that association: (a) that  $Y \Rightarrow X$  (i.e., *endogeneity*, for instance by *simultaneity* or reverse causality) and (b) that some  $Z \Rightarrow Y$  and  $Z \leftrightarrow X$  (*spuriousness*).<sup>8</sup> Now we can see why the RCT is the gold standard for causal inference. *Experimental control* (of  $dx$ ) assures that movements in  $x$  could not have been caused by  $y$ ; the analysts know  $y$  did not move  $x$  because the analysts themselves moved or manipulated  $x$ .<sup>9</sup> *Experimental randomization* in which unit-times receive  $dx$  rules out spuriousness because if the values of  $dx$  are successfully independently randomized across a very large number of observational units, then  $dx$  will be unassociated

with any alternative causal-factor  $Z$  – observed or unobserved (or even unimagined!) – by definition of *independent*.

The validity of the estimated empirical associations as test statistics for causal inference rests on the strength of the argument that the causal arrow underlying those associations runs as theoretically postulated. In some rare situations,  $Y \Rightarrow X$  may be ruled out *a priori*: e.g., few  $Y$  could logically possibly cause race or gender  $X$ , but experimentation – i.e., *successful* control and randomization (and large samples<sup>10</sup>) – usually offers the strongest possible argument. In these cases, so-called *nonparametric causal inference* – i.e., causal inference that does not rely upon a pre-specified structural model (no model beyond the additive and separable treatment effects inherent in the difference-in-means definition of *causal ‘effect’* in (1)) – may be feasible. Even here, though, the validity of the causal-effect interpretation of any empirical estimate of (1) requires that Stable Unit Treatment Value Assumption (SUTVA) hold. The SUTVA conditions can be understood as the conditions under which the empirical  $dx$  is validly as-if experimental, i.e., controlled and randomized, and they amount practically to the following:

The probability of one unit receiving treatment, the *homogenous* magnitude of the treatment, and the *homogenous* effect of treatment are independent of each other and of any other unit(s) receiving treatment, the sizes of treatments in those others, or effects of treatments in those others.

As one of POF’s founding protagonists suggests, ‘The two most common ways in which SUTVA can be violated [are] when (a) there are versions of each treatment varying in effectiveness or (b) there exists interference between units’ (Rubin, 1990: 282). If SUTVA is violated, for instance by treatment – ‘effect’ heterogeneity or conditionality and/or by spillovers or contagion across units  $i$  and time periods  $t$  – and such heterogeneity and interdependence are ubiquitous in socio-politico-economics – empirical estimates of

(1) by the sample-mean difference of  $y$  given  $x = 0$  or  $x = 1$

$$\widehat{E}(y | x = 1) - \widehat{E}(y | x = 0) \quad (2)$$

will not be valid or, speaking more precisely and generally, will be *inadequate* estimates of the causal effect of  $X$  on  $Y$ , or the expected empirical response of  $Y$ ,  $dy$ , to an exogenous movement in  $X$ , i.e., treatment,  $dx$ . In general, reclaiming valid causal-effect (existence) inference, and *a fortiori* any hope to claim valid causal-effect (response) *estimation*, will require econometric modeling beyond that of estimating (1) by its empirical analog (2).

In sum to this point, for purposes of establishing causality and non-spuriousness in the experimental sample, i.e., for *internal validity*, the RCT is indeed the gold-standard ideal (see Morton and Vásquez-Cortés, Chapter 51, this *Handbook*). Of course, all scholars accept that practical and ethical considerations constrain what can or should be experimentally manipulated in the purview of social science. Even beyond those feasibility limitations, however, except for purely descriptive purposes of determining what was true in the observed experimental unit-times, analysts are more concerned with inferring from that experimental sample to what would be true in new data, outside that observed sample, i.e., with *external validity*.<sup>11</sup> And for that purpose, three significant challenges of *representativeness* – of the experimental sample to the intended population of inference, of the experimental treatment to the causal variable of interest, and of the experimental context to that of the socio-politico-economic outcomes of interest<sup>12</sup> – hinder what can usefully be inferred from these high-internal-validity RCT studies to target populations of interest. As a practical, empirical, applied matter (see also note 11), it seems as though external validity dominates internal validity in mean-squared-error terms, where potentially biased observational studies in proper context generally yield smaller mean-squared errors than do unbiased experimental studies conducted

in *necessarily*<sup>13</sup> incorrect contexts (Pritchett and Sandefur, 2015). Moreover, even an ideal RCT is generally mute on other potential causes and says little about the magnitude of the treatment effects from the study relative to other effects<sup>14</sup> and relative to variation in the outcome variable of interest in the actual (external) context of interest.

Experiment[s] will have nothing whatsoever to say about other causes. What it will do, and do well, is to determine *whether* [...treatment...] had a positive or negative effect, or none at all. (Kellstedt and Whitten, 2009: 70; emphasis added)

Regarding external-validity concerns but staying within this *causal inference* or *testing-for-causal-effects* mode of empirical analysis, there has been much advancement in extra-laboratorial field- and survey-experimental research designs (see Sinclair et al., Chapter 52, this *Handbook*) and observational-study research designs (see Bowers and Leavitt, Chapter 41, this *Handbook*; Nielsen, Chapter 42, this *Handbook*; Keele, Chapter 43, this *Handbook*; Cattaneo et al., Chapter 44, this *Handbook*) to yield pseudo-experimental conditions for this causal 'effect' as defined in the POF (equation (1)). Treatment uptake by subjects is necessarily less strongly controlled in the field than in the lab, therefore, relative to the RCT laboratory experiment, field-experimental studies essentially trade some loss of purity in control and randomization for some enhancement of representativeness, perhaps of all three sorts (see note 12). Survey experiments, somewhat analogously, buy enhanced representativeness of subjects, given a scientific survey-design appropriate to the intended population, at the cost of representativeness of the treatment – mention or emphasis in a survey question, question ordering etc., are generally quite unlike the conceptual cause of interest in the theory – and of the context – answering a survey is usually very unlike the context to which the results are intended to be inferred.

For these reasons, social scientists sometimes must, and often *choose*, to work with

observational data, especially for purposes of inference beyond sample, i.e., of inferring a causal relationship to exist in some target population of interest, and not only that a cause operated in some (specific, observed, and past) experimental sample. As shall be demonstrated below, the move to econometric modeling of observational data becomes especially judicious as the aim of the analysis moves beyond establishing that some causal effect exists (*causal inference*), to estimating causal responses,  $dy/dx$  (*causal estimation*). With these moves beyond internal causal inference to external causal inference and, especially, further beyond to causal estimation, empirical analyses in social-science observational studies confront not one, but at least four, fundamental challenges; namely, in socio-politico-economic reality (Franzese, 2007):

- 1 *Multicausality*: just about everything matters;
- 2 *Causal heterogeneity and context conditionality*: how everything that matters varies – how everything matters depends on just about everything else, i.e., on context;
- 3 *Dynamic causality*: just about everything is temporally, spatially, or spatiotemporally dynamic, not static;
- 4 *Omnicausality*: just about everything causes just about everything else.

Further exacerbating these four challenges is a fifth (or zero-th) challenge, which is that even with the enormous quantities of data now obtainable from internet, social-media, satellite/geospatial, and other big-data sources (Nyhuis, Chapter 22, this *Handbook*; Barberá and Steinert-Threlkeld, Chapter 23, this *Handbook*; Darmofal, Chapter 24, this *Handbook*), observational empirical analysts often find relatively little useful empirical variation with which to surmount these hurdles, even in those oceans of data. In the first instance, this is where econometric modeling becomes essential: given heterogeneity, dynamics, or simultaneity, without some structural model to reduce the parameterization of the problem, the number of quantities

to estimate necessarily grows faster than the number of observations with which to estimate them.

Consider the following representation of empirical relations for one outcome of interest:

$$y_{it} = f_{it}(\mathbf{x}_{js}, \boldsymbol{\beta}_{js}, \boldsymbol{\varepsilon}_{js}); \boldsymbol{\varepsilon} \sim (\mathbf{0}, \boldsymbol{\Sigma}_{it}); \quad (3)$$

$$i, j = 1..N, t, s = 1..T, n = NT$$

In this perhaps most-general possible model,<sup>15</sup> there are  $k$  parameters,  $\boldsymbol{\beta}_{it}$ , linking right-hand-side variables,  $\mathbf{x}_{js}$ ,<sup>16</sup> to the outcome of interest,  $y_{it}$ , plus a mean-zero stochastic component,  $\boldsymbol{\varepsilon}$ , characterized by an  $n \times n$  variance-covariance matrix, itself possessing  $\frac{1}{2}n^2 + \frac{1}{2}n$  (which is greater than  $n$ ) parameters. In total, there are generally  $k + \frac{1}{2}n^2 + \frac{1}{2}n$  parameters to estimate *per function, per observation*. This number of quantities to estimate grows exponentially faster than does the number of quantities observed (a  $k + 1$  vector of  $y, \mathbf{x}_{it}$ ). Thus, without some extremely strong structural-modeling assumptions, there could be no empirical analysis at all. From this perspective, we see that so-called nonparametric causal inference POF approaches applying (2) are actually highly structurally modeled: (a) empirical relations are assumed constant across all observations (within a bin if some heterogeneous effects are allowed) so there is only one function,  $f$ , to estimate; (b) random components are assumed orthogonal and homogenous across observations (or assumed zero with deterministic relationships such that the only randomness enters through the experimental manipulation); and (c) the parameters,  $\boldsymbol{\beta}$ , are also assumed constant across all observations,  $it$  (within a bin).<sup>17</sup> Notice that these are essentially identical to the assumptions of classical regression analysis. Indeed, the typical empirical model in POF-based studies, (2), is in many ways much more restrictive than the typical empirical model in regression-based studies: additive, separable,

homogenous treatment effects (usually of a homogenous treatment:  $X = 1$  or  $X = 0$ ). The assumptions are the same because the logical necessity of some (radical) parameter reduction is the same. Therefore, the *arguments* or claims made about the research design, and not the estimation model, are the basis for POF causal-inference studies' claims to have ruled out spuriousness and simultaneity (again reflecting that causality is theoretical, not empirical).

Much of the econometric modeling deployed in the service of causal-inference studies focuses on ruling out spuriousness, i.e., some  $Z$  related to  $X$  actually causes  $Y$ :  $Z \leftrightarrow X$  and  $Z \Rightarrow Y$ . *Matching*-based inference (see Nielsen, Chapter 42, this *Handbook*), for example, leverages the idea that, if the researcher can observe and measure all relevant  $\mathbf{z}$ , then comparing  $y|x = 1$  to  $y|x = 0$  for 'balanced' groups of data – meaning data for which the empirical *distributions* (sample means, variances, etc.) of all  $\mathbf{z}$  are equal (or statistically indistinguishable) – yields a difference in means between treated and untreated observations that could not possibly be due to those  $\mathbf{z}$ . Note that matching, unlike the RCT, cannot control in this way for unobserved  $\mathbf{z}$ . Notice also that matching control for  $\mathbf{z}$  is exactly like regression control for  $\mathbf{z}$ , except that the former is much more robust. Multiple regression controls effects of  $\mathbf{z}$  that manifest in the manner modeled (e.g., linear effects only in linear regression), whereas matching controls effects of  $\mathbf{z}$  in any manner they may manifest.<sup>18</sup> One might thus say 'Matching control is regression control on steroids'. Finally, also like regression, matching *per se* offers absolutely no address of simultaneity; like regression, claim for the matching-based estimation of (2) to be causal rests entirely on the adequacy of the controls.

Another causal-inference econometric-modeling approach that is focused on eliminating the possibility of spuriousness is the difference-in-difference (DID) design (see Keele, Chapter 43, this *Handbook*), and, relatedly, the difference-in-difference-in-difference

(DID or 3D) design and fixed-effects (FE) designs. The key notion underlying DID econometric modeling is that differencing the data,  $y_{it} - y_{it-1}$ , removes any time-constant factor in  $y$ , including any unobserved (time-constant)  $\mathbf{z}$ . Observed  $\mathbf{z}$ , including time-varying  $\mathbf{z}$ , may be addressed by regression or matching control; scale-variation or other functional-form issues may likewise be addressed by (structural) econometric modeling. Empirical implementation of the DID design is very simple. One needs observations on two groups, both in a pre-treatment period in which the  $X$  of interest has not been applied and a post-treatment period in which  $X$  has been applied in one but not the other group. Regression analysis with an indicator for post-treatment period, an indicator for treatment status ( $x = 1$  or  $x = 0$ ), and the interaction of those two dummies yields a coefficient on the interaction of the (treatment) difference in (time) difference, i.e., of the causal ‘effect’ in (2), under the maintained assumptions. Like matching and regression (after all, DID is commonly implemented by estimating a simple dummy-variable-interaction regression model), DID *per se* offers no address to the possibility of endogeneity. Units may select the treatment because of values of  $y$  or expected values of  $y$ , for instance, invalidating the causal interpretation of the DID estimate.

The (Regression) Discontinuity Design ((R)DD) is also an econometric approach to causal inference (see Cattaneo et al., Chapter 44, this *Handbook*) but one focused on addressing simultaneity bias as well as *unobserved confounds*, a.k.a. omitted-variable bias. The DD capitalizes on situations in which a treatment,  $x = 1$ , is triggered – a discontinuous jump in the probability of treatment suffices – as an observed continuous *index variable*,  $v$ , crosses some threshold value,  $v_c$ . For instance, a candidate wins a plurality-election office when his/her vote share crosses the plurality threshold (e.g., Caughey and Sekhon, 2011) or a party’s probability of entering parliamentary government

jumps discontinuously upward when its seat share crosses the plurality threshold (Hays et al., 2019). Provided (a) there are no systematic differences at the threshold in variables,  $\mathbf{z}$ , other than the treatment variable (which can be evaluated empirically for observed  $\mathbf{z}$ ), and (b) no endogeneity in which observations fall near to either side of the threshold (called *sorting*, in this context), then exactly at, or at least near the threshold, it is completely random, or mostly random, whether the observation receives treatment. The causal ‘effect’ as defined in (1) is thus identified at the threshold as if by RCT: any observed or unobserved  $\mathbf{z}$  should be equal on either side very near the threshold (and this can be verified for observed  $\mathbf{z}$ ), and treatment is ‘applied’ randomly. Of course, like the RCT it aims to mimic, the DD estimate lacks external validity of its estimated treatment effect for conditions unlike those at the threshold (e.g., for not-close elections, which greatly limits the applicability of DD estimates of US Congressional incumbency advantage, e.g.). With some additional assumptions, one can estimate (2) by an RDD regressing  $y$  on a flexible polynomial in index,  $v$ , an indicator for treatment status,  $x = (0,1)$ , and the interaction of the polynomial terms with  $x$ . The coefficient on the  $x$  is then the RDD-identified effect.

The more full-throated econometric-modeling approach to causal inference relies upon instrumental variables (IV) (see Carter and Dunning, Chapter 40, this *Handbook*; see also selection modeling in Böhmelt and Spilker, Chapter 37, this *Handbook*) and, more full-throated still, systems estimation (see, e.g., Jackson, 2008). The causal-identification strategy of instrumentation is well known: given a causal relation,  $y=f(x\beta, \square)$ , about which there may be concerns that  $y \Rightarrow x$  as well, find some  $z$  that (a) covaries with  $x$  but (b) not with  $\square$  – alternatively, with more substantive appeal, this variable  $z$ , called an *instrument*, needs (a) to relate to  $x$  but (b) not to  $y$ , except through that relationship to  $x$  – and then estimate the relationship of  $y$  with  $z$  instead by indirect least-squares (ILS), for example:

$$\begin{aligned}
 & \left. \begin{aligned}
 (i) \quad y_{it} &= \beta x_{it} + \gamma z_{it}^y + \varepsilon_{it}^y \\
 (ii) \quad x_{it} &= \alpha y_{it} + \delta z_{it}^x + \varepsilon_{it}^x
 \end{aligned} \right\} \Rightarrow y_{it} \\
 & = \beta(\alpha y_{it} + \delta z_{it}^x + \varepsilon_{it}^x) + \gamma z_{it}^y + \varepsilon_{it}^y \\
 & \Rightarrow y_{it} = \frac{\beta\delta}{1-\beta\alpha} z_{it}^x + \frac{\gamma}{1-\beta\alpha} z_{it}^y \\
 & \quad + \frac{1}{1-\beta\alpha} \varepsilon_{it}^y + \frac{\beta}{1-\beta\alpha} \varepsilon_{it}^x \quad (4)
 \end{aligned}$$

The ILS coefficient-estimates may be solved to retrieve estimates of  $\beta$  and the other coefficients (once the residual correlation is accounted), but, for solely causal-inference *testing* purposes, the significance of the estimated coefficient on  $z_{it}^x$  may be evaluated directly. Note that instrumentation strategies, even in the causal-inference modality that aims to minimize modeling assumptions, must pre-specify enough about the causal process to at least offer a causal diagram (Pearl, 1995), if not a fully specified system of equations, to establish IV-identification conditions (a) and (b).

Two-stage least-squares (2SLS) is a convenient implementation of IV-estimation. 2SLS estimates equation (i) in (4), for example by regressing  $x$  on (any exogenous variables across the system as given by the model/graph and)  $z$ , or on  $\mathbf{z}$  if more than one instrument is available (stage 1), and then regressing  $y$  on that fitted  $x$  (and any exogenous variables in equation (i)) (stage 2). The 2SLS procedure puts the fitted- $x$  regressor in the same scale as the endogenous  $x$  so the 2SLS estimated coefficient on instrumented- $x$  estimates directly, and if there are multiple instruments, the *regression* of stage 1 is the optimal procedure for projecting multidimensional information  $\mathbf{z}$  to unidimensional  $x$  and  $y$ . Single-equation three-stage least-squares (3SLS), which is asymptotically equivalent to limited-information maximum-likelihood (LIML), gains efficiency relative to 2SLS by accounting the necessary non-sphericity in the stochastic component of the model seen in the compound error term in the last line of (4). For

further efficiency gains, the full system of equations (i) and (ii) can be estimated jointly by multi-equation 3SLS or by (asymptotic equivalent) full-information maximum-likelihood (FIML).<sup>19</sup> Systems approaches also facilitate the incorporation of cross-equation substantive/theoretical knowledge into the estimation, such as. e.g., that some coefficients are equal, proportionate, or oppositely signed across equations.

Strategies for addressing simultaneity and the other challenges for applied empirical social science can perhaps be enumerated from most to least structural (excepting item 0<sup>20</sup>) thusly:

- 0 Time ('the poor man's exogeneity');
- 1 Full-system specification and estimation;
- 2 (Single-equation) instrumentation;
- 3 Matching;
- 4 Difference-in-difference;
- 5 Discontinuity designs;
- 6 Survey and field experimentation;
- 7 Laboratory experimentation.

For *causal-inference* testing purposes, the ordering also lists in generally increasing *credibility*, given their decreasing reliance on information beyond the theory to be tested and the empirical data. Indeed, given the tremendous advantages of controlled randomization against spuriousness and reverse causality, what could possibly argue for econometric modeling, or model-based estimation in general, over the RCT or nonparametric causal-inference strategies in general? At broadest, and in general, the answer is: external validity.

Firstly, prior to any external-validity concerns, note that for description, summarization, and measurement purposes, causality is simply irrelevant. Experimentation would be exceedingly cumbersome, and piles of nonparametric estimates – being necessarily unconnected by any formula – tend to offer only poor summary and poorer understanding.<sup>21</sup> The dominance of model-based approaches of diverse kinds for textual-data analysis, scaling, or classification (see Benoit,

Chapter 26, this *Handbook*; Ergerod and Klemmensen, Chapter 27, this *Handbook*; Bouchat, Chapter 28, this *Handbook*), sentiment or network description (Curini and Fahey, Chapter 29, this *Handbook*; Calvo et al., Chapter 30, this *Handbook*), and latent-concept recovery (Fariss et al., Chapter 20, this *Handbook*; Leemann and Wasserfallen, Chapter 21, this *Handbook*; Treier, Chapter 48, this *Handbook*) is therefore natural and optimal. Rather than the RCT, the gold standard for measurement exercises is *usefulness* in conveying summary description or in subsequent analyses.

Likewise, for purely predictive and forecasting purposes, the gold standard is not recovery of some ideal-experimental results; it is (obviously) *out-of-sample prediction/forecast error* (see, e.g., Schrodtt and Gerner, 2000; for a similar view but comparing prediction to explanation instead of causal inference, see Ward, 2016). Again, internal validity is irrelevant insofar as the aim is to predict the value of some  $y_{j_s=i_t}$ , full stop; external validity is the only relevant consideration for pure prediction (see note 11). Here, too, econometric model-based strategies dominate, but in this case it is perhaps due more to the inherent limitations of non-parametrics than those of causal inference. Nonparametric estimates, by construction, offer no connection from  $E(y|x = x_0)$  to  $E(y|x = x_1)$ ; consequently, as the possible values that a potentially large number of useful predictors, their interactions, and interdependencies may take grows, the number of nonparametric estimates needed expands at least exponentially (and possibly combinatorially).<sup>22</sup> The forecasting device must somehow dampen this meteoric proliferation of necessary estimands; the preferred methods, having proved most effective, i.e., performing best by the sole relevant criterion, *out-of-sample prediction/forecast error*, include sophisticated econometric modeling with Bayesian methods (see Park and Shin, Chapter 47, this *Handbook*; Gill and Heuberger, Chapter 50, this *Handbook*),

particularly Bayesian model-selection and model-averaging (see Hollenbach and Montgomery, Chapter 49, this *Handbook*), Bayesian structural vector autoregression (Kilian and Lütkepohl, 2017), and machine-learning and artificial-intelligence methods (see Mikhaylov and Chatsiou, Chapter 55, this *Handbook*; Shoub and Olivella, Chapter 56, this *Handbook*).

As analysts' aims move beyond measurement, prediction, and *causal inference* or *testing* for (existence of) causal effects to *causal estimation* or *estimating causal responses*, the limitations of the experimental paradigm in the face of the four fundamental challenges for empirical research in social science become more pronounced. *Multicausality*, that there tends to be many relevant causes of effects, is least problematic, being addressed by control and, in many respects – as just discussed – ideally, by experimental control, at least for causal-inference purposes.<sup>23</sup> The limitations with respect to that first fundamental challenge relate to representativeness and external inference: comparing the treatment in the experimental sample and context to the intended treatments (causes) in their intended population and contexts. Effect heterogeneity raises more serious challenges. The structure of the Neyman–Holland–Rubin (NHR) causal model is of additive, constant, separable effects.<sup>24</sup> Effect heterogeneity or conditionality can, in principle (though see notes 22 and 24), be managed by binning observations with effects that are assumed homogenous within bins. However, to see how limiting this can be given socio-politico-economic reality, consider the simple case of the sigmoidal non-linearity implied in binary-choice and other binary-outcome contexts simply by the nature of probabilities or proportions. The essential substance of the matter dictates that for all binary outcomes, probabilities, or proportions,

$$\Pr(y = 1) \equiv p(y) = f(x, \beta, \varepsilon) \quad (5)$$

$f$ -being sigmoidal with  $0 \leq f \leq 1$

**Figure 31.1** The logically necessarily sigmoidal relation  $p(y) = f(x)$

A model of causal effects on probabilities that does not respect these first principles – the relationship between  $x$  and  $p(y)$  tapers toward its 0 and 1 bounds, (because it surely would not kink at those bounds) and so is steeper in some manner in between such as in Figure 31.1 (the NHR with  $\frac{dp}{dx} = c$  constant is one such non-respecting model) – is unlikely to yield very good *estimates* of those causal effects for external inference, especially for estimates traversing more curved portions of the S-curve and especially not beyond support. If nonlinearities like these are common, or more generally if effects in socio-politico-economic reality are typically heterogeneous and context-conditional as contended here, then the NHR causal model is a poor basis for *causal-effect estimation*, although it may remain a strong model for *causal inference* (see, e.g., Imai and Ratkovic, 2013; Egami and Imai, 2015).

The limitations of nonparametric causal inference in confronting causal heterogeneity and context conditionality are debilitating

for causal-effect estimation, for which purpose econometric modeling is inescapably essential. Far from an unavoidable detraction, however, estimation of an econometric model reflecting the theory and substance of the context is the very goal of the causal-estimation exercise. In this *Handbook*, as examples, see Fukumoto, Chapter 35, for a discussion of appropriate modeling of duration or survival contexts, and see Steenbergen, Chapter 36, for effective empirical-modeling strategies for parameter heterogeneity in multilevel/hierarchical contexts. For a quick illustration of how substantively theoretically specified econometric-model estimation can yield interesting and useful empirical science beyond proofs of causal existence, consider the implications of principle-agent/multi-actor bargaining for policy outcomes (Franzese, 2003, 2010). Equilibrium policy-outcomes in principle-agent and other shared-policy-control situations are some convex combinations of the two (or more) actors' optimal policies, e.g., a linear-weighted average, such as:

$$\begin{aligned}
 y &= \underbrace{c_p(\mathbf{z}) \times f(\mathbf{x}_p)}_{\text{principal control} \times \text{p action}} + \underbrace{[1 - c_p(\mathbf{z})] \times g(\mathbf{x}_a)}_{\text{agent control} \times \text{agent action}} \\
 \Rightarrow \frac{dy}{dx \in \mathbf{x} \equiv (\mathbf{x}_p \cup \mathbf{x}_a)} &= h(c_p(\mathbf{z})) \quad (6) \\
 \text{and } \Rightarrow \frac{dy}{dz \in \mathbf{z}} &= q(\mathbf{x})
 \end{aligned}$$

In words, the effect on the outcome of anything to which principal and agent (the bargainers) would respond differently depends on the degree to which each of the players is in control, which depends in a typical principal-agent model, e.g., on monitoring and enforcement conditions, represented in (6) by  $c_p(\mathbf{z})$ . Conversely, the effect of anything that shapes monitoring and enforcement costs and efficacy,  $z \in \mathbf{z}$ , depends on everything to which the players would respond (differently):  $x \in \mathbf{X}$ . By virtue of the shared influence of the bargainers over the outcome, the effect of any  $x \in \mathbf{X}$  to which they would respond differently depends on all  $\mathbf{z}$  in  $c_p(\mathbf{z})$ , the weight of each actor in determining the outcome, and, *vice versa*,<sup>25</sup> the effect of any  $z \in \mathbf{z}$  that influences the actors' relative control depends on all  $x \in \mathbf{X}$  to which the actors respond differently.

How can empirical researchers effectively estimate complexly context-conditional effects like these? One strategy is to impose the substantively known structure in the empirical model. Franzese (1999) estimates an empirical model like (6) to show how the anti-inflationary effects of central bank independence (CBI) – a situation of shared monetary-policy control, agent central bank and principal government – depend on political-economic conditions that would make governments more inflationary (bigger effect) or less inflationary (smaller effect). The convex-combinatorial form of (6) implies that only one additional parameter needs be estimated to capture all of these theoretically/substantively implied interactions; namely, this parameter is the factor of proportionality by which the central bank independence measure dampens inflation from the government's to the bank's preference as CBI increases. By a further nested pair of weighted

averages, Franzese (2003) extends the central bank/government domestic-actors model of 1999 to the open and institutionalized economy, wherein exchange-rate pegs effectively delegate from these two domestic actors to the peg-currency policy, and infinitesimally small capital-open economies, which effectively constrain domestic policy to the global average. Notice from the estimation model and results in Figure 31.2 that the 'theory-informed' model requires just two more parameter estimates than the linear-additive model, which completely lacks interactions, and 50 fewer than the linear-interactive model requires to generate comparable interactivity. And yet the coefficient estimates on small capital-openness,  $E$ , on single- and multi-currency pegs,  $SP$  and  $MP$ , and on CBI,  $C$ , are easily interpretable as the proportionate constraint each of those measures places on the opposite actors in its convex combination (see model (14) in Figure 31.2). The graphs illustrate two of the (many) rich substantive insights yielded about the context-conditional amplitude of partisan inflation-cycles at the top-right and about the generally declining anti-inflationary bite of CBI since about the 1970s, coinciding with the acceleration of the postwar and current great globalization.<sup>26</sup>

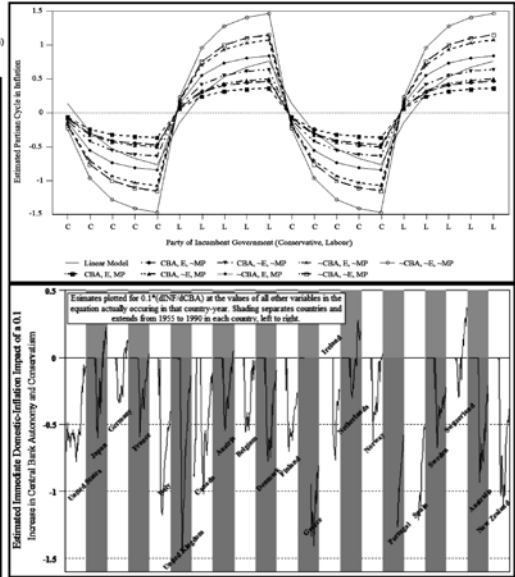

Next, consider how temporal and spatial dynamics highlight the inadequacy of the NHR model to causal-response estimation. Notice that the NHR estimand (1) and its typical empirical estimate (2) yield a scalar estimate, a single number, as the causal 'effect' of  $x$  on  $y$ . In a temporally dynamic context, in contrast, taking the simplest example to illustrate:

$$\begin{aligned}
 (i) \quad y_i &= \rho y_{i-1} + \beta x_i + \varepsilon_i \\
 (ii) \Rightarrow \frac{dy_i}{dx_i} &= \beta \\
 (iii) \Rightarrow \frac{dy_{LR}}{dx_{LR}} &= \underbrace{\beta dx}_{\text{period 0}} + \underbrace{\rho \beta dx}_{\text{period 1}} + \underbrace{\rho^2 \beta dx}_{\text{period 2}} + \underbrace{\rho^3 \beta dx}_{\text{period 3}} + \dots \\
 &= \underbrace{\sum_{s=0}^{\infty} \rho^s \beta dx}_{\text{assuming } |\rho| < 1 \Rightarrow \text{L.R multiplier}} = \frac{1}{1-\rho} \times \beta \times \underbrace{dx}_{\text{perm. shock}} \quad (7)
 \end{aligned}$$

$$E(\pi_t) = \beta_0 + \beta_1 E\pi_t + \beta_2 \pi_{t-1} + (1 - \beta_1) E\left\{ \begin{aligned} &(\beta_{10} GP + \beta_{11} ET + \beta_{12} UP + \beta_{13} BC + \beta_{14} AW + \beta_{15} FS + \beta_{16} TE + \beta_{17} \pi_t) \\ &(-\beta_{18} C) - \beta_{19} C_{t-1} \\ &(-\beta_{20} SP - \beta_{21} MP) + \beta_{22} SP + \beta_{23} MP + \beta_{24} \pi_t \end{aligned} \right\} \quad (14)$$

**Table 1** Alternative models of inflation in 21 OECD democracies, 1957–1990

**Figure 31.2** ‘Multiple Hands on the Wheel’ model of complex context-conditionality in monetary policymaking

A causal-inference study designed to test whether  $x$  causes  $y$  will estimate  $\beta$ , which the second line of (7) demonstrates is only the contemporaneous response,  $dy_t$ , to a shock (treatment),  $dx_t$ , in that same period. As the lines (iii) show, if the shock persists (and nothing else occurs), the subsequent period experiences an additional  $\rho\beta$  and the period after that an additional  $\rho^2\beta$ , and so on. If the shock persists infinitely, the long-run steady-state (LRSS) response equals the long-run or temporal steady-state multiplier of  $1/(1-\rho)$  times the initial response,  $\beta$  (for further development and application, see Linn and Webb, Chapter 32, this *Handbook*; for fullest textbook treatment, Hendry, 1995). The single scalar<sup>27</sup> in (2) is obviously an inadequate-answer to the question, ‘what is the effect of  $x$  on  $y$ ?’, in the temporally dynamic context. In fact, the question is underspecified in the dynamic context: ‘the effect of (a movement in)  $x$ , when?, on (movements in)  $y$ , when?’<sup>28</sup>

Temporal dynamics matter greatly for substantive conclusions about causal-effect size.

Consider, e.g., the many well designed causal-inference studies on the effects of voter-registration hurdles, which typically find ‘very small effects’ on turnout (e.g., Hershey, 2009, reviews), but these are impulses,  $\beta$ , not effects,  $dy/dx$ . The considerable evidence that voting is a habit slowly acquired over repeated elections (e.g., Gerber et al., 2003) implies that voter turnout evolves dynamically, as in (7), so the response of voter turnout to registration-easing legislation is not a snapshot-in-time scalar but a vector over time, and with  $\rho$  being large, the long-run cumulative effects,  $\beta/(1-\rho)$ , are many times those previously estimated ‘very small’ causal parameters. Another illuminating example, from Franzese (2002), shows (in Figure 31.3) dynamic estimates from an econometric model of responses of public debt in developed democracies, counterfactually (a) to the actual OECD average real interest-rate (net growth) series 1954 to 1995 and (b) to hypothetical permanent a plus-one standard-deviation shock in real interest-rates proceeding indefinitely into the future, both

**Figure 31.3 Substantive dynamic-effect estimates of real interest-rate net of growth impacts on public debt**

Source: Franzese (2002).

starting from different initial debt-to-GDP ratios. Substantively, these dynamic estimates demonstrate that interest rates, i.e., monetary policy, could have enormous effects on the long-term accumulation of public debt and that, in fact, much of the post-1970s emergence of public-debt crises owed to that stagflationary era’s adverse shocks to growth and unemployment, inducing deficits which were followed by tight monetary-policy that spiked interest rates on those newly accumulating debts.

The inadequacies of the NHR model and estimand are highlighted further and amplified in the time-series cross-section (TSCS) and spatially/spatiotemporally dynamic contexts (see Troeger, Chapter 33, this *Handbook*; Cook et al., Chapter 39, this *Handbook*; relatedly, for dyadic-data and network analyses, see Neumayer and Plümper, Chapter 38, this *Handbook*; Victor and Khwaja, Chapter 45, this *Handbook*; Schoeneman and Desmarais, Chapter 46,

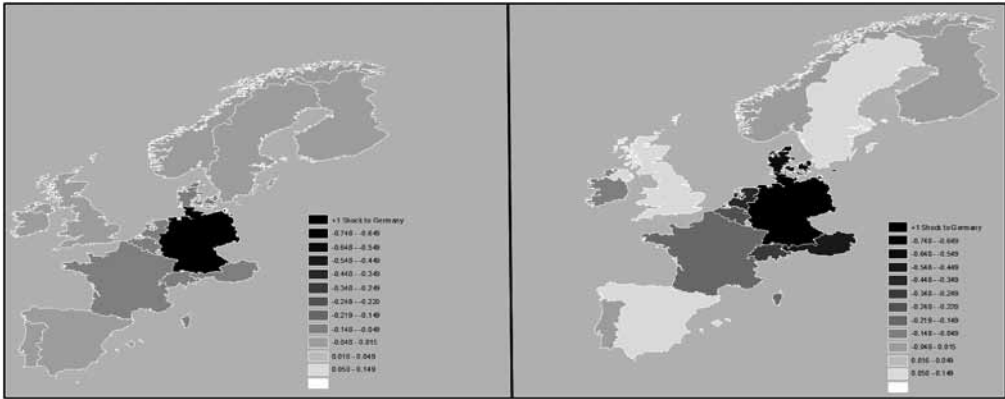

this *Handbook*). A very low-dimensional example, an  $n = 3$ -units cross-section with simultaneous first-order spatial-autoregressive interdependence (i.e., outcome contagion), suffices to demonstrate:

$$\begin{aligned}
 (i) \quad & \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} \\
 = \rho & \begin{bmatrix} 0 & w_{12} & w_{13} \\ w_{21} & 0 & w_{23} \\ w_{31} & w_{32} & 0 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} \\
 + \beta & \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} + \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \end{bmatrix} \\
 (ii) \quad & \mathbf{y} = \rho \mathbf{W} \mathbf{y} + \beta \mathbf{x} + \boldsymbol{\varepsilon} \\
 (iii) \Rightarrow & \mathbf{y} = [\mathbf{I} - \rho \mathbf{W}]^{-1} [\beta \mathbf{x} + \boldsymbol{\varepsilon}] \\
 (iv) \Rightarrow & d\mathbf{y} = [\mathbf{I} - \rho \mathbf{W}]^{-1} \beta \times d\mathbf{x}
 \end{aligned} \tag{8}^{29}$$

Again, the NHR estimand (1) and its empirical estimate (2), which a well designed and conducted experiment would produce, correspond to  $\beta$ , which we can call the ‘pre-dynamic *impulse*’ from  $x$  to  $y$ , and not ‘the effect of  $x$  on  $y$ ’, understood as how  $Y$  responds to movements in  $X$ , which is instead given by line (iv) of (8). Once again, the NHR estimand (1) and estimate (2) are in the wrong dimensionality, and the question is ill posed. Neither treatment nor effect are scalars: both are vectors/matrices and the effect statement is underspecified. In spatial/spatiotemporal contexts, the fully specified statement is ‘the effect of movements in  $\mathbf{x}$ , where (and when)? on movements in  $\mathbf{y}$ , where (and when)?’. In fact, in this case, the *impulse* is not even observable: the response in unit 1 – e.g., to some  $dx$  in, say, unit 1 itself – begins with the *impulse*,  $\beta \times dx$ , but that *instantaneously* induces proportionate movements  $\rho w_{1j}$  in units 2 and 3, which *instantaneously* induces proportionately smaller<sup>30</sup> movements  $(\rho w_{1j})^2$  in units 1 and 3, and so on, reverberating through the units across space analogously to the temporal-dynamics case, but *omnidirectionally* and all *simultaneously*. Thus, the pre-dynamic impulse,  $\beta$ , never manifests observably at all, only its steady-state implications in (iii) and (iv) show empirically. Figure 31.4 maps the estimated responses in a spatiotemporal econometric model from Franzese and Hays (2006), regarding active labor-market (ALM) spending to a hypothetical 1€ (per unemployed worker) spending increase in Germany. The left panel shows the estimated response across all EU countries<sup>31</sup> in the time period contemporaneous to the shock (inclusive of that period’s spatial feedback but exclusive of any time dynamics); the right panel shows the LRSS accumulated response, inclusive of all spatiotemporal feedback. The econometric model uncovered free-riding behavior, i.e., negative spatial interdependence; the characteristic oscillating pattern of negative autoregression is apparent in the right panel.

The case of spatial interdependence also underscores the radically limited scope for nonparametric causal inference, even with regard only to testing, in a socio-politico-economic reality characterized by omnidirectional causality (fundamental challenge number four). Notice from (8) that the effects of  $X$  on  $Y$ , i.e.,  $dy/dx$  in line (iv), impinge in general on all units,  $d\mathbf{y}$ , and vary – the *vector* of effects differs – depending on (a) which units are treated, i.e., the specific allocation of treatments across units,  $d\mathbf{x}$ , and (b) on  $\mathbf{W}$ , the relative connectivity among units, i.e., the specific set of  $\{w_{ij}\}$  connecting units according to which the contagion diffuses. Thus, proceeding nonparametrically, each possible allocation of 1s and 0s across the  $n$  units – there are  $2^n$  such permutations – corresponds to a different treatment; the effect of each such vector of treatments depends further on  $\mathbf{W}$ , which in general has  $n(n-1)$  potentially unique elements (yielding  $2^{n(n-1)}$  possible  $\mathbf{W}$  if connectivity is binary and  $\infty$  if continuous). Thus, there are minimally  $2^n \times 2^{n(n-1)} \gg n$  treatment effects to estimate nonparametrically: obviously impossible without considerable structure (which can be productively imposed in the form of Bayesian hyperpriors in this context, see, e.g., Best et al., 2005). Because at  $\rho = 0$  the allocation of treatments and contents of  $\mathbf{W}$  are irrelevant, a sharp null hypothesis may be formed to test *whether* spatial interdependence is present, but that is the extent of the possible nonparametrically:  $\rho$  and  $d\mathbf{y}/d\mathbf{x}$  are inestimable without considerable structure. Indeed, notice that spatial *association*, i.e., correlation, leaving aside causality entirely, cannot even be measured until the elements of  $\mathbf{W}$  are specified and thereby *proximity* defined.

Simultaneous spatial interdependence is also illustrative as a special case of causal-systems simultaneity, with line (i) of (8) giving a system of equations with three endogenous variables:  $y_1, y_2, y_3$ . Thus the discussion from the spatial-interdependence

**Figure 31.4** Maps depicting the initial (left panel) and LRSS (right panel) spatial ALM-spending responses to +1 shock in Germany

Source: Franzese and Hays (2006).

case applies also, *mutatis mutandis*, to causal systems of simultaneous equations more generally. Socio-politico-economic contexts with cross-unit contagion,  $y_i \leftrightarrow y_j$ , or other simultaneous causality,  $y_i \leftrightarrow x_j$ , imply processes like:

$$\begin{aligned}
 (i) \quad & y = \alpha_0 + \alpha_1 x + \alpha_2 z_y + \varepsilon_y \\
 & x = \beta_0 + \beta_1 y + \beta_2 z_x + \varepsilon_x \\
 \Rightarrow (ii) \quad & y = \alpha_0 + \alpha_1 (\beta_0 + \beta_1 y + \beta_2 z_x + \varepsilon_x) \\
 & \quad + \alpha_2 z_y + \varepsilon_y \\
 y = & \frac{[\alpha_0 + \alpha_1 \beta_0 + \alpha_1 \beta_2 z_x + \alpha_2 z_y + \varepsilon_y + \alpha_1 \varepsilon_x]}{(1 - \alpha_1 \beta_1)} \\
 \Rightarrow (ii) \quad & \frac{dy}{dx} = \frac{\alpha_1}{1 - \alpha_1 \beta_1}, \text{ and not } \frac{dy}{dx} = \alpha_1
 \end{aligned}
 \tag{9}$$

A well designed experiment, or a valid discontinuity or instrumentation design, will identify and estimate  $\alpha_1$ , which is indeed sufficient to test *whether X affects Y*, since

that effect,  $\frac{dy}{dx} = \frac{\alpha_1}{1 - \alpha_1 \beta_1}$ , is zero if  $\alpha_1 = 0$ , but it is clearly insufficient to *estimate* the effect, i.e., the causal response. This is because experiments work to identify the *existence* of causal effects precisely by preventing *estimation* of causal *responses* in the actual simultaneous system of interest. Specifically, causal-inference designs aim to block, *internally*, the feedback from  $y$  to  $x$  that actually occurs *externally* in the inference population. In the contexts of actual interest and intended application, if one ‘moved’  $x$ , this would create *impulse*  $\alpha_1$  to  $y$ , but that in turn would spur  $\beta_1$  further movement in  $x$ , which would move  $y$  some more, which in turn would move  $x$ , and so on.<sup>32</sup> Thus, ironically, experiments and non-parametric causal-inference designs estimate causal *parameters*, like  $\frac{\partial y}{\partial x} = \alpha_1$ , not causal *effects*, like  $\frac{dy}{dx} = \frac{\alpha_1}{1 - \alpha_1 \beta_1}$ .

In other words, notwithstanding that the NHR labels the estimand (1) and its empirical estimate (2) ‘the causal effect’, the aim of studies deploying them is actually *causal inference*, i.e., to establish *whether* a particular causal relation *exists* and not *causal-effect estimation*. The latter is to *estimate how* (not whether) outcomes of interest respond to inputs of interest, i.e., to estimate  $\frac{dy}{dx}$ , where those are expressly total rather than partial derivatives or differences, and the response,  $dy$ , and/or the treatment,  $dx$ , may actually be vectors or matrices of counterfactuals.

As already discussed, causal inference naturally emphasizes internal validity, whereas description and prediction instead stress external validity. Causal-response estimation, for its part, is similar to prediction in that its gold-standard ideal is an out-of-sample performance of the response estimate, emphasizing external validity; but, it is also similar to causal inference in that the external responses it aims to estimate are *causal effects*, not merely to predict  $E(y_{it}|x_{jt})$ , but to predict how  $y_{it}$  would respond (conjunctive tense) causally to hypothetical movements in  $x_{jt}$ : predictive (counterfactual) causal-response estimation. Internal causal validity is also crucial.

Given that the NHR model is inadequate, for causal-response-estimation purposes, to meet the challenge of ubiquitous simultaneity, progress under *omnicausality* (‘just about everything causes just about everything else’) will rely on substantively/theoretically informed econometric modeling, as it did also in fruitfully addressing effect heterogeneity and context conditionality, and spatial, temporal, and spatio-temporal dynamics.<sup>33</sup> To begin, consider the general case of (linear) systems simultaneity, noticing the similarity to the spatial simultaneity in (8) and the bivariate case in (9):

$$\begin{aligned}
 (i) \quad & \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ \vdots \\ y_m \end{bmatrix}'_i \begin{bmatrix} \gamma_{11} & \gamma_{12} & \cdots & \gamma_{1m} \\ \gamma_{21} & \gamma_{22} & \cdots & \gamma_{2m} \\ \vdots & \vdots & \vdots & \vdots \\ \vdots & \vdots & \vdots & \vdots \\ \gamma_{m1} & \gamma_{m2} & \cdots & \gamma_{mm} \end{bmatrix} \\
 & + \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ x_k \end{bmatrix}'_i \begin{bmatrix} \beta_{11} & \beta_{12} & \cdots & \beta_{1m} \\ \beta_{21} & \beta_{22} & \cdots & \beta_{2m} \\ \vdots & \vdots & \vdots & \vdots \\ \vdots & \vdots & \vdots & \vdots \\ \beta_{k1} & \beta_{k2} & \cdots & \beta_{km} \end{bmatrix} \\
 & = \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \vdots \\ \vdots \\ \varepsilon_m \end{bmatrix}'_i \\
 (ii) \quad & \underline{\mathbf{y}}'_i \begin{bmatrix} \Gamma \\ \Gamma \\ \vdots \\ \Gamma \end{bmatrix} + \underline{\mathbf{x}}'_i \begin{bmatrix} \mathbf{B} \\ \mathbf{B} \\ \vdots \\ \mathbf{B} \end{bmatrix} \\
 & = \underline{\boldsymbol{\varepsilon}}'_i \left\{ \begin{array}{l} \text{which normalizing diagonal } \gamma_{ii} \text{ to 1 and} \\ \text{reversing sign of } \gamma_{ij} \text{ can be written for} \\ \text{all } N \text{ obs:} \end{array} \right. \\
 (iii) \quad & \underline{\mathbf{Y}} = \underline{\mathbf{Y}} \begin{bmatrix} \Gamma^* \\ \Gamma^* \\ \vdots \\ \Gamma^* \end{bmatrix} + \underline{\mathbf{X}} \begin{bmatrix} \mathbf{B} \\ \mathbf{B} \\ \vdots \\ \mathbf{B} \end{bmatrix} + \underline{\mathbf{E}} \\
 & \Rightarrow \mathbf{Y} = (\mathbf{X}\mathbf{B} + \mathbf{E})(\mathbf{I} - \Gamma^*)^{-1} \\
 (iv) \quad & \Rightarrow d\mathbf{Y} = (d\mathbf{X})\mathbf{B}(\mathbf{I} - \Gamma^*)^{-1}
 \end{aligned}
 \tag{10}^{34}$$

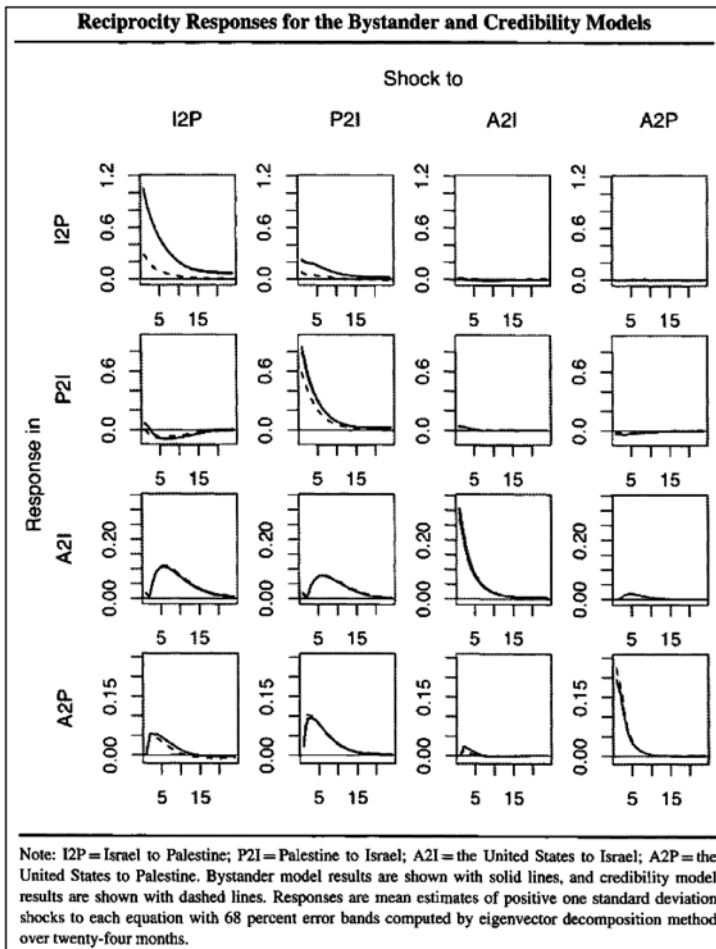

Thus, the translation from the causal-parameter estimates yielded by a well-designed experiment or single-equation causal-inference strategy like discontinuity or instrumental-variable designs to causal-response estimates involves a systems steady-state multiplier,  $(\mathbf{I} - \Gamma^*)^{-1}$ , analogous to the temporal multiplier in (7), spatial multiplier in (8), and bivariate-system multiplier in (9). Thus, causal-effect estimation requires systems estimation (Jackson, 2008, is an excellent exposition<sup>35</sup>), or at least somehow an estimation of all the parameters of the properly modeled system relevant to some desired out-of-sample causal-response estimation. Unfortunately,

political science and international relations rarely focus attention on system estimation, despite *strategic interdependence* being definitionally core to both. The emphasis on theory testing and its consequent idealization of nonparametric causal inference likely bears some blame for this, notwithstanding that systems interdependence greatly complicates even hypothesis testing and makes econometric modeling inescapably essential to causal-effect estimation.<sup>36</sup>

One econometric-modeling approach that does focus squarely on dynamic systems of endogenous equations is the Bayesian

Structural Vector Autoregression (BSVAR) framework. In one illustrative application, Brandt et al. (2008) uncover the reciprocity and other reactions between the Israeli government and military, Palestinian groups, and US official diplomatic and foreign-policy actions (Figure 31.5).<sup>37</sup> The discussions above prove that these rich substantive interrelations could not be estimated in a nonparametric causal-inference approach and that, in fact, even testing for the existence of causal effects related to the alternative reciprocity, accountability, and credibility theories of these actors' strategically interdependent behavior would likely

**Figure 31.5 BSVAR Estimated responses from a system of Israel↔ Palestinian, US→Israel, US→Palestinian actions**

Source: Brandt et al. (2008).

fail using such a framework due to ubiquitous ‘heterogeneity and spillovers’ (see Rubin (1990: 282) again).

## CONCLUSION

Empirical analyses in political science and international relations have at least one of four different goals: description, prediction, causal inference, and causal estimation.<sup>38</sup> The different aims carry with them different sets of weights on desiderata like internal and external validity, robustness, flexibility, efficiency, and richness. For causal-inference theory-testing purposes, the aim is to establish empirically the *existence* of a causal relationship as credibly as possible. For these purposes, the (a) randomized (b) controlled trial, being the strongest-possible guard against spuriousness and reverse causality and with the greatest possible nonparametric purity against ‘model dependence’, represents the gold-standard ideal. However, these causal internal-validity strengths generally come at some costs in terms of representativeness of experimental sample, treatment, or context, thereby limiting the utility of the causal inferences in practical applications, which necessarily require extra-sample inference and therefore external validity, which are not strengths of *laboratory* experimentation. Accordingly, social-science experimentation moves into the field and the survey to enhance representativeness, and from there into econometric-modeling techniques like matching, difference-in-difference, discontinuity, and instrumentation designs in observational data, which tend to maximize representativeness of the sample to the population and context of intended inference. From this perspective, the remaining threats to valid causal inference are effect heterogeneity and spillovers, violations of SUTVA that would bias causal hypothesis tests. In fact, the challenges of multicausality – effect heterogeneity and context-conditionality,

temporal, spatial, spatiotemporal dynamics and interdependence (spillovers), and omnicausality (spillovers) – are ubiquitous, indeed virtually definitionally central, in social-science and in socio-politico-economic reality. From a causal-inference perspective, econometric modeling is aimed to address these challenges to valid designed-based testing of positive social-science theory. Beyond causal inference, however, this chapter has noted that, in the first instance, causality is irrelevant for measurement and prediction empirical purposes. The gold-standard ideal for measurement is neither internal nor external validity, but rather *usefulness*,<sup>39</sup> toward providing summary descriptions and conveying information and understanding thereof. For prediction, the ideal is out-of-sample performance, i.e., prediction or forecast error. Whether the prediction input-output algorithm involves causal relationships or simply associations is irrelevant; external rather than internal validity is crucial. Econometric modeling can play central roles in both prediction and measurement, but its essential and most important role lies in causal-response estimation. As this chapter has demonstrated, valid causal-inference studies can at best provide estimates of causal *parameters*, not causal *effects*. Given the complex causal heterogeneity and context conditionality that characterizes socio-politico-economic reality, in fact, even causal-parameter estimation is impossible without considerable ‘structure’, ideally via theoretically/substantively informed econometric-model specification. The limitations of (so-called) nonparametric causal inference, even solely for testing theories, and the necessity and virtues of econometric modeling become even more pronounced given the temporal, spatial, spatiotemporal, and systems causal interdependence of socio-politico-economics. Careful theoretically/substantively informed specification of econometric models is the essential heart of empirical analysis for purposes of estimating causal effects, and the aim of and gold

standard for empirical modeling is to provide *useful empirical simplifications* of the actual, empirical causal processes of interest.<sup>40</sup> From this perspective, far from an unavoidable detraction, estimation of an econometric **model** reflecting the theory and substance of the context is the very goal of the causal-estimation exercise.

## Notes

- 1 *Positive* here opposes *normative*, positive theory being about how the world works in actuality as opposed to how the world *ought* to work normatively or would work in some fictional *ideal*.
- 2 One can also distinguish two types of empirical questions: factual questions ('what happened or will happen?') and causal questions ('why did or will something happen?'). The former have empirically extant, finite populations and deterministically true answers – 'what percentage of the citizens of certain country approve of the government's performance?' – and the latter have hypothetical populations and uncertainly estimated answers (of theoretical *because*s): 'what characteristics of citizens, governments, and performance affect citizens' approval of governments?'
- 3 To offer a definition, (the purpose and evaluative standard of) an *econometric model*, analogously to a theoretical model in Clarke and Primo (2012), is (to be) a *useful empirical simplification*.
- 4 The variables  $x$  and  $y$  are empirical measures, here assumed to be wholly unproblematic, of the theoretical concepts,  $X$  and  $Y$ ;  $dx \Rightarrow dy$  is the empirical implication derived from the theoretical argument,  $X \Rightarrow Y$ .
- 5 Notice the word used in this testing context is *inference*, and not *estimation*; this is because the central aim is to infer the existence of a causal effect, i.e., to establish that  $dY/dX \neq 0$ , rather than to estimate it. The empirical estimand from a causal-inference design is most usually but not necessarily, a difference in means,  $E(y|x = 1) - E(y|x = 0)$  (see Bowers and Leavitt, Chapter 41, this *Handbook*), which will only in very specific (and likely exceedingly rare in social science) conditions equate to an empirical estimate of the true causal effect of  $x$  on  $y$ , understood as  $dy/dx$ , i.e., how  $y$  responds to a causal impetus from  $dx$ .
- 6 The POF, also called the Neyman–Rubin or Holland–Neyman–Rubin *causal model*, is indeed a model: the causal effects described in (1) are discrete, static, additive, and separable. Indeed, precisely these characteristics of the POF/(H)NR causal model simultaneously make it so powerful for *causal inference* (testing theorized causal-effect existence) and yet so limited for *causal estimation* (estimating empirical causal effects or responses). See also note 17 and the discussion throughout the rest of this chapter.
- 7 Other counterfactually defined estimates have been proposed for causal inference/testing (in political methodology, e.g., see Bowers, 2013), but by far the most common practice is to define the causal quantity of interest as in (2).
- 8 Double-lined arrows indicate causal relationships and single-lined arrows empirical ones, i.e., associations.
- 9 Some scholars go so far as to suggest that if  $x$  cannot be manipulated, *race* for example, then it cannot be causal, but this confuses the empirically implementable with the logically possible. *Causality*, being a theoretical and not empirical concept, involves only the latter; the former is irrelevant (see, e.g., Woodward, 2016 for a fuller discussion).
- 10 If empirical outcomes,  $y$ , are less than perfectly fully determined by the experimentally controlled  $x$ , such that there remains some residual component in  $dy$ , even if orthogonally random but especially if possibly systematically caused or related to alternative causes  $Z$ , then a large sample, successful randomization, and some reliance upon some form of central limit theorem are also essential to proper interpretation of test statistics from a RCT.
- 11 Some scholars contend oppositely, that internal validity has lexical priority over external validity, that internal is more important and without it external has no value. Imbens (2010), e.g., suggests that instances where one could conduct the appropriate experiments and would choose observational data instead are inconceivable. To debate whether internal or external validity is more important or, especially, which is lexically prior is obviously inane: of course, one wants *both*, the aim being to infer (a) validly and (b) from the observed and already known to new contexts. If we must debate priority though, clearly the more defensible position is the reverse: external validity without internal validity (i.e., non-causal empirical associations within sample that obtain also beyond sample) is still useful, e.g., for prediction, whereas an internally validated causal relationship with no external validity has only descriptive value within the already observed and known sample and zero use in any context beyond the study, i.e., for *inference*.

- 12 The representativeness of an experimental sample to the intended population of inference refers to the equivalence of the subjects in the experimental sample and the external units to which the results of the study are to be inferred: college sophomores in a certain class compared to voters in actual democracies, for example. Representativeness of treatment analogously refers to the equivalence of the experimentally manipulated treatment to the concept theoretically understood as causal in the population of inferential interest, e.g., mention of party affiliation in a paragraph that trial subjects are given to read compared to the actual partisanship of actual bill sponsors in actual political contexts. Representativeness of context refers to the equivalence of the situation of the experimental subjects and treatments relative to each other and relative to the relevant socio-politico-economic reality outside the experiment compared with the situations in these regards of the intended inference population: randomized application of a campaign strategy that subjects read about or experience in a media lab in an experiment's contrived campaign compared to campaign *strategies* (by definition) strategically (which means interdependently) chosen by competing parties in actual campaigns where publics are going about their lives, not engaging in a social-science experiment.
- 13 The RCT obtains its strong causal-inference properties precisely by designing an unnatural context: feedback, which exists in nature, is severed by experimental control, and experimentally randomly independently assigned treatments are in nature likely non-randomly and often even strategically assigned. See also note 12.
- 14 Conjoint experiments offer some advances in this specific regard (see, e.g., Hainmueller et al., 2014).
- 15 The  $i, j, s, t$  subscripts are intended to signify that  $y_{it}$  may be a function of  $\mathbf{x}$ ,  $\beta$ ,  $\varepsilon$  in any units  $i$  or  $j$  and periods  $s$  or  $t$ .
- 16 To be as fully general as possible,  $\mathbf{x}_{j_s}$  may include  $y_{j_s}$  and/or temporal and/or spatial lags of  $\mathbf{x}_{i_t}$  as well.
- 17 To elaborate these points more precisely, the POF estimand can be conceived as nonparametric estimate of some *average* treatment 'effect' (ATE), regardless of what functions,  $f$ , may have generated that average difference in means, and this may be adequate for purposes of testing whether this ATE is non-zero (the orthogonality of unobserved random components still seems necessary). However, to interpret this ATE as an *effect*, i.e., as an estimate of how  $y$  would respond to some exogenous  $dx$  *outside of the observed sample*, is to treat it as a model.
- 18 In fact, the similarity of matching and regression control extends further: regression controls  $\mathbf{z}$  to the degree its effects manifest as modeled; matching controls any manifestation of effects of  $\mathbf{z}$  provided, or to the degree, the appropriate form of  $\mathbf{z}$  is included in the matching balancing.
- 19 Jackson (2008) offers a more complete introduction to instrumental-variable and systems estimation.
- 20 *Time* here refers to arguments that 'it happened yesterday, therefore it's exogenous', which is not guaranteed in socio-politico-economic applications, where human foresight can give causal weight to current expectations of futures. Moreover, exclusive reliance on temporal precedence for identification is highly susceptible to specification error.
- 21 *Nonparametric* here references methods that yield large numbers of discrete, unconnected values as distinct from methods explicitly intended to produce (likely graphical) descriptions that are not *a priori* structured but are smoothed descriptions (see Pagan and Ullah, 1999, for far fuller coverage of nonparametric econometrics).
- 22 Again, see Pagan and Ullah (1999) for a much fuller view of nonparametric analyses; here, we intend nonparametric causal inference or causal estimation specifically, which necessarily entail distinct causal 'effect' estimates for each and every context, there being allowed no functional smoothing connections between 'effects' in different conditions. A paradigm labeled *evidence-based medicine*, which carries considerable weight in the biomedical sciences, is illustrative here. The notion is that, if a well and credibly designed RCT yields reliable results that treatments of certain medicines in certain doses to patients with certain conditions, characteristics, and histories produces some estimated net-benefits, then, regardless of whether that RCT-estimated effect has some theoretical explanation, the treatment is to be applied. This is a purely predictive approach but one that attempts to retain the nonparametric foundations of the RCT. As such, the model on which it relies for external validity, i.e., the predictive basis on which to prescribe the treatment, is like that of matching: matching treatments applied to patients with matching conditions will have the same effect. No basis is provided for applying only *similar* treatments to only *similar* patients; that would require more of a model.
- 23 Chapter 2 of the classic text *Statistics* (Freedman et al., 2007 [1978]) extols the two great virtues of experimentation. Even in the examples

- mooted there, though, some doubts of universal unmitigated virtue may be raised. For instance, when double-blind randomization is assumed vindicated because surgeons who know the health of their patients and the nature and severity of their ills yielded significantly beneficial results of an experimental surgery whereas blinded ones insignificantly so, this could, instead of suggesting pernicious bias, suggest effect heterogeneity, about which the non-blinded surgeons in the study know, as would – crucially – surgeons in actual practice. Chapter 3 then warns severely of the dangers of observational studies, lacking those two great experimental virtues. An interesting pattern develops, however: each example observational study's conclusion is overturned later by ...another observational study, plus *arguments* that the latter was better designed...because *causality is ultimately a theoretical, not an empirical, matter*. Finally, the examples have also shifted from primarily clinical-medical in Chapter 2 to primarily epidemiological in Chapter 3, and epidemiology, like '[macro]economics [and most political science and international relations] is not an experimental science' (Sims, 2010).
- 24 In practice, treatments are also nominal,  $x = (0,1)$ . Although claim is often made to straightforward extensions for continuous treatments, in fact the extension is generally complicated and incompatible with nonparametric causal inference, as explained in the surrounding text (see also note 22).
  - 25 All interactions are symmetric in this way: how  $\mathbf{z}$  moderates the effect of  $\mathbf{x}$  on  $y$ ,  $d(dy/d\mathbf{x})/d\mathbf{z}$ , is identical to how  $\mathbf{x}$  moderates the effect of  $\mathbf{z}$  on  $y$ ,  $d(dy/d\mathbf{z})/d\mathbf{x}$ , because interactive effects, i.e., effects on effects, are cross derivatives, and the order of differentiation in a cross derivative is irrelevant.
  - 26 In 'The multiple effects of multiple policymakers'; Franzese (2010) shows how one can leverage the distinct aspects of multiple policymakers – effective (common pool) vs raw numbers (veto actors) of parties, variance (common pool) vs range (veto actors) polarization of parties, and the ideological distribution of parties (bargaining compromise) – along with the different ways these different aspects of multiparty government affect policy outcomes (common pool: proportionate over/under-action; veto actor: adjustment-rate retardation; bargaining-compromise: convex combinations) to separately model, and so to separately identify and estimate, the veto-actor, common-pool, and bargaining-compromise effects of multiple policymakers.
  - 27 So-called 'dynamic' nonparametric-causal-effect estimates are either estimates of  $\beta$  from the static (2) in moving-windows of data, or estimates using static (2) of the period effects in (7) (iii), without the model, i.e., not estimates of the model and its parameters  $\rho$  and  $\beta$  separately, without which they are incapable of generating dynamic response-path or LRSS estimates.
  - 28 Indeed, we could expand here to note that all data, all outcomes of interest, occur in some (space and) time, and so these issues actually arise universally, ubiquitously in all applied empirical analysis, experimental or observational.
  - 29 The elements  $w_{ij}$  of the spatial-weights matrix,  $\mathbf{W}$ , give the relative connectivity from  $j$  to  $i$ , and  $\rho$  the strength of interdependence (contagion) operating in that predetermined pattern.
  - 30 Assuming  $\rho\mathbf{W}$  is the matrix equivalent of 'less than 1', such that  $\|\mathbf{I}-\rho\mathbf{W}\|\neq 0$  so the inverse spatial-multiplier exists. Note that the spatial multiplier derives from an infinite sum of the reverberating spatial feedback analogously to the temporal case (of forward-propagating-only 'feedback'):  $(\mathbf{I}-\rho\mathbf{W})^{-1} = \mathbf{I} + \rho\mathbf{W} + \rho^2\mathbf{W}^2 + \rho^3\mathbf{W}^3 + \dots + \rho^\infty\mathbf{W}^\infty$ .
  - 31 Franzese and Hays (2006) use a modified border-contiguity  $\mathbf{W}$  to define proximity in this application.
  - 32 These feedback reverberations are dampening provided  $\alpha_1\beta_1 < 1$ , so the system is not explosive (see also note 30).
  - 33 Semi- and flexible parametric designs offer a promising way forward for the (likely ubiquitous) combination of causal heterogeneity and causal simultaneity (see, e.g., Marra and Radice, 2011).
  - 34  $\Gamma$  in line (ii) has  $\mathbf{1}$  on its diagonal;  $\Gamma^*$  in line (iii) has  $\mathbf{0}$  on its diagonal and reverses sign of all off-diagonal elements from  $\Gamma$ .
  - 35 Also in this context, see methods specifically designed for complex or high-dimensional systems of endogenous dynamic equations, such as structural vector-autoregression (e.g., Kilian and Lütkepohl, 2017, for textbook exposition, and Pickup, Chapter 34 in this *Handbook*).
  - 36 In this regard, empirical-methodological practices in physics could serve as better exemplar for social science than biomedicine (see note 23). In physics, experimental statistics often yield not only tests of causal theoretical hypotheses but also estimates of the parameters in well-specified theoretical models, and it is the empirical-estimate-calibrated model rather than the experiment's test statistics that are used for causal-response estimates and prediction.
  - 37 The model assumes the United States influences but is not influenced by the other two actors.
  - 38 Furthermore, their empirical questions can be factual – 'who voted for Hitler?' – and so pertain to

defined, finite, and extant *populations* or theoretical – ‘what characteristics of voters and contexts contribute to right-wing populist support?’ – and so have populations of intended inference that are hypothetical and unlimited.

- 39 The analogy to Clarke and Primo’s (2012) declaration of *usefulness* as the aim of theoretical modeling is intentional and perfect.
- 40 Again, the analogy to Clarke and Primo’s (2012) declaration that theoretical models are to be *useful simplifications* is intentional and perfect.

# A Principled Approach to Time Series Analysis

Suzanna Linn and Clayton Webb

Everything is dynamic. Mass attitudes, public policy outcomes, state budgets, and international conflicts operate over, or in, time. The applied time series analyst's goal is to answer questions about dynamic relationships through a process of theory development, model specification, hypothesis testing, and inference. However, political reality is complex, and our theories are rarely rich enough to dictate specific dynamic specifications. Even when theory is rich, model estimation is constrained by the available data.

The challenges posed by dynamic modeling have fostered a number of misguided approaches to time series analysis. One approach treats the dynamic features of the data as a nuisance. Analysts often include lags of the regressand to 'control for' serial correlation or use robust standard errors to purge the dynamic features of the data from the residuals. These approaches treat serial correlation as a disease rather than a symptom of dynamic misspecification.

Another approach posits dynamic specification as a theoretical problem. Proponents of this perspective profess a priori knowledge of the complex details by which mostly continuous data generating processes (DGPs) are sampled and aggregated to produce observed data – but this theoretical 'knowledge' often amounts to little more than folk-logics and pseudo-theories that have become common rationalizations for particular dynamic specifications. Some will include  $y_{t-1}$  because 'investment last year should determine investment this year' or omit  $y_{t-1}$  because 'lagged dependent variables wash out the effects of the other regressors.' Others will include  $x_{t-1}$  'to remove the potential for endogeneity' and will only include one lag because 'one lag is usually enough.' Some of the stories are more elaborate, even referencing the sampling interval and level of temporal aggregation, but these are not theories about the DGP.

These approaches are problematic. A single lag of the regressand suggested by 'theory' may be sufficient with some annual data

but may be insufficient for the same variables sampled at quarterly or monthly intervals. Robust estimation procedures remove serial correlation from the residuals, but estimates will still be biased if the serial correlation was a consequence of dynamic misspecification (King and Roberts, 2015). Analysts may be able to rely on their idiosyncratic approaches in some settings but are likely to face problems if they try to generalize these strategies.

Most political phenomena are dynamic: they change over time. How these dynamics manifest in an empirical model depends on measurement. Time series data are defined by specific sampling windows, sampling intervals, and levels of spatial and temporal aggregation. The empirical model for a political relationship measured at the annual level will have a specific dynamic structure and distinct dynamic features from an empirical model for the same relationship measured at the quarterly or monthly level. These models may change if the data are sampled at different periods of time. This suggests that the following principle should guide time series analysis: dynamic specification is an empirical problem. Theory informs the variables that belong in the empirical model, the data inform the dynamic structure of the empirical model. Our empirical models must be compatible with the features of our data.

Our goal in this chapter is to outline a principled approach for model building and statistical analysis of time series data. We propose a general approach to dynamic specification that incorporates features from several popular schools of econometric practice (Pagan, 1987; Granger, 1990; Spanos, 1990; Hendry, 1995; Campos et al., 2005). The analyst begins with a plausible general model (PGM). The PGM is a tentative empirical specification that encompasses the relationships proposed by the theoretical model. It draws on relevant information from prior theory and evidence, our knowledge of the data and its measurement, and our research goals. The analyst conducts diagnostic tests to ensure the PGM is dynamically complete.

If the PGM has good statistical properties, the analyst iteratively tests downward to produce a parsimonious representation of the relationship that is also dynamically complete. The selected empirical model is then estimated, and the results are used for a variety of goals including hypothesis testing, description, policy analysis, and forecasting. While this process will not resolve all the challenges inherent to dynamic empirical modeling, it will produce empirical models capable of generating reliable inferences.

The chapter is organized as follows: we begin by outlining our approach to dynamic specification; we explain how the analyst specifies the PGM, tests the statistical adequacy of the PGM, and simplifies the model; we briefly discuss the different strategies analysts can use to estimate dynamic models before highlighting the diverse set of tools that are available for interpretation and inference for time series analysis. Throughout, we illustrate our approach with reference to general questions about presidential approval. We close by discussing additional challenges analysts are likely to confront when building dynamic models and offering concluding comments that fit time series analysis into the broader social-scientific enterprise.

## **A PRINCIPLED APPROACH TO DYNAMIC SPECIFICATION**

Our empirical models must be compatible with the features of our data. If data are sampled at regular intervals over time, the empirical model must be built to capture the dynamic features of the data. With this in mind, time series analysis proceeds in four stages. The analyst (1) develops a PGM, (2) uses diagnostic tests to verify the PGM is dynamically complete, (3) simplifies the PGM to arrive at a parsimonious model that makes the most efficient use of the information in the data, and (4) draws inferences from the model. If analysts follow this

procedure, they can be confident in their inferences and conclusions. In this section we discuss the first three steps of this process.

### ***How to Specify a General Model***

The PGM is an empirical model that is *plausible* because the primary feature of the model is that it is reasonable given the information available to the analyst and *general* because it is not restricted in any way that is not explicitly determined by theory. The analyst has two types of information to use in the specification process. There is information the analyst brings with them: their goals, their theoretical arguments – as well as complementary and competing theoretical arguments – and previous findings. There is also information in the data: the details about the measurement and the observed features of the data. Some varieties of information are more useful for some decisions than others and there is no direct mapping from information to the PGM. Ultimately, the specification of the PGM will result from an interplay of theory and data (Pagan, 1987).

Analysts must make a variety of choices when identifying the PGM. They must: (1) select the variables to include in the model; (2) choose whether to use a single equation or multivariate model; and (3) identify the model. Identification of the model involves the selection of a functional form, a parameterization, and a general lag specification that encompasses all plausible dynamic relationships that exist in the data.

Among the most influential pieces of information available to analysts is their motivation for the analysis. Generally, our goals lie in describing linkages and testing hypotheses derived from theory, but we may also wish to forecast behavior. Our specific interest can influence whether the PGM is a single or multiple equation model, as well as the variables in the model.

Theory determines the variables that enter the PGM. By variables we mean constructs in the theory that must be measured and included in the statistical model – concepts like trust, optimism, or presidential approval. Analysts should include all the variables necessary to test their theories and account for competing theories and previous findings. If we are to believe that one theory explains the finding of another, both theories must be represented in the empirical model.

Data determine the structure of the empirical relationships in the PGM. Three features of measurement are particularly important: the sampling interval of the data, the levels of spatial and temporal aggregation, and the temporal window of the series. Highly aggregated data mask causal relationships and higher frequency data tend to exhibit more complex dynamic properties (Freeman, 1989). One example is seasonality. Patterns of time dependence often vary predictably over the calendar year.<sup>1</sup> Monthly data may exhibit this type of dependence every twelfth period. Consider a monthly time series of automobile accidents, accidents tend to increase in the winter months when roads are icy. The PGM should be sufficiently general to capture plausible patterns given the periodicity of the data. A PGM for monthly data should have at least 12 lags. A PGM for quarterly data should have at least four lags. Analysts should consider multivariate PGMs in cases where the data are sampled or aggregated at levels that could induce simultaneity. The interaction between the sampling window and the sampling interval is particularly important. The series sampled over 100 weeks will contain different information than the same variable sampled over 100 years.

In addition to information about measurement, analysts can use empirical information about the individual time series to guide specification of the PGM. Time series plots, unit root tests, tests for structural breaks, and period-to-period correlations can highlight dominant features in the data and identify dynamic patterns that need to be accounted

for in the PGM. If the data are stationary – that is, the data have stable long run means and variances – we suggest that the analyst choose a general lag structure for the PGM that, at least, encompasses the highest order of autocorrelation observed in the PACF for the dependent variable and that it be sufficiently large to capture potential seasonal patterns in the variable.<sup>2</sup> If the data contain unit roots – that is, the means or variances of the data are unstable – the analyst should test for cointegration and, in the absence of cointegration, may need to difference the data.

We use two examples to illustrate how available information can inform specification of the PGM. First, consider an analyst interested in the relationship between economic performance and presidential approval. Drawing on previous theory and evidence, our analyst expects that both subjective evaluations and objective economic outcomes shape evaluations of the president and that controls must be included to account for dramatic events, presidential administrations, and the like (MacKuen et al., 1992; Erikson et al., 2002; De Boef and Kellstedt, 2004). The analyst decides to use monthly inflation ( $I$ ), unemployment ( $U$ ), and the Michigan Index of Consumer Sentiment ( $CS$ ) to model presidential approval ( $App$ ). The PGM might be given by the following:

$$App_t = \alpha_0 + \sum_{i=0}^p \alpha_i App_{t-i} + \sum_{i=0}^q \beta_i^{CS} CS_{t-12} + \sum_{i=0}^q \beta_i^U U_{t-12} + \sum_{i=0}^q \beta_i^I I_{t-12} + BX_t + \varepsilon_t$$

Where  $X$  is a series of intervention variables included to capture differences between presidencies and salient events and  $B$  is a vector of parameters that describe those effects. The PGM includes 12 lags to capture any periodicity or seasonality that may exist in the data.

A second analyst might argue that the weak exogeneity assumption of the first

analyst is overly restrictive because evaluations of the president influence economic perceptions. In this scenario, the analyst might begin with a monthly vector autoregression (VAR) PGM. Given the large number of parameters that must be estimated in a VAR, the analyst adopts a single measure of economic performance ( $E$ ): the Conference Board's Lagging Economic Indicator Index. This VAR PGM could be written as:

$$\begin{aligned} App_t &= \alpha_0 + \sum_{i=0}^p \alpha_i App_{t-i} + \sum_{i=0}^q \beta_i^{CS} CS_{t-12} \\ &\quad + \sum_{i=0}^q \beta_i^E E_{t-12} + BX_t + \varepsilon_{1t} \\ CS_t &= \gamma_0 + \sum_{i=0}^p \gamma_i CS_{t-i} + \sum_{i=0}^q \theta_i^A App_{t-12} \\ &\quad + \sum_{i=0}^q \theta_i^E E_{t-12} + \Theta X_t + \varepsilon_{2t} \\ E_t &= \psi_0 + \sum_{i=0}^p \psi_i E_{t-i} + \sum_{i=0}^q \phi_i^A App_{t-12} \\ &\quad + \sum_{i=0}^q \phi_i^{CS} CS_{t-12} + \Phi X_t + \varepsilon_{3t} \end{aligned}$$

where the different parameters, variables, and errors are given for each equation or more compactly as:

$$Y_t = \Gamma_0 + \Gamma Z_t + \varepsilon_t$$

where  $Y_t$  is a matrix containing each of the endogenous variables at  $t$ ,  $\Gamma_0$  is a vector of intercepts,  $Z_t$  is a matrix containing all the other lags and contemporaneous values of the variables,  $\Gamma$  is a matrix of parameters that describe or constrain these effects, and  $\varepsilon_t$  contains the random errors from each equation.<sup>3</sup>

Once an analyst has specified a PGM, they must conduct an initial round of tests to determine whether the model is statistically adequate given the data. An adequate PGM is a model that is dynamically complete, it includes all the information necessary to

accurately characterize the relationships of interest. A dynamically complete PGM will have white noise residuals. There are several tests for this null hypothesis (e.g., Ljung-Box and Breusch-Godfrey). Analysts should also consider tests for parameter constancy and heteroskedastic errors; we will discuss these issues in more detail below.

Diagnostic tests (not reported) suggest that the single equation PGM and the VAR PGM are sufficiently general. While we could stop here and use the PGMs for estimation and inference, the general models are not well suited for inference because they are overparameterized. In the next section we explain the rationale for, and the process of, simplifying the PGMs to arrive at specifications that are dynamically complete and parsimonious.

### ***How to Simplify the Models***

An acceptable PGM incorporates a sufficient number of variables, including their lags, to encapsulate every plausible dynamic specification. There may, however, be more parsimonious forms of the model that are also dynamically complete. With other things equal, analysts should prefer parsimonious models. Multicollinearity in most PGMs will undermine the efficiency of estimates and compromise hypothesis tests.

How does the analyst select a simplified model? The analyst moves from a PGM to a parsimonious model by iteratively testing both the validity of successive model restrictions and the dynamic completeness of the restricted model. If the restrictions are reasonable and the resulting model is dynamically complete, the model is acceptable. If either is not true, the restricted model should be discarded. The iterative testing procedure allows the analyst to identify a set of dynamically complete models. Measures of model fit can be used to select the model for analysis and interpretation from this restricted set.

There are a number of ways the analyst can simplify the PGM. The most obvious tools are *t*-tests and *F*-tests. Some might criticize this practice as data mining. This criticism is misguided. Data mining refers to an unstructured search of a data set. A general-to-specific simplification search is structured by theory and data through the specification of the PGM (Granger, 1990: 10). The simplification search is not ‘p-hacking’ because the tests of interest in each step are not the *t* or *F* statistics that will eventually be used to test theoretically relevant hypotheses. Instead, the analyst is interested in the results of the diagnostic checks for dynamic completeness conducted after each restriction.

Where should the analyst begin? There are a number of potential starting points. No strategy is best, but some are particularly bad. In lieu of a specific set of instructions, we offer a set of admonitions and suggestions: (1) do not test too many restrictions, iteratively or jointly, on highly collinear regressors; (2) do not remove all lags of any variable from the model: ‘A good model should not only explain the data, but it should also explain both the successes and failures of rival models’ (Gilbert, 1990: 289); (3) do not be overly reliant on measures of model fit, fit statistics tell us nothing about the statistical adequacy of the model; (4) consider multiple starting points;<sup>4</sup> and (5) allow variables to have unique lag structures, including different onset effects.

We demonstrate the general-to-specific simplification search in the context of the PGMs outlined in the last section. Table 32.1 presents a subset of models estimated based on simplifications of Equation 1. We present the *p*-values for the Breusch-Godfrey (BG) serial correlation tests. We include results for 12 and 24 lags for each model. We present three measures of model fit: Akaike’s information criterion (AIC), the Bayesian information criterion (BIC), and  $\bar{R}^2$ .

Our strategy for paring down the single equation PGM began with block *F*-tests. We began with 12 lags of each variable and restricted

the model to include 11 lags of each variable, 10 lags, 9 lags, and so on; instead of, removing one set of lags at a time. If a restriction imposed no loss of information, we tested for serial correlation. The restriction was accepted as long as the model remained dynamically complete. In the final iteration of this initial testing process, the block  $F$ -test rejected the null associated with the static specification in favor of the ADL(1,1) model. This is the first

model presented in Table 32.1. The BG tests suggest this specification is dynamically complete. From here, we could have taken many paths, choosing to either test restrictions on this simplified model or testing alternative sets of restrictions on the PGM. We chose the former strategy. From the ADL(1,1), the partial adjustment (PA) model restricts all the lags of all the regressors to zero, the dead start (DS) model restricts the contemporaneous values

of all the regressors to zero, and the finite distributed lag (FDL) includes the contemporaneous and lagged values of the regressors but omits the lag of approval. These models are presented in columns 3, 4, and 5. The PA and DS model are dynamically complete but the FDL model is not.

We also considered more nuanced lag specifications. The ADL, PA, DS, and FDL models impose common dynamic restrictions on the regressors. The Mixed 1 and Mixed 2 models allow the restrictions to vary among the independent variables. Comparing the ADL and PA models, the coefficient on inflation is significant when lagged inflation is omitted from the model. Mixed 1 removed lagged inflation. The coefficients for contemporaneous and lagged unemployment have similar magnitudes but opposite signs in the ADL. This is consistent with changes in unemployment included in Mixed 2. The results of the iterative simplification process would be the same if one began with an ECM parameterization rather than an ADL. This is reflected in the similarity of the results from the Mixed 2 model and the ECM representation of that model presented in column 8.

To select a final model, we balance the tradeoffs of fit (achieved in the PGM) and

parsimony. The  $\bar{R}^2$  and information criteria capture this trade-off by reporting penalized fit statistics. The penalty is based on the number of regressors in the model. In our example, the AIC and  $\bar{R}^2$  select the Mixed 2 specification in column 7 (or equivalent ECM in column 8). The BIC selects the PA model in column 2.<sup>5</sup> With the exception of the FDL, any of the models presented in Table 32.2 could be used for hypothesis testing.

The VAR is simplified using similar logic but the simplification strategies we entertained are more straightforward in the context of VAR.<sup>6</sup> We successively tested restrictions on the order of the lag length in the VAR using likelihood ratio tests. In each step, we also confirmed that the system was stable by estimating the largest root in the system and dynamically complete by testing for serial correlation in the residuals.

We selected the VAR with four lags. The likelihood ratio test for the VARs including 11 and 10 lags suggest a (nearly) significant loss of information. All other successive restrictions, up to four lags, resulted in no other significant loss of information. At the same time, the Portmanteau (Ljung-Box) tests (12 lags) for each VAR (p) provide no evidence of serial correlation in the residuals

**Table 32.2 Model simplification in the VAR of presidential approval, economy, and consumer sentiment<sup>a</sup>**

<i>Model lags</i>	<i>Portmanteau (12 lags, p-value)</i>	<i>Stable root</i>	<i>Likelihood ratio test (p-value)</i>	<i>AIC</i>	<i>BIC</i>
12	0.167	Yes	0.998	5120.48	5727.94
11	0.371	Yes	0.633	5118.22*	5689.57

5	0.326	Yes	0.371	5141.73	5495.48
4	0.346	Yes	0.013	5144.54	5461.87
3	0.192	Yes	0.420	5167.22	5448.10
2	0.205	Yes	0.000	5171.80	5416.18
1	0.016	Yes	0.007	5198.01	5405.85*

until only one lag was included in the system. The roots of the system were less than one in all cases. Notice that the information criteria select vastly different models and that the BIC selects a model that is not dynamically complete. This latter problem illustrates the danger of making specification choices based on fit alone.

Having settled on simplified versions of our exemplar PGMs, we are nearly ready to turn to the problems of inference and interpretation. Before doing so, we briefly discuss issues in estimation.

## APPROACHES TO ESTIMATION

The ‘dynamic’ in dynamic model refers to the specification of the relationships among the variables over time, it does not suggest a particular estimation strategy. The three primary methods of estimation are ordinary least squares (OLS), maximum likelihood estimation (MLE), and Bayesian estimation methods. Each approach has unique benefits and limitations. Which method is most appropriate often depends on the preferences and goals of the analyst.

Dynamic linear models are often estimated using OLS. The primary benefit of OLS is simplicity. A large number of linear models can be estimated using OLS in a short period of time. Advances in computing have narrowed the gap between least squares and the other methods, but these efficiency gains can be non trivial for large or complex models. Optimization and sampling algorithms can be more time consuming and alternative estimation procedures may require additional diagnostic tests.

The primary limitations of OLS are the strong assumptions OLS makes about the error process. OLS residuals must be white noise. Bayesian and likelihood-based models make it easier to accommodate more complex error structures like the autoregressive, integrated, moving average (ARIMA)

models popularized by Box and Jenkins (1976). Bayesian and likelihood-based methods are also necessary to estimate models of the conditional variance of the series – a process we will discuss in more detail below.

There are a handful of additional advantages offered by Bayesian estimation. Bayesian priors are simultaneously a cost and benefit of Bayesian dynamic modeling. On the one hand, Bayesian priors offer analysts a means of incorporating previous knowledge into the modeling process. Limiting the parameter space using prior information may make estimation more efficient in some circumstances and may facilitate analyses that would otherwise be intractable. For example, Brandt and Sandler (2012) develop a Bayesian Poisson VAR model for multivariate count models and Brandt et al. (2008) use Bayesian Structural VAR models to compare different recursive structures suggested by competing theories about public opinion and international conflict. On the other hand, the iterative procedure we outline in the last section often requires a large number of models to be estimated. Specifying the priors for all the parameters in the PGM can be tedious and time consuming.

Most models can be estimated using OLS, MLE, or Bayesian estimation methods. Unless the analyst has a specific rationale for choosing one method over another, it is usually best to choose the method that is most convenient and best suits the analyst’s needs. As long as the analyst is able to recover estimates from the parameters, how the analyst arrived at the estimates is only of secondary importance. In the next section, we describe how these estimates can be used for inference and interpretation.

## INFERENCE AND INTERPRETATION

Static and dynamic regression models can be estimated using the same procedures, but there are important differences in

interpretation. The dynamic modeler has a more robust arsenal of interpretational tools that can be used to understand dynamic relationships. In this section we discuss these tools and highlight them in the context of our examples.

The most dramatic change in interpretation as one moves from a static model to a dynamic model pertains to the interpretation of the regression coefficients. A regression coefficient in a static OLS regression gives the average change in the regressand associated with a one unit increase in the regressor. In a dynamic model, the coefficient, or impact multiplier, is interpreted as the instantaneous change in the regressand. If there are  $q$  lags of a regressor, the effect of the shock is distributed over  $q$  periods of time. If a lag of the dependent variable is included in the model, the effects of shocks propagate over time. The full effect of a variable in a dynamic regression is represented by the long run multiplier (LRM). The LRM is equal to the sum of the impact multipliers divided by one minus the sum of the coefficients on the lagged values of the dependent variable

$$\sum_{i=0}^q \hat{\beta}_q / \left( 1 - \sum_{i=1}^p \hat{\alpha}_p \right).$$

De Boef and Keele (2008) describe how the formula can be modified to accommodate parameterizations from the GECM.

The impulse response functions (IRFs) and cumulative impulse response functions (CIRFs) can be used to illustrate how shocks to the regressors propagate into the regressand over time. The first value of the IRF is the impact multiplier. It reflects the instantaneous change in the outcome associated with a shock. The next  $t+1, t+2, \dots, t+p$  steps of the IRF depict the rate at which the shock dissipates from the series over time. The effect of a shock dissipates at a rate that is inversely proportional to  $\sum_{i=1}^p \hat{\beta}_p$ . The CIRF for a model shows how the effect of the shock accumulates over time. The first value in a CIRF is also the impact multiplier but the next  $t+1,$

$t+2, \dots, t+p$  steps of the CIRF show how the effect increases from this initial level to the final value given by the LRM. One depicts these patterns by plotting the values over time.

The median and mean lag lengths are useful quantities. The median lag length is the first lag at which at least half of the shock has dissipated from the series, or at which half of the adjustment back toward the long-run equilibrium series has occurred (De Boef and Keele, 2008). The mean lag length is the amount of time it takes for the series to adjust back to its equilibrium, or the amount of time it takes for a shock to play out. The mean and median lag lengths are calculated by dividing the IRFs for a variable by the LRM for that variable and summing those standardized IRFs until one reaches 50% of the LRM (median lag) and 99% of the LRM (mean lag).

We illustrate the utility of these interpretational tools in the context of the presidential approval models presented in Table 32.1. Two points bear repeating. First, one should only interpret results from models that are dynamically complete. One should not interpret the results from the FDL model in Table 32.1. Second, one can use fit criteria to arbitrate among dynamically complete models. Both the PA and Mixed 2 specifications can be used for interpretation and inference. These specifications produce similar inferences because the models contain the same information. A notable exception is the DS model. The fit for the DS model is substantially worse than the fit for the PA and Mixed 2 models. This reflects that there is some amount of information loss with the DS model.

The results presented in Table 32.1 speak to the question raised by the first analyst. Consumer sentiment has a positive and statistically significant effect on presidential approval. The impact multipliers for consumer sentiment sum to 0.9 ( $0.9 = 0.16 - 0.7$ ). The LRM for consumer sentiment is 0.63. These quantities reflect the average response in approval to a one-unit shock in sentiment. While this is illuminating, the

effect of a one-unit shock may not be substantively interesting to our analyst. The analyst could calculate the expected effect of a one standard deviation change in consumer sentiment. A standard deviation change in consumer sentiment is 13 points. In the long run, a one standard deviation change in consumer sentiment is expected to increase presidential approval by eight points. The analyst can learn even more about the dynamic features of the relationship by looking at the IRF and CIRF.

Figure 32.1 shows the IRF and CIRF for a one-unit change in consumer sentiment from the Mixed 2 model in Table 32.1. The left panel of Figure 32.1 shows the IRF. The right panel of Figure 32.1 shows the CIRF. The first bar in the IRF plot corresponds to the coefficient on  $ICS_t$  from the mixed model. The 0 denotes that the positive 0.16 shift in approval occurs in the period where the shock occurred. There is a dramatic drop in the next period because the coefficient for  $ICS_{t-1}$  is negative. After these initial periods, the effects of the change in consumer sentiment and lagged consumer sentiment continue to propagate into approval over the next 24 periods. The cumulative effect

is depicted in the right panel. The first bar in the CIRF also corresponds to the coefficient on  $ICS_t$  but the value of the CIRF in the next period is greater than the value in the first period. The second value in the CIRF is the accumulated effect over the first two periods. The rate at which these effects accumulate is the same as the rate at which the shocks dissipate in the IRF. We can summarize the information contained in the impulse response functions using the median and mean lag lengths.

The IRF and CIRF are based on the Mixed 2 regression from Table 32.1:

$$App_t = \alpha_0 + \alpha_1 App_{t-1} + \beta_0^{CS} CS_t + \beta_1^{CS} CS_{t-1} + I_t + \Delta U_t + \epsilon_t$$

The responses are based on a one unit increase in consumer sentiment. The responses are plotted for the first 30 periods following the change.

The median lag for consumer sentiment is 4 and the mean lag for consumer sentiment is 25. The short median lag and long mean lag suggest that approval error corrects quickly after a shock to consumer sentiment, but that it takes a long time for the full effect of

Figure 32.1 IRF and CIRF for the effect of consumer sentiment on presidential approval

that shock to be realized. People's economic perceptions change their perceptions of the president quickly, but these attitudes are sticky. These features of the dynamic relationship are born out in the plots presented in Figure 32.1.

The interpretation of multivariate time series models relies on many of the same tools but there are notable differences. The individual regression coefficients and the associated  $t$ -statistics are not useful for inference in most circumstances because multicollinearity among the variables and their lags inflate the standard errors for the individual coefficients. This collinearity does not affect the performance of  $F$ -tests. Block  $F$ -tests on the groups of lags associated with different variables in the component regressions of a VAR can be used for inference. If a block of lags of one variable enters significantly into the component equation for another, that first variable is said to 'Granger cause' the other variable (Enders, 2015: 305).<sup>7</sup> These Granger causality tests are the most basic inferential tool available in VAR analysis. In the four lag VAR including economic performance, consumer sentiment, and presidential approval; consumer sentiment ( $p = 0.035$ ) and approval ( $p = 0.008$ ) Granger cause economic performance but none of the other relationships in the system reach conventional levels of significance. While Granger causality tests are a useful tool, these tests are limited because they do not reflect the direction and strength of the relationships among the variables.

The primary tools for the interpretation and inference of VAR models are vector moving average (VMA) impulse response functions and forecast error variance decompositions (FEVD). Collectively, these tools are referred to as 'innovation accounting' (Box-Steffensmeier et al., 2014: 113). A VAR process can be rewritten as a VMA process where the variables in the system are expressed in terms of the current and past values of the errors. This representation allows one to trace the time path of shocks

to the system using impulse response functions similar to the IRFs calculated for single equation models. Confidence intervals can be calculated for the IRFs in a number of ways (Brandt and Freeman, 2006). A response is interpreted as statistically significant as long as the interval does not include zero.

Figure 32.2 presents the VMA IRFs for the four lag VAR model of lagging economic performance (Economy), consumer sentiment (ICS), and presidential approval (Approval). The IRFs depict the responses of the system to one standard error of regression shocks in the endogenous variables. The column headings indicate the variables being shocked. The row headings indicate the response variables. The diagonal plots demonstrate the rates of decay in each variable following the shock to itself. The solid black lines are the impulse responses and the dotted black lines are the 90% confidence intervals for the shocks.

A set of restrictions must be placed on the contemporaneous relationships among the variables to interpret the results. The IRFs are sensitive to these restrictions. The default set of restrictions used in most software packages is the Choleski decomposition that produces the triangular pattern observed in Figure 32.2. The instantaneous responses in the functions plotted below the diagonal are restricted to zero. These restrictions only affect the initial values of the IRFs. There may be theoretical reasons to prefer one set of restrictions over another. Brandt and Freeman (2009) describe strategies analysts can use to test competing restrictions using Bayesian Structural VAR models.

The results in Figure 32.2 offer a comprehensive depiction of the relationships among the variables. The plots in the second and third rows of the array depict the relationships between presidential approval and consumer sentiment. The shock to consumer sentiment produces a positive and statistically significant response in presidential approval (row 3, column 2). Like the results from the single equation model, the effect is moderate but persistent. A shock to presidential approval

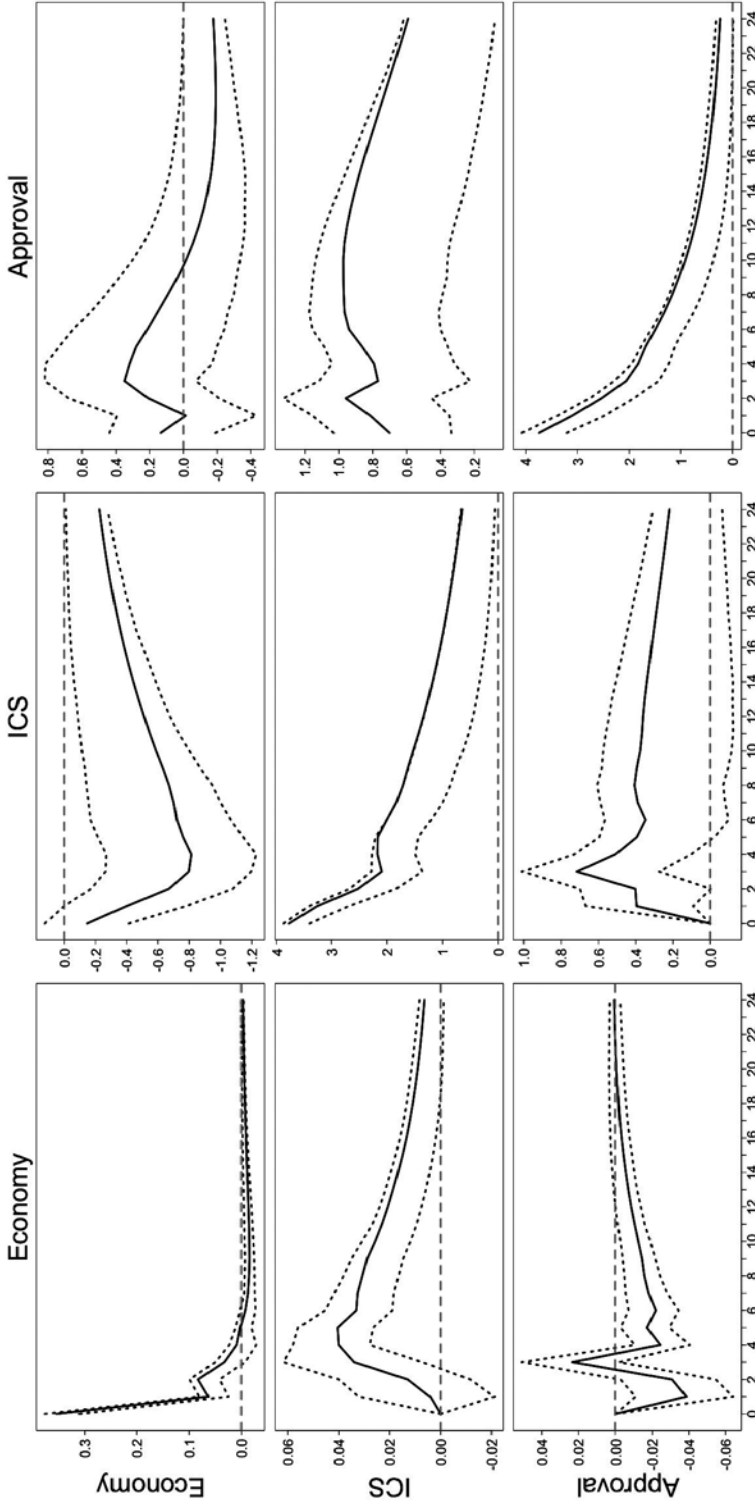

Figure 32.2 The IRFs for three variable VAR model of economic performance, consumer sentiment and, presidential approval

also produces a positive and statistically significant response in consumer sentiment (row 2, column 3). This suggests that public perceptions of the president influence public perceptions of the economy. This effect is more persistent, the response is still reliably different from zero two years after the initial shock.

The array of IRFs allows one to identify indirect relationships among the variables. Consistent with expectations, improved economic performance increases consumer sentiment (row 2, column 1). The shock in economic performance produces an erratic response in approval (row 3, column 1), but the economic performance has a positive, indirect effect on approval through consumer sentiment.

FEVDs offer another tool analysts can use to understand the relationships among the variables in the system. The forecast error variance can be calculated for the  $t$ -step ahead forecasts from a VAR model and the forecast error variance can be calculated as a function of these estimates. The variance of these forecasts can then be categorized in terms of the proportion of the variation caused by each variable. Even at long time-horizons, most variables explain a majority of their 'own' forecast error variance, but the proportions of the variance explained by other variables offer analysts clues about the importance of specific relationships. In the case of the lagging indicators series, presidential approval and consumer sentiment jointly explain less than 10% of the variation in economic performance after 12 periods and only 11% after 24 periods.<sup>8</sup> This is consistent with the small and insignificant responses in the IRFs. There does appear to be an important relationship between consumer sentiment and approval. Consumer sentiment explains more than 25% of the variation in presidential approval after 24 periods, compared with the 1% explained by lagging indicators. Combined with IRFs presented in Figure 32.2, this evidence suggests that consumer sentiment is more important

for understanding changes in presidential approval than changes in objective economic indicators.

Both our analysts have a lot of information they can use to assess their expectations. The dynamic models each analyst estimated offer a richer view of the relationships between approval, the economy, and consumer sentiment than can be reflected with a regression table. Which interpretational tools are most useful depends on the analysts' goals. While the analyses presented in this section seem straightforward, there are a number of things that could complicate these analyses that should be considered. In the next section we discuss some of these considerations.

## ADDITIONAL CONSIDERATIONS

The model specification strategy we outline in this chapter provides a principled approach to the challenges of dynamic specification. The analyst chooses a PGM that encompasses the relationships of interest, tests that the PGM is dynamically complete, and simplifies the PGM to identify an estimable model. This procedure only works if the analyst is able to identify a dynamically complete model. In some cases, a PGM will be inadequate because the general lag structure chosen by the analyst is insufficient but, in many cases, the PGM will fall short because the analyst has not accurately modeled all the features of the relationship of interest. In this section, we briefly describe some of those features and describe how these features of the data can be addressed.

Dynamic modeling can be complicated by nonstationary time series. A stationary series is characterized by a predictable long-run equilibrium. Shocks to a stationary series can move the series away from its equilibrium, but these shocks tend to dissipate and the series returns to its long-run mean. The mean and variance of a stationary series are constant over time. In contrast, the mean and/or

variance of nonstationary series change over time. This can occur because a series is trending or because random shocks to the series do not dissipate like shocks to stationary series. Instead, the shocks integrate into the series causing the series to wander unpredictably. These 'random walk' series are said to be integrated of order  $d = 1$ , or  $I(1)$ , where  $d$  is the number of times the series must be differenced to produce a stationary series. Random walk series do not exhibit mean-reverting behavior. This makes these series difficult to model.

A dynamic model of a nonstationary series can only be dynamically complete if the model is balanced. That is, the regressors must account for the dominant features of the regressand. If the regressand is an  $I(1)$  variable, one or more of the regressors must also be  $I(1)$  variables for the equation to exhibit balance. If such a relationship exists, the variables are said to be cointegrated. Cointegrating variables exhibit equilibrating behavior with respect to one another. Balance is a necessary but not sufficient condition for dynamic completeness. If one regresses one  $I(1)$  variable on another and the residuals from that regression are not white noise, the model is not dynamically complete. The standard errors from such regressions will be incorrect and the limiting distributions for the test statistics will be nonstandard. Variables from these kinds of regressions will often appear to be related when they are not. This is the classic spurious regression problem. Standard practices dictate that analysts apply a series of pre-tests to determine whether the series in a model are  $I(1)$ . There are also tests for cointegration, but these tests rely on the assumption that the series are  $I(1)$  (Philips, 2018). The unit root and stationarity tests used to classify series as  $I(1)$  or  $I(0)$  processes play a critical role in applied time series analysis because classification dictates decisions about model choice and influences interpretation and inference.

This is a problem because unit root and stationarity tests are notoriously unreliable

(Campbell and Perron, 1991; Banerjee et al., 1993; Perron and Ng, 1996; Juhl and Xiao, 2003). The tests have low power in optimal circumstances. The performance of these tests depend upon the analyst accurately identifying the features of the data and modifying the test to accommodate these features. Results, also often hinge on the analysts's chosen level of statistical significance. Different tests often produce competing results. The uncertainty associated with these pre-testing procedures are not reflected in final analyses. This uncertainty plagues standard approaches to applied time series analysis but a number of methods have been developed that can accommodate uncertainty about the univariate properties of the data. Webb et al. (2019; 2020) develop a hypothesis testing procedure that uses critical value bounds for the LRM  $t$ -statistic to accommodate this uncertainty. Brandt and Freeman (2006, 2009) also discuss how uncertainty about univariate dynamics can be incorporated into structural VAR models using Bayesian priors.

Dynamic modeling is also complicated by the presence of structural breaks. A structural break is an abrupt change in the mean of a series. A break may reflect a fundamental change in the underlying parameters of the DGP or a simple change in the mean caused by a shock or intervention. For example, the number of international skyjackings changed after metal detectors were introduced in airports. Structural breaks represent another dominant feature of a variable that must be accounted for in the model. Structural breaks will generate non random patterns in model residuals and can frustrate the already sensitive unit root tests just mentioned. Ignoring a structural break is tantamount to ignoring a critical omitted variable and omitting the structural break creates omitted variable bias problems. Analysts can test for structural breaks and can include variables in models to partial out the effects of these changes on the series or test hypotheses about the breaks.

Dynamic modeling can also be complicated by changes in the variance of a series over time. The models described in this chapter, and many of the diagnostic tests used in the prescribed modeling procedure, rely on the assumption that errors are white noise. White noise residuals are not only random with respect to one another, they also have constant variance. Many time series are characterized by autoregressive conditional heteroskedasticity (ARCH). The variance of the series changes as a function of time. Autoregressive conditional heteroskedasticity affects standard error estimates and can influence the results of diagnostic tests. More importantly, a model cannot be said to be dynamically complete unless it captures these features of the data as well. Engle (1982) developed a test, and model, for ARCH residuals. This model has been extended by Bollerslev (1986) and others to accommodate different dynamic patterns in the conditional variance.

Finally, single equation models rely on the assumption that the regressors are weakly exogenous to the regressand. This assumption is difficult to verify. There are no direct tests of the assumption but analysts can use a number of tools that shed light on the veracity of the assumption. If one variable Granger causes another, the latter variable cannot be exogenous to the former. This will also be reflected in IRFs and FEVDs. Violations of parameter non constancy in single equation regressions may also suggest violations of weak exogeneity but may indicate other kinds of omitted variables.

Unit roots, structural breaks, ARCH errors, and endogeneity create challenges for dynamic modeling because these phenomena constitute important information that must be accounted for in a dynamically complete model. Analysts should strive to identify the important features of their data and incorporate this information into the model selection process. This is true of all empirical models, not just time series analysis.

## CONCLUSION

Quantitative political scientists endeavor to make general statements about the relationships that hold in the complex political world. We are armed with abstract theory and left to fend with imperfect data. This is true of virtually all domains of quantitative analysis. But time series analysis is unique in two aspects. First, there is typically no theory-guided map for dynamic specification. That is, theory is silent as to whether economic performance affects evaluations of the president immediately, the next month, or two months into the future. Second, temporal aggregation and other features of time series measurement complicate identification of the appropriate lag structure. The same construct measured over different time periods will exhibit different dynamic structures. For example, if economic performance influences approval in the following month, the effects will change when the data are aggregated to quarters. We need to draw not only on theory but also on information in the data in order to arrive at acceptable empirical models of the relationships we care about.

Traditionally, analysts have buried their heads in the sand, maintaining the illusion that theory dictates an empirical specification that can be validated (or not) with the available data, no matter how it is aggregated, if we just 'fix' the statistical problems that manifest with dynamic misspecification. But ignoring the realities of the data and eschewing the evidence of dynamic misspecification means such models cannot tell us about the dynamic relationships in the data. Perhaps more problematically, they give rise to unexpected incongruencies between theory and data that limit scientific progress.

The principled approach we outline in this chapter provides analysts a strategy for dynamic specification that incorporates information from theory and data. The end product is a statistically adequate model that can be used to produce inferences about theorized

relationships that tell us something about the more complex political world. The approach does not guarantee the model is useful. The final model will only be as good as the information we bring to the modeling process. If we find our inferences implausible, we may lack relevant theoretical information because we simply do not understand the world well enough, our measures may poorly tap the theoretical constructs of interest, the level of aggregation in the data may obscure relationships, or the time period we have chosen may be too short or too unusual. In these cases, we need to gather more information. This search for additional information to incorporate in our models of the world is the hard work of a progressive scientific program. Dynamic specification should reflect this basic principle: use all the information available in theory and data.

## Notes

- 1 Regular patterns of autocorrelation need not be tied to the calendar year. For example, one might observe weekly patterns in daily financial time series data.
- 2 Various unit root and stationarity tests that have been proposed to classify series as stationary or non stationary. For a more in-depth discussion of unit root tests and the limitations of unit root tests, see Choi (2015).
- 3 For a more complete treatment on Vector Autoregression, see Brandt and Williams (2007).
- 4 Some software packages offer automated procedures that select models using information criteria. We caution against these strategies because these processes only consider the statistical information in the models and can produce specifications that are not dynamically complete.
- 5 Note that the AIC and BIC presented for the ECM cannot be compared to those for the other models as the dependent variable is different.
- 6 If one chose to estimate a system of seemingly unrelated regressions with varying lag structures, more options would exist.
- 7 A Granger-causal relationship does not imply a causal relationship in the classic sense, only a specific type of statistical relationship.
- 8 For the sake of brevity, we do not present the FEVDs.

# Time-Series-Cross-Section Analysis

Vera Troeger

## INTRODUCTION

The use of pooled time series cross section (PTSCS) data has become ubiquitous in observational analyses across the social sciences. Even the identification revolution that swept through empirical social science in the last two decades finds some merit in using data that combines observations across units and over time, because it allows identification through differences-in-differences approaches exploiting within unit variation. In *Mostly Harmless Econometrics* (Angrist and Pischke, 2009) – which has obtained cult-like status in applied empirical economics – the authors recommend the use of diff-in-diff or unit fixed effects approaches to identification, requiring pooled data, if an experiment is infeasible, a meaningful discontinuity, or exogenous variation in the form of an instrument cannot be found.

Pooled data analysis has become the standard for analyzing observational data in quantitative political analysis. This is particularly true in sub-disciplines like International

Relations, Comparative Politics, and Comparative Political Economy, but it has even extended to fields that use micro data, such as Political Behavior or American Politics. Because more survey data over time is available, these fields are using more PTSCS data. Panel data pool cross-sectional information (number of units  $N$ ) with information over time (number of time points  $T$ ), for example, data on individuals or firms at different points in time and information on countries and regions over time etc. Thus, panel data consist of repeated observations on a number of units. We can distinguish between cross-sectional dominant data (Cross-Section Time-Series (CSTS)), time-series dominant data (Time-Series Cross-Section (TSCS)), or pooled data with a fixed number of units and time-points. The data structure has implications for the model choice, since asymptotic properties of estimators for pooled data are either derived for  $N \rightarrow \infty$  or  $T \rightarrow \infty$ . In addition, violations of full ideal conditions and specification issues have more or less severe

effects for bias and efficiency, depending on whether the number of units exceeds the number of observations over time, or vice versa. Below, we discuss the strengths and weaknesses of this method and various ways to cope with some of the inherent problems.

Some have argued that TSCS and CSTS data consist of observations at different points in time for fixed units of theoretical interest, such as countries or dyads. In contrast, in panel data, the units, mostly individuals in surveys, are of no specific interest and are randomly sampled from an underlying population with all inferences dedicated to uncovering the relationships in the population. Textbooks and articles, however, use these terms quite loosely. This entry will follow this trend and discuss general estimation procedures and specification issues with respect to different kinds of data pooling cross-sectional and time series information.

For each specification issue, this entry briefly discusses the solutions presented in commonly used textbooks like Wooldridge (2010) and then turns to more recent discussions in the political methodology literature.

## ADVANTAGES AND DISADVANTAGES OF PTSCS DATA ANALYSIS

Panel data pool observations for units ( $i$ ) and time periods ( $t$ ). The typical data generating process can be characterized as:

$$y_{it} = \alpha + \sum_{k=1}^K \beta_k x_{kit} + \epsilon_{it}, \quad i = 1, \dots, N; \quad t = 1, \dots, T \quad (1)$$

with  $k$  independent variables  $x$  which have observations for  $N$  units ( $i$ ) and  $T$  periods ( $t$ ). The dependent variable  $y$  is continuous (though in principle it can be a limited dependent variable, which requires non-linear estimation procedures) and also observed for  $i$  and  $t$ .  $\epsilon_{it}$  describes the error term for observations  $i$ ,  $t$  and we can assume a  $NT \times NT$  Variance-Covariance Matrix  $\Omega$  of the error term with the typical element  $E(\epsilon_{it}, \epsilon_{js})$ . In case all

Gauss–Markov assumptions are met (the error term is iid) this model can be straightforwardly estimated by OLS. Since PTSCS data combine time-series and cross-section information, this is rarely the case. However, the analysis of PTSCS data offers significant advantages over the analysis of pure time series or pure cross-sectional data. First, using pooled data increases the number of observations and therefore the degrees of freedom which means that more complex arguments can be tested by employing more complex estimation procedures. More importantly, most theories in the social sciences generate predictions over space and time, and it seems imperative therefore to test these hypotheses by using data providing repeated information for theoretically interesting units. PTSCS data analysis can be used to model dynamics, which is impossible when examining pure cross-sections and may lead to spurious regression results. Finally, it is possible to control for unit heterogeneity when analyzing pooled data, beyond the inclusion of additional right-hand side (RHS) variables. Accordingly, we use pooled data to eliminate some kinds of omitted variable bias, make the best of the available information, test theories that predict changes, and test theories that predict parameter heterogeneity.

The most obvious disadvantage of panel data analysis is that an econometrically sound model specification is typically hard to find, since the data structure combines all of the problems of cross-sectional and time-series data, but these problems typically arise simultaneously. Specification problems in pooled data analysis can be summarized as follows:

- 1 The residuals are typically serially correlated and not independent of each other
- 2 The residuals have different variances for different units (panel heteroskedasticity)
- 3 The residuals of different units are contemporaneously correlated
- 4 The residuals of unit  $i$  co-varies with residuals of unit  $j$  for different points in time
- 5 The expected mean of the error term deviates from zero for different units

While each single violation of the underlying model assumptions is often straightforwardly accounted for by existing econometric measures, combinations of problems might not be solved simultaneously in a satisfying manner. Econometric solutions are often incompatible with theories. Sometimes it is hard to find models that are at the very same time econometrically sound (unbiased, efficient) and provide an appropriate test of the theory. When weighing advantages and disadvantages of pooled data analysis, the positive aspects certainly prevail – especially because the analysis of pooled data allows testing complex arguments over space and time, which is characteristic for the social sciences. From this perspective, the steep increase in the popularity of panel data analysis does not seem surprising. However, the big challenge using pooled data is how to deal with simultaneously occurring violations of the underlying assumptions.

First, I will discuss common violations of underlying assumptions and solutions for each misspecification separately and will later turn to attempts to account for simultaneously occurring specification problems.

### **HETEROSKEDASTICITY AND CONTEMPORANEOUS ERROR CORRELATION IN PTSCS DATA**

Heteroskedasticity in pooled data presents a more complex problem than in pure cross-sections since (a) the error term can have unit-specific variances (panel heteroskedasticity), (b) the error term can be contemporaneously correlated, that is, the error term of unit  $i$  is correlated to that of unit  $j$  in the same year, and (c) the error term of one unit  $i$  can be correlated with the error term of unit  $j$  at different points in time. In addition, the error term can have time dependent error variances (autoregressive conditional heteroskedasticity). Panel heteroskedasticity mainly occurs if the model specification fits different units with a

different degree of accuracy. Correlations of the errors across units are determined by unobserved features of one unit that are linked to another unit. Both features violate Gauss–Markov assumptions: while they leave the simple estimators consistent, such estimators are now inefficient and standard errors may be incorrect. More importantly, both heteroskedasticity and error correlation often signal omitted variables bias, since in both cases something that should have been included into the structural part of the equation was left out.

This problem can be solved in a substantive way by identifying the causes of the omitted variable bias and including these variables into the right-hand side of the models. Often, this approach is not feasible because the sources for heteroscedasticity are not known or excluded factors cannot be measured. In this case, several econometric solutions have been proposed. Parks (1967) and Kmenta (1986) were the first to propose a Feasible Generalized Least Squares (FGLS) estimation which is characterized by a  $NT \times NT$  block diagonal matrix with an  $N \times N$  matrix  $\Sigma$  that contains contemporaneous covariances along the block diagonal. Parks (1967) and Kmenta (1986) also suggest an  $\Omega$  matrix with panel specific AR1 error structure and contemporaneously correlated errors, but, in principle, FGLS can handle all different correlation structures. Because the true structure of  $\Sigma$  and  $\Omega$  is unknown, this procedure requires estimating a very large number of parameters in order to obtain the error covariances, which in turn leads to very inefficient, and therefore unreliable, results. Beck and Katz (1995) show that the Parks' method highly underestimates standard errors and therefore induces overconfidence in estimation results. As a result, this estimation procedure has fallen into disuse in recent work using pooled data.

Beck and Katz (1995) suggest a different way of dealing with panel heteroskedasticity. They argue that coefficient estimates of OLS are consistent but inefficient in pooled data

and that the degree of inefficiency depends on the data and the exact error process. They suggest using OLS and correcting the estimated standard errors by taking the specific panel structure of the data into account:

$$Var[\beta] = (X'X)^{-1} X' \Omega X (X'X)^{-1} \tag{2}$$

with

$$\Omega = (E'E / T) \otimes I_t \tag{3}$$

This method is dubbed panel corrected standard errors. Other violations of Gauss–Markov assumptions, such as serial correlation of the error term, have to be treated beforehand. Since this approach only manipulates the standard errors of an OLS model, the coefficients are biased whenever OLS is biased.

### DYNAMICS IN POOLED DATA ANALYSIS

As pooled data combine information across units and over time, another problem arises if dynamics are present and the error term is serially correlated. The error term in  $t$  is dependent on the error term in  $t-1$ :

$$\epsilon_{it} = \rho_i \epsilon_{it-1} + \xi_{it} \tag{4}$$

From a formal econometric point of view, violating the independence assumption only influences the efficiency of the estimation. Yet, since the residual of a regression model picks up the influences of those variables that have not been included, persistence in excluded variables is the most frequent cause of serial correlation. Several remedies for serial correlation are available, all of which have different consequences for the model specification and interpretation of the estimation results.

A substantive solution to the problem of serial correlation is the inclusion of a lagged dependent variable  $y_{it}$  (LDV) to the right-hand side of the regression equation:

$$y_{it} = \beta_0 y_{it-1} + \beta_k x_{kit} + u_i + \epsilon_{it} \tag{5}$$

In many cases this is enough to eliminate serially correlated error terms. However, there are also many perils to adding an LDV to the list of regressors. One of the main problems arises because the inclusion of an LDV makes it very hard to interpret the effects of the substantial RHS variables directly and correctly, since the conditional effect of  $x$  on  $y$  is dynamic and aggregated over all periods. It can be described by the following polynomial:

$$y(x)_{t_1 \rightarrow t_p} = \beta_1 x_{it} + \sum_{p=1}^{t_p} (\beta_0^{t-p} \beta_1 x_{it}) \tag{6}$$

the long-term effect of  $x_k$  reduces to:

$$\frac{\widehat{\beta}_k}{(1 - \beta_0)} \tag{7}$$

Unfortunately, the standard errors of the function in Equations 6 and 7 cannot be easily calculated. Since including an LDV resembles a shortened distributed lag model, we implicitly assume that all variables exert an equally strong one period lagged impact on the dependent variable. Therefore, finding a non-significant coefficient of a theoretically interesting explanatory variable in an LDV model does not necessarily mean that this variable has no effect. It only tells us that this variable does not affect the dependent variable contemporaneously, but it might still have a lagged effect. From this, it follows that the coefficient of the LDV estimates at best the average dynamic effect of all substantive RHS variables, rather than the actual dynamic effect of each explanatory variable. When including an LDV into the specification, it is very important to calculate or simulate the short- and long-term effects of all RHS variables to correctly interpret effects, their size, and significance. Recent work by Williams and Whitten (2011) shows how to simulate long-term dynamics for autoregressive series in pooled data.

Another problem occurs when combining an LDV with the estimation of unit-specific effects by a fixed effects specification or a

least squares dummy variable model (see the next section for a more detailed description). This leads to biased estimates since the LDV co-varies with the time-invariant part of the error term. This problem is called Nickell-bias (Nickell, 1981). The Nickell-bias is sizable in panel data with very short time periods (Pickup, 2018) but becomes negligible as  $T$  increases. The best known suggestions tackling the problem of Nickell-bias are the instrumental variable approach by Anderson–Hsiao (Anderson and Hsiao, 1981) (AH), the differenced GMM (Generalized Methods of Moments) model by Arellano–Bond (Arellano and Bond, 1991) (AB), and the Kiviet (1995) correction, which proposes a corrected within estimator that subtracts a consistent estimate of the bias from the original fixed effects estimator. The first two approaches solve the bias problem by taking the first difference of both sides of the regression equation and instrumentation of the LDV with higher order lags of the LDV. Therefore, AH is only using the two periods lagged LDV as an instrument while AB can make use of all possible lags of the LDV and all exogenous variables in the model. Both approaches generate asymptotically consistent estimation results, but AB produces more efficient estimates due to the exploitation of all moment conditions. In finite samples, however, both estimators are problematic with regard to efficiency, as recent Monte Carlo experiments examining the finite sample properties reveal (Pickup, 2018). Higher lags of the LDV provide good instruments only in the case where  $y$  is highly persistent over time. Unfortunately, in such a case, the probability that the instruments also co-vary with the error term remains high. From this perspective, both estimators cannot solve the problem of Nickell-bias if  $y$  is highly persistent or solve the problem very inefficiently, in case of low persistence. More recent research by Pickup (2018) shows evidence that transformed-likelihood estimators – for example, the orthogonal reparameterization (OPM) fixed-effects approach proposed by

Lancaster (2000) and the quasi-maximum likelihood (QML) fixed-effects approach by Hsiao et al. (2002) – outperform the so called dynamic panel models discussed above by far, especially for very short  $T$ .

A Prais–Winsten (PW) transformation of the model offers another solution to serial correlation. The advantage of the Prais–Winsten approach lies in the transformation of both the left and the right-hand side of the equation, which allows a direct interpretation of the regression coefficients. Prais–Winsten is estimated by GLS and is derived from the AR(1) model for the error term. First a standard linear regression is estimated:

$$y_{it} = x_{it}\beta + \epsilon_{it} \quad (8)$$

An estimate of the correlation in the residuals is then obtained by the following auxiliary regression:

$$\epsilon_{it} = \rho\epsilon_{it-1} + \xi_{it} \quad (9)$$

A Cochrane–Orcutt transformation is applied for observations  $t = 2, \dots, n$

$$y_{it} - \rho y_{it-1} = \beta(x_{it} - \rho x_{it-1}) + \zeta_{it} \quad (10)$$

And the transformation for  $t=1$  is as follows:

$$\sqrt{1 - \rho^2} y_{i1} = \beta(\sqrt{1 - \rho^2} x_{i1}) + \sqrt{1 - \rho^2} \zeta_{i1} \quad (11)$$

Equation 11 shows that another advantage of the Prais–Winsten transformation is the preservation of the first period. The differences between a PW and an LDV model might be substantial depending on  $\rho$  and the serial correlation in both  $y$  and  $x$ .

Dynamics in pooled data estimation presents one of the major challenges, because the sources of the dynamics often remain unknown to the researcher. Therefore, specifying dynamics in panel data is difficult. A researcher may believe that the data generating process (DGP) for their data contains a lag of the dependent variable, lags of the independent variables, and/or serial correlation in the errors. If researchers could observe

the DGP, they could select the corresponding model and, in doing so, account for the dynamics. Unfortunately, they cannot and if residuals show clear evidence of serial correlation this could indicate missing dynamics in either the mean or the error equation (or both). There is no straightforward statistical test that can determine which is one it is. This leaves the researcher uncertain how to proceed. Some scholars suggest always adding dynamics to the mean equation (Wilkins, 2018) or at least ensuring the data model includes many lags of the dependent and independent variables as there are in the data generating process (Wooldridge, 2010: 194). However, the consequences of doing so when the DGP dynamics are in the error equation remain largely unknown. Pickup and Troeger (2019) explore theoretically and empirically whether the source of the dynamic process makes a difference for bias and efficiency of the estimation. They also show that the consequences for bias can be severe when dynamics are included in the mean equation when they should be in the error equation and vice versa.

Whether the dynamics in a particular set of panel data need to be accounted for in the error term or in the mean equation can be unclear. There are four common DGPs that might create uncertainty for the researcher as to whether they require a static model with a control for serial correlated errors or a dynamic model: (a) slow dissipation of effects due to covariates included or not included in the estimation equation; (b) lags of the covariates that are included in the estimation; (c) errors in the DGP that are serially correlated, often due to measurement artifacts; and (d) autoregressive covariates omitted from the estimation.

The first two types of DGPs are dynamic in the mean equation. The first is dynamic in the dependent variable and the second is dynamic in the independent variable. The third and fourth types are static in the mean equation. The third is dynamic in the error equation. The fourth is static in the error equation but if the autoregressive covariate is excluded from the data model, the DGP for the residuals

will be dynamic. Given that the DGP may be dynamic in the mean equation or in the error equation and given that the researcher does not typically observe the DGP, it is important to consider the consequences of: (a) using a model that is dynamic in the mean equation; or (b) static in the mean equation with a control for dynamics in the error equation: first, if a dynamic model is used (correctly or incorrectly), it must be dynamically complete. That is an autoregressive distributive lag (ADL(p,q)) model with p lags of the dependent and q lags of the independent variables needs to be estimated to avoid bias:

$$y_{i,t} = \alpha_1 y_{i,t-1} + \dots + \alpha_p y_{i,t-p} + \beta_1 x_{i,t} + \beta_2 x_{i,t-1} + \dots + \beta_q x_{i,t-q} + u_i + \epsilon_{i,t} \quad (12)$$

Second, if the dynamic model is incorrectly used, it will either not lead to incorrect inference (in the case of AR errors and assuming dynamic completeness) or it will result in MA serially correlated errors. In the latter case, the estimation will likely generate some degree of bias. The magnitude of this bias will depend on  $T$  and the degree of serial correlation. Clearly, it is of utmost importance to specify the dynamic processes as closely to the true DGP as possible. Otherwise, biased estimates will occur. As a consequence, testing for serial correlation and detecting misspecification in dynamic panel models is very important.

However, in reality, applied researchers often perceive serially correlated errors as noise rather than information (DeBoef and Keele, 2008). Yet, serially correlated errors clearly indicate a potentially severe model misspecification, which can result from various sources and occur either in the mean- or error-equation. Perhaps most obviously, serially correlated errors are caused by: incompletely or incorrectly modeled persistency in the dependent variable, time-varying omitted variables or changes in the effect strengths of time-invariant variables, or misspecified lagged effects of explanatory variables. Conditionality makes modeling dynamics

more complicated (Franzese, 2003a, 2003b; Franzese and Kam, 2009). Few empirical analyses model all potential conditioning factors of the variables of interest. If, however, treatment effects are conditioned by unobserved time-varying factors then treatment effects vary over time, and the strength of these effects also changes over time as unmodeled conditioning factors change. Finally, serially correlated errors may result from misspecifications that, at first sight, have little to do with dynamics – for example, from spatial dependence. Yet, spatial effects are certainly misunderstood if they are perceived as time-invariant: ignoring spatial dependence causes errors to be serially correlated (Franzese and Hays, 2007).

In an ideal world, these model misspecifications would be avoided: dynamics should be directly modeled to obtain unbiased estimates. This proves difficult in reality. Since dynamic misspecifications are manifold and complex, econometric tests for dynamics, at best, reveal serially correlated errors, but they are usually unable to identify the underlying causes of autocorrelation. Often, these tests are also weak and do not reveal the true dynamic structure of the DGP, which may lead to overfitting of the data (Keele et al., 2016). Thus, empirical researchers often try to simplify their empirical model and to treat problems such as serially correlated errors with straightforward econometric textbook solutions, such as lagged dependent variables, period dummies, and simple homogeneous lag structures.

Plümper and Troeger (2019) show that econometric textbook solutions are not correct per se because they are usually not modeling the true dynamic process in the underlying DGP. In addition, if dynamics occur in combination with other misspecifications, for example, unit heterogeneity, treating one problem can render the effects (bias) of another violation worse.

One strategy that may reduce the size of the problem is to use less constrained econometric solutions. Distributed lag models, models with a unit-specific lagged dependent

variable, panel co-integration models, models with heterogeneous lag structure (Plümper et al., 2005), more attention to periodization (Franzese, 2003a), and better specified spatial models (Franzese and Hays, 2007) may all reduce the size of the problem. However, as the number of possible dynamic specifications increases, a higher order problem of model selection arises: since all of these different models generate different estimates and often demand different inferences, the next question is how empirical researchers select their preferred model. To eliminate, or at least reduce, the arbitrariness of model selection, DeBoef and Keele (2008: 187) suggest a testing down approach, starting with a full autoregressive distributive lag model and stepwise removing parameters according to predetermined criteria, often the significance of parameters. This procedure will result in a dynamic specification that maximizes the variance absorbed by the minimum number of parameters. As with all testing down approaches, this approach suffers from the arbitrariness in the choice of a starting model because we do not have an infinite number of degrees of freedom. Pickup (2018) similarly suggests a general-to-specific approach to modeling dynamics especially for panel data with small  $T$  to find a plausible dynamic specification before dealing with other misspecifications, such as unit heterogeneity.

The issue of specifying dynamic processes in pooled data becomes even more complicated if this problem is coupled with other potential misspecifications such as unit heterogeneity. The Nickell-bias discussed here is the least of the problems that occurs when addressing both issues separately, as is discussed below.

## HETEROGENEITY

The identification revolution has not failed to impact the analysis of PCSTS data. Since Angrist and Pischke (2009) published *Mostly*

*Harmless Econometrics*, the so-called Fixed Effects Model has become the workhorse specification when using pooled data of any kind. Clearly, one of the advantages of analyzing pooled data is the possibility of controlling for heterogeneity across units. When examining cross-sectional data, it is impossible to tell whether the estimated effects are contingent on unobserved effects that are specific to each unit, and therefore biased. PTSCS data analysis rests on the assumption that units are similar enough to be pooled together. If that is not the case, we can still find appropriate specifications that allow accounting for differences across units, which might influence the estimation results. Textbooks usually discuss this problem under the header unit-heterogeneity and offer remedies such as fixed effects or random effects models. However, these models only deal with time invariant unit-specific effects: units can also be heterogeneous with respect to slope parameters, dynamics or lag structures. The following sections discuss different versions of unit heterogeneity, approaches to dealing with them, and their advantages and disadvantages.

### Unit Heterogeneity

When units have specific characteristics which cannot be measured and are time invariant, they offer different initial conditions which might bias the estimated coefficients. For example, geography is often considered time invariant – a country or region can be landlocked or on the European continent, cities have a certain distance to the next port, etc. Other examples are inheritance, being a former colony, the sex of an individual, or her genetic pool. These are inherited specific to this unit and do not change over time, especially if these time invariant unit-specific effects are correlated with any of the RHS variables, for example, if the gender of a person determines specific behavior such as party identification or voting, coefficient estimates are distorted by

omitted variable bias. If that is the case and we do not control for unit-specific effects, the Gauss–Markov assumption of  $x$  being deterministic is violated:

$$y_{it} = \sum_{k=1}^K \beta_k x_{kit} + \sum_{m=1}^M \gamma_m z_{mi} + u_i + \epsilon_{it} \quad (13)$$

where  $u_i$  denotes the unit-specific effects and  $z$  other explanatory variables that are time invariant but can be measured and are of theoretical interest. If  $u_i$  is excluded from the estimation, it becomes part of the overall error term, and will make the model less efficient in the case that it does not co-vary with any of the  $x$  or  $z$  but induces bias if  $u_i$  co-varies with any of the regressors. Econometrically, we can solve for correlated unit-specific effects by including a dummy variable for each unit into the right-hand side of the model which generates unit-specific intercepts. This estimation procedure is called a Least Squares Dummy Variable (LSDV) model.

$$y_{it} = \sum_{k=1}^K \beta_k x_{kit} + \gamma_{n-1} D_i + \epsilon_{it} \quad (14)$$

The unit-specific dummy variables ( $D_i$ ) are multi-collinear to any time invariant variable  $z$ , the coefficients for  $z$  are therefore not identified. We also can employ fixed effects (FE) specification which is econometrically equivalent to a LSDV model. The fixed effects model first de-means all variables in the model by subtracting the unit-specific mean and then estimates the transformed equation by OLS.

$$y_{it} - \bar{y}_i = \sum_{k=1}^K \beta_k (x_{kit} - \bar{x}_{ki}) + \epsilon_{it} - \bar{\epsilon}_i + u_i - \bar{u}_i \quad (15)$$

$$\equiv \dot{y}_i = \sum_{k=1}^K \beta_k \dot{x}_{kit} + \dot{\epsilon}_i \quad (16)$$

with

$$\bar{y}_i = \frac{1}{T} \sum_{t=1}^T y_{it}, \quad \bar{x}_i = \frac{1}{T} \sum_{t=1}^T x_{it}, \quad \bar{\epsilon}_i = \frac{1}{T} \sum_{t=1}^T \epsilon_{it}$$

The fixed effects transformation eliminates the unit-specific effects, but also time invariant variables that might be of theoretical

interest. FE can become highly inefficient because it only uses the within information of all variables. Yet, not controlling for unit-specific effects leads to biased estimates if unit effects exist and are correlated with any of the regressors.

If unit-specific effects do exist but do not co-vary with any of the RHS variables, not controlling for unit effects does not bias the estimates but instead increases the sampling variation of the OLS estimator, and therefore generates less efficient estimates. A straightforward remedy is a random effects (RE) specification which treats the  $u_i$  as a random unit-specific part of the error term. The random effects model only quasi-demeans the variables: rather than removing the time average from the explanatory and dependent variables at each  $t$ , RE removes a fraction of the time average. The RE estimator generates more efficient results than the FE estimator but the RE model produces biased estimates if RHS variables co-vary with the unobserved unit-specific effects. RE resembles a feasible GLS estimator where the  $\Omega$  matrix (VC matrix of the error term) has a specific RE structure which only depends on two parameters:  $\sigma_u^2$  and  $\sigma_e^2$ . RE and FE estimates tend to grow similar if  $T$  gets large or the variance of the estimated unit effects increases, as compared to the error variance.

Since the RE estimator is more efficient than FE if the unit effects are uncorrelated with the regressors, it is useful to determine which of the two specifications should be used. Textbooks typically suggest employing the Hausman test. The Hausman test (Hausman, 1978) is based on the following logic: since the RE estimator is biased if unit-specific effects are correlated, differences between FE and RE estimates are interpreted as evidence against the random effect's assumption of zero covariance between  $x$  and  $u_i$ . Econometricians attest that the Hausman test has good asymptotic properties. Nevertheless, in finite samples, the test results are influenced by the trade-off between bias and efficiency. The Hausman

test is only powerful in the limit: since FE is consistent, the difference of RE and FE estimates can only be caused by biased RE estimates. In finite samples, however, the differences can result from two sources: biased RE estimates and unreliable FE point estimates due to inefficient estimation of variables with low within variation. The Hausman test actually mirrors this trade-off since it divides the difference between RE and FE estimates by the difference in the asymptotic variances of the RE and FE estimates. From this, it follows that the test results are especially unreliable if the estimation equation contains regressors which are both correlated with the unit-specific effects and are rarely changing over time. Recent research (Pickup and Troeger, 2019; Plümper and Troeger, 2019) shows that the Hausman test is highly unreliable, especially when the estimation also suffers from dynamic misspecifications or uses econometric fixes to model dynamics. The Hausman test is generally biased towards a fixed effects specification. Pickup and Troeger (2019) also show that the Mundlak formulation of the Hausman test is always preferable (especially when the estimation is dynamically more complete) because it does not rely on estimating the differences in variance between the fixed effects and random effects estimates.

The estimation of time-invariant or nearly time-invariant variables is highly problematic in a FE specification. It is easy to see that including completely time-invariant variables would be a problem, but it is less obvious that estimating rarely changing variables would be problematic, because FE specifications generate an estimate. However, this estimate might be very inefficient since FE eliminates all cross-sectional variation and only the variance over time is used to compute the coefficient. If this within unit variation is very small, the sampling variation of FE estimates increases dramatically, which leads not only to large standard errors but also to very unreliable point estimates. In empirical analyses across the social sciences, we are often

interested in the effect of variables that only change once in a while, for example, the level of democracy in a country, electoral rules, central bank independence, marital status, family income.

In the case of time invariant variables, applied researchers often resort to a simple pooled OLS or a RE model which permits the estimation of coefficients for time-invariant variables. These estimates are biased if the unit-specific effects co-vary with the regressors. Hausman and Taylor (1981), as well as Amemiya and MaCurdy (1986), propose estimators that use the uncorrelated RHS variables as instruments for the correlated regressors. The models are based on a correlated random effects model (Mundlak, 1978) and use instrumental variables for the endogenous RHS variables. The underlying assumption is that only some of the time-varying ( $x_{it}$ ) and time-invariant ( $z_i$ ) variables are correlated with the unit-specific effects  $u_i$ . The uncorrelated  $x_{it}$  and  $z_i$  therefore can be used as instruments for the correlated RHS variables. The within transformed  $x_{it}$  serve as instruments for the correlated  $x_{it}$  (these are estimated by FE) and the unit means of the uncorrelated  $x_{it}$  ( $\bar{x}_i$ ) as well as the uncorrelated  $z_i$  serve as instruments for the correlated  $z_i$ . However, if the instruments are poor, Hausman–Taylor produces highly inefficient parameter estimates.

Of course, a fixed effects estimator generates clean estimates for the within effect. However, theories often do not tell us whether we should observe an effect between or within units and whether these effects should be the same. Given that the fixed effects estimator generates highly unreliable estimates if RHS variables are slow moving, and specification tests are highly unreliable, more recently there has been a lot of focus on the conditions under which one should use a fixed or random effects formulation. Plümper and Troeger (2007, 2011) show that it depends on the ratio of within to between variation of the RHS variables whether a fixed or random effects formulation produces better (that

is, estimates with lower Root Mean Squared Error) results. Clark and Linzer (2015) focus on the relationship between the number of units and within unit time points. Bell and Jones (2015), in comparison, demonstrate that it is important for the choice of estimator whether a panel is balanced or not.

### ***Parameter Heterogeneity***

We observe parameter heterogeneity if the coefficient of an explanatory variable differs significantly across units or over time. If parameters change across time or units, we are likely to deal with unobserved, and therefore excluded, interaction effects or we have assumed the wrong functional form of the statistical relationship. If the source of parameter heterogeneity is known or our theoretical model even predicts differences in parameters across units or time periods, we can straightforwardly specify the correct model by including interaction terms between time periods or groups of units and the specific right-hand side variables.

In case the source of parameter heterogeneity is unknown, seemingly unrelated regressions (SUR) or random coefficients models (RCM) offer an econometric solution to the problem. SUR models estimate a single regression for every unit but exploit the panel structure of the data by assuming a joint error process for all units. This increases efficiency of estimation by borrowing strength. SUR models only generate acceptable parameter estimates for long time-series – that is, when  $T$  largely exceeds  $N$ . SUR models employ a GLS type estimator for the VC matrix, which weights the standard errors by the cross-section specific mean squared errors. The random coefficients estimator (Beck and Katz, 2007) provides a compromise between estimating the fully pooled model and a fully unpooled estimate (separate OLS for each unit). Pooled OLS depends on the stark assumption of unit homogeneity, whereas separate OLS estimation for each unit produces inefficient results. The RCM borrows strength

by shrinking each of the individual unit OLS estimates back to the overall (pooled) estimate. It is, therefore, also a good test for poolability of the data. The RCM generalizes the RE estimator from the intercept to all parameters of interest:

$$y_{it} = \alpha + \beta_{ki} \sum_{k=1}^K x_{kit} + \delta_m \sum_{m=1}^M w_{mit} + \epsilon_{it} \quad (17)$$

$$\beta_i \sim N(\beta, \sigma_\beta^2)$$

The RCM can be made more useful by allowing the  $\beta_i$  to be functions of other unit-specific variables.

### ***Heterogeneity of Dynamics and Lag Structures***

In pooled data, not only coefficient estimates but also dynamic effects can vary across units. In addition, different RHS variables might exert a differently lagged impact on the dependent variable and the lag length can differ across units. Different dynamics can be straightforwardly incorporated into RCM or SUR models by including an LDV with unit-specific coefficients. Prais–Winsten specifications also allow for unit-specific autoregressive processes in the error term.

Since statistical tests for heterogeneous dynamics or lag structures are not readily available, specific dynamics should be defined on theoretical grounds. Unit-specific dynamics then can be more directly modeled by interacting the relevant regressors or the LDV with dummies for specific groups of units. Since different explanatory variables can have differently lagged effects across units as well, it is not plausible to just vary the estimates of the LDV, because the marginal effect of an RHS variable at time  $t > 1$  partially depends on the estimate for the LDV.

In summary, different kinds of unit heterogeneity do not prevent pooling of information over time and across units. Theoretically, unit heterogeneity leads to interesting research questions which can be empirically analyzed

with the appropriate model specification. The possibility of controlling for unit heterogeneity renders pooled data analysis more attractive than pure cross-section or time series analysis.

### ***Dynamics and Unit Heterogeneity***

Since PCSTS data, by definition, pool information over different dimensions, in this case space and time, the main challenge when using pooled data is dealing with simultaneously occurring violations of the underlying assumptions. Textbooks usually discuss the underlying assumptions of an estimator and, thus, solutions to violations of individual assumptions, separately. However, it is highly unlikely that only one assumption is violated – for example, in pooled data, we usually observe dynamics and unit heterogeneity at the same time. The main problem results from the expectation that solving one specification issue will reduce the overall bias. Unfortunately, this is not the case, and treating one problem might make another problem worse – that is, increase the overall bias.

Plümper and Troeger (2019) demonstrate this theoretically and with Monte Carlo experiments for the simultaneous occurrence of correlated unit-specific effects and dynamic misspecifications. They look at three common dynamic DGPs that all lead to serially correlated errors: omitted time-varying variables, omitted trends, and misspecified lag structures of the RHS variables. They then estimate six different dynamic specifications for each DGP (including an LDV, Prais–Winsten, Period fixed effects, ADL) and include unit fixed effects. They show that if the econometric solution does not match the DGP, a fixed effects approach increases the bias substantially, especially when compared to not including fixed effects. This exercise shows that misspecification issues need to be addressed simultaneously and focusing on one issue (unit heterogeneity) but ignoring another (dynamics) can increase the overall bias.

Testing for dynamics turns out to be especially challenging in pooled data because individual effects, autoregressive errors, and moving average errors can all present as serial correlation, and the sequence of testing for different violations of Gauss–Markov severely affects the conclusions we draw. For example, as shown by Plümpner and Troeger (2019), the Hausman test (1978) for correlated unit-specific effects performs very poorly under different dynamic DGPs and specifications.

As we know, a model with individual effects has composite errors that are serially correlated by definition. The presence of the time-invariant error component gives rise to serial correlation that does not die out over time. As a consequence, standard tests applied to pooled data always reject the null of spherical residuals. As discussed above, dynamic processes in the mean equation that are not specifically modeled, and serial correlation in the error term, can both result in biased estimates. Therefore, researchers need to test for these misspecifications. However, given the likelihood of individual effects in pooled data (whether correlated or not with RHS variables) testing for serial correlation in concurrence with individual effects is indispensable.

Pickup and Troeger (2019) analyze the performance of the most relevant specification tests for pooled data to determine under what conditions researchers can identify whether dynamic misspecifications and unit-specific effects (correlated or not) occur simultaneously. Since unit-specific effects generate serially correlated errors, the sequence of testing for fixed effects and serial correlation and/or the performance of joint tests becomes very important. They look at a large set of dynamic and static DGPs and estimation specifications for pooled data with (correlated) unit-specific effects and test the performance of the Wooldridge (2010) test for serial correlation, the Born–Breitung test (Born and Breitung, 2016) for serial correlation under FE, the Inoue–Solon (2006) test for serial correlation under FE, the Baltagi–Li test (Baltagi and Li, 1995) for serial correlation

under random effects and vice versa, and the Hausman (1978) and Mundlak (1978) tests for correlated unit-specific effects. None of these tests are designed to uncover the source of potential dynamics. The authors show that while most of the tests underperform for a large set of DGPs and estimation specifications, some guidance for applied researchers can be drawn from this exercise:

- 1 The Inoue–Solon test for serial correlation is extremely biased towards rejecting the Null of no serial correlation.
- 2 When the estimation includes a lagged dependent variable, most tests for serial correlation in pooled data are oversized.
- 3 Tests for serial correlation in pooled data perform best when lags of the RHS variables but not the LDV are included.
- 4 The Mundlak test always outperforms the Hausman test.
- 5 Both Hausman and Mundlak tests are biased towards rejecting the Null of uncorrelated unit effects when an LDV is included.
- 6 The Mundlak test performs relatively well when the estimation includes lags of the RHS variables and is more dynamically complete.
- 7 The Baltagi–Li test for random effects works best with more dynamically complete specifications.

In general, as has been discussed previously, a careful, dynamically complete specification is of utmost importance before dealing with other issues such as unit heterogeneity.

## PCSTS DATA WITH LIMITED DEPENDENT VARIABLES

In principle, all typical limited dependent variable models (Binary choice, Count, Tobit, etc.) are also applicable to PCST Data. As for linear models, the pooled data structure adds problems for specification that are sometimes hard to solve. I will briefly discuss specification issues in binary choice models with pooled data. The implications for other limited dependent variable models are similar.

In binary choice models, the presence of unit-specific effects complicates matters significantly, whether they are correlated with explanatory variables or not. As in the linear case, it is possible to add  $N - 1$  unit dummies to the RHS of the estimation equation to control for correlated unit-specific effects, but only when estimating a logistic or logit model. This is called the unconditional fixed effects logit model. Since the normal CDF used in the probit binary choice model has no closed form representation, adding  $N - 1$  dummies will not allow for the model to be identified. The unconditional FE logit estimator is generally inconsistent, but as Katz (2001) demonstrates, the bias is negligible for  $T \geq 20$ .

Another alternative is the conditional logit fixed effects model (Chamberlain, 1980). This estimator uses a conditional likelihood where only units that switched from zero to one or vice versa are used for estimation. This eliminates the unit-specific effect  $u_i$ . Chamberlain derives this procedure for  $T = 2$ . There has been some discussion (Greene, 2004) whether this model can easily be applied to cases where  $T > 2$ . Chamberlain (1980) proposes a solution in the form of maximizing a conditional version of the likelihood function. The intuition is that the  $u_i$  disappear from the likelihood if the likelihood of a given period of peace (i.e., of a given country) is calculated conditioning on the total number of periods (years) of peace for that country. The unit fixed effects are eliminated from the conditional logit likelihood via a transformation that is analogous to first differencing in linear pooled data models. The units for which the outcome is always 0 or always 1 do not contribute to the likelihood. In other words, the information that they provide is not used to estimate  $\beta$ . These units are unaffected by the explanatory factors. However, if, for example, 99% of the sample is in this situation, we may still estimate a significant  $\beta$  using the 1% of the sample which changed outcome during the observation period. No weight would be given to the fact that, for the vast majority

of the sample, the explanatory factors do not affect the outcome. This is similar to the linear case with slowly changing explanatory factors. Finally, this conditional likelihood approach cannot be adopted in the presence of lagged dependent variables.

Conditional fixed effects probit estimation is not feasible because the conditional likelihood approach does not yield computational simplifications for the FE probit. The  $u_i$  cannot be swept away, and maximizing the likelihood over all the parameters including the fixed effects will, in general, lead to inconsistent estimates for large  $N$  and fixed  $T$ .

In case the unit-specific effects remain uncorrelated with the RHS variables, a Random Effects Probit model can be estimated. MLE, in this case, yields a consistent and efficient estimator of  $\beta$ , but MLE is computationally costly since one has to compute the joint probabilities of a T-variate normal distribution, which involves T-dimensional integrals. This, however, becomes infeasible if  $T$  grows very large. However, it is possible to reduce the computation to a single integral.

There has been a lot of recent research focusing on fixed effects in binary choice and rare events data. Most methodologists dealing with pooled binary TSCS data agree that unobserved unit-specific effects generate a problem for estimation, but there is no clear consensus on how to deal with this problem. As discussed above, it is commonly believed that one of the major problems with rare events data is the fact that estimating a conditional fixed effects model generates inefficient estimates. Cook et al. (2020) revisit this issue and demonstrate that the main concern with fixed effects models of rare events data is not inefficiency, but rather biased estimation of marginal effects. They argue that only evaluating switching units generates a biased estimate of the baseline risk and thus incorrect estimates of the effects. The authors propose a penalized maximum likelihood fixed effects (PML-FE) estimator, which retains the complete sample by providing finite estimates of the fixed effects for each unit.

As with linear models, serially correlated errors violate the independence assumption of most MLE, Logit, and Probit models. Therefore, serially correlated errors encounter similar problems as in the linear case. Chamberlain (1993) shows that Binary Choice Models using a Lagged Dependent Variable are not identified. Beck et al. (1998) argue that Binary Choice PCSTS data are grouped duration data and suggest adding a series of period dummies to account for time dependency. These dummies account for the time elapsed since the last failure (1):  $k_t - t_0$ . This is equal to assuming duration dependence in a hazard model and measuring the length of non-eventful binary spells. Thus corrected, the logit resembles a BTSCS event history model. One can use a Likelihood Ratio test to check whether all included period dummies are jointly zero. This means that if  $T$  grows large, there will be many dummy variables, which could pose a degrees of freedom problem. In this case, period dummies can be transformed into cubic splines instead. The researcher has to specify a number of knots that define what segments of the time variable will have a cubic polynomial fit to it. These splines can be interpreted as hazard rates: the estimated coefficients measure the effect of the calculated base vector on the probability of and outcome, for example, war. Carter and Signorino (2010) advocate the use of the exponential of the time variable instead ( $t, t^2, t^3$ ). They argue that important elements of the splines are ad hoc and have no theoretical justification, which could lead to bias. Exponentials of  $t$  are more readily interpretable.

## CONCLUSION

This entry gives a short overview of basic estimation procedures and specification issues in PTSCS data. Due to space constraints, other important topics such as spatial effects in pooled data, non-stationarity, and the usefulness of error correction models, as well as

a detailed discussion of estimation procedures and specification issues in limited dependent variable models for pooled data, have to remain untouched. While estimators and statistical tests are discussed in most econometric textbooks, a thorough discussion of specification problems in pooled and panel data remains important. This is also true for the question of how asymptotic properties of estimators translate to finite sample analysis. There have been many recent exciting developments in PTSCS data analysis in the social sciences. For example, much has been done to properly model spatial effects and spatio-temporal effects both in linear (Franzese and Hays, 2007; Franzese et al., 2010) and limited dependent variable models (Franzese et al., 2016) for pooled data. In addition, the identification revolution in empirical social sciences has influenced the analysis of pooled data. Blackwell and Glynn (2018), for example, use potential outcomes to define causal quantities of interest in dynamic PTSCS models, and clarify how standard models like the ADL can generate biased estimates of these quantities because of post-treatment conditioning. They propose inverse probability weighting and structural nested mean models to deal with these post-treatment biases. The major challenge to the analysis of data that combines different dimensions – for example, pooling cross-sectional and time-series information – remains the treatment of simultaneously occurring misspecifications, because existing tests cannot discriminate effectively between different sources of misspecifications.

# Dynamic Systems of Equations

Mark Pickup

This chapter explores dynamic systems of equations in three parts. First, the topic is motivated by a discussion of why a researcher might use a dynamic model and might go beyond a single-equation model to a system of equations. This discussion is structured in terms of the violations of exogeneity that such models are designed to resolve. Second, the chapter describes common multiple-equation dynamic models: structural vector autoregression (SVAR), reduced form vector autoregression (VAR) and vector error-correction (VEC). Third, the chapter describes the state-space approach to dynamic modelling, showing that it encompasses these models and additional models, such as dynamic-factor and dynamic seemingly unrelated regression (SUR) equations.

## **Dynamics**

Giving the parameter estimates of any model a causal interpretation requires some form of

exogeneity assumption. For example, if the model were:

$$y_t = \beta_0 + \beta_1 x_t + \varepsilon_t,$$

a strict exogeneity assumption would be:

$$E(\varepsilon_t | x_{t+h}) = 0, \forall h$$

and a contemporaneous exogeneity assumption would be:

$$E(\varepsilon_t | x_t) = 0.$$

These are examples of the zero-conditional-mean assumption, and when it is violated we say that  $x_t$  is endogenous for the estimation of  $\beta_1$  in the model. Most readers will be familiar with the particular violation of this assumption that causes omitted variable bias. Let us say we are interested in testing the causal effect of  $X_t$  on  $Y_t$ :

$$X_t \longrightarrow Y_t$$

and our data model is:

$$y_t = \beta_0 + \beta_1 x_t + \varepsilon_t,$$

but the data generating process is:

$Z_t$  is an omitted variable if it is causally prior to and correlated with current values of  $X_t$  and  $Y_t$ . (Note:  $Z_t$  does not have to cause  $X_t$ ; it is enough that it is correlated.) If this is the case,  $E(\varepsilon_t | X_t) \neq 0$ , and the consequence is that the standard ordinary least squares (OLS) estimate of  $\beta_1$  will be a biased estimate of the causal effect of  $X_t$  on  $Y_t$ <sup>1</sup>:

$$E(\hat{\beta}_1 | X_t) = \beta_1 + X_t' X_t^{-1} X_t' \eta \neq \beta_1$$

where  $\eta = E(\varepsilon_t | X_t)$ .

An omitted variable  $Z_t$  can be of different types, resulting from different data-generating processes (DGP). As an example, say that  $Y_t$  is an aggregate measure of government vote intention and that  $X_t$  is an aggregate measure of subjective evaluations of how the economy has performed:

but both current government vote intention and current economic evaluations are a function of current leadership evaluations:

The omission of leadership evaluations from our data model will result in a biased estimate of

the relationship between current economic evaluations and current government vote intention.

Another possibility is that the omitted variable is a past value of ( $X_{t-1}$ ) that is causally prior to and correlated with current values of  $X_t$  and  $Y_t$ . For example, both current government vote intention and current economic evaluations are a function of past economic evaluations, resulting in a biased estimate of the relationship between current economic evaluations and current government approval:

A third possibility is that  $Z_t$  is a past value of  $Y_t$  that is causally prior to and correlated with current values of  $X_t$  and  $Y_t$ . For example, both current government vote intention and current economic evaluations are a function of past government vote intention:

The omission of past vote intention will result in a biased estimate of the causal relationship between current economic evaluations and current government approval.

In practice, we can resolve these endogeneity problems by including the omitted variable.<sup>2</sup> In addition to specifying which variables to include, it also means specifying which lags of  $X_t$  and  $Y_t$  to include (the lag structure).

Any model that includes a lag of  $Y_t$  (i.e., a lagged dependent variable) is known as a dynamic model. A common dynamic model is the autoregressive distributed lag (ADL) model. With a single  $x_t$ , this model is:

$$y_t = \alpha_0 + \sum_{j=1}^p \alpha_j y_{t-j} + \beta_1 x_t + \sum_{i=1}^m \beta_{i+1} x_{t-i} + \varepsilon_t \tag{1}$$

with  $\varepsilon_t \sim NID(0, \sigma_\varepsilon^2)$

The ADL(p,m) includes  $p$  lags of the dependent variable (included as independent variables) and  $m$  lags of the other independent variable(s), in addition to the non-lagged independent variable(s) (see Troeger, Chapter 33, this *Handbook*; Cook et al., Chapter 39, this *Handbook*; Neumayer and Plümper, Chapter 38, this *Handbook*).

An alternative to the ADL is the autoregressive moving-average model (ARMA). It models dynamics in  $Y_t$  by combining an autoregressive AR( $P$ ) process with a moving-average MA( $Q$ ) process:

$$y_t = \alpha_0 + \frac{\sum_{i=1}^p \alpha_i y_{t-i}}{AR(P)} + \frac{\sum_{j=0}^q \phi_j \varepsilon_{t-j}}{MA(Q)} \tag{2}$$

An ARMA model with  $P$  lags of  $Y_t$  and a  $Q$  lag of  $\varepsilon_t$  is denoted ARMA( $P, Q$ ). Box et al. (1994) developed an approach to determine the optimal values for  $P$  and  $Q$ . The lag structure of the  $X_t$  to be included in the model are then determined by a second procedure developed by Box et al. (1994). The procedures these researchers developed have minimal prediction errors and parsimonious models as their goals. Meanwhile, ADL models are more common when estimating causal effects are the goal and it is believed that a data model can be specified that has a lag structure that encompasses that of the DGP.<sup>3</sup> Either way, the use of these and other dynamic models is motivated by the need to address violations of exogeneity caused by not accounting for the dynamics in the DGP.

**Multiple Equations**

Another way the zero-conditional-mean assumption (i.e., exogeneity) may be violated is through simultaneity. This occurs when  $X_t$  and  $Y_t$  concurrently have causal

effects on each other, not because of their relationship with any other variable but simply because they each cause the other at the same point in time:

In terms of our economic voting example, we may expect one’s vote intention to influence one’s evaluation of the economy. A Republican voter under a Republican incumbent president may evaluate the economy differently to someone who intends to vote for the Democratic candidate, because viewing the economy as performing well feels consistent with their intention to vote for the Republican incumbent. Other examples of potentially simultaneous relationships include defence expenditures in country A and defence expenditures in country B; the relationship between foreign policy and presidential popularity; and public perception of a political event and the media’s coverage of the event.

The possibility of simultaneity requires us to consider a model that not only includes an equation for  $Y_t$  but also for  $X_t$ ; in other words, a system of equations, known as a multi-equation model. For example, we have discussed the following endogeneity problem created by omitting a lag of the dependent variable, where we previously denoted  $y_{1t}$  as  $y_t$  and  $y_{2t}$  as  $x_t$ . We are interested in this:

and we need to take this into account.

We have also noted that the following will produce an endogeneity issue. In addition to

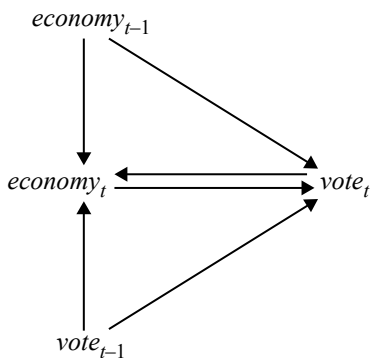

$y_{2t}$  contemporaneously causing  $y_{1t}$ ,  $y_{1t}$  also contemporaneously causes  $y_{2t}$ ;

The following will also produce an endogeneity issue. In addition to the bidirectional, contemporaneous relationship between  $y_{1t}$  and  $y_{2t}$ , past values of  $y_{2t}$  predict  $y_{1t}$  and  $y_{2t}$ ;

Returning to our economic voting example, in addition to past economic evaluations and past vote intentions being causally prior to current vote intentions, we might expect vote intentions (current and past) to have a causal effect on one's evaluation of the economy's performance and past economic performance to be causally prior to current economic performance and vote intention:

These potential relationships are captured by the following system of equations:

$$\begin{aligned} y_{1t} &= \alpha_1 + \alpha_{10}y_{2t} + \gamma_{11}y_{1t-1} + \gamma_{12}y_{2t-1} + \mu_{1t} \\ y_{2t} &= \alpha_2 + \alpha_{20}y_{1t} + \gamma_{21}y_{1t-1} + \gamma_{22}y_{2t-1} + \mu_{2t} \end{aligned} \quad (3)$$

$$\text{where } \mu_{1t} \sim \mu_{2t} \left( 00, \begin{pmatrix} \sigma_{11}^2 & \sigma_{12} \\ \sigma_{12} & \sigma_{22}^2 \end{pmatrix} \right)$$

Note that no assumption is made about the independence of the errors. The covariance between the errors in the two equations is allowed to be non-zero:  $\sigma_{12}$ .

This is a structural model that captures the expected causal effects between the variables.<sup>4</sup> This particular structural model includes an equation for each endogenous variable, and each equation includes lags of each of the endogenous variables. This is known as a SVAR model. Before we discuss SVAR models, we will discuss the reduced form VAR model.

### REDUCED FORM VAR

Because of the contemporaneous relationships between  $y_{1t}$  and  $y_{2t}$  in (3), it cannot be estimated simply. Unless  $\alpha_{20} = 0$ , the OLS estimate of  $\alpha_{10}$  in the first equation will not be consistent because of the simultaneity and violation of the zero-conditional-mean assumption:  $E(\mu_{1t}|y_{2t}) \neq 0$ .<sup>5</sup> Equivalently, unless  $\alpha_{10} = 0$ , the OLS estimate of  $\alpha_{20}$  in the second equation will not be consistent:  $E(\mu_{2t}|y_{1t}) \neq 0$ . We can get consistent estimates if we can apply restrictions, such as  $\alpha_{10} = 0$ , but these restrictions must be valid. This is equivalent to knowing something about the causal relationships between the endogenous variables *a priori*. For example, knowing that economic evaluations have a contemporaneous effect on vote intention but vote intention does not have a contemporaneous effect on economic evaluations (although it

may have a lagged effect). If we do not wish to make such identifying restrictions, we can do the following.

The system of equations in (3) can be transformed through a straightforward use of algebra (Brandt and Williams, 2007: 16–17). We substitute the equation for  $y_{2t}$  into  $y_{1t}$  and solve for  $y_{1t}$ . Conversely, we substitute the equation for  $y_{1t}$  into  $y_{2t}$  and solve for  $y_{2t}$ . The result is the following system of equations, called a *reduced form VAR* model:

$$\begin{aligned} y_{1t} &= \beta_{10} + \beta_{11}y_{1t-1} + \beta_{12}y_{2t-1} + \varepsilon_{1t} \\ y_{2t} &= \beta_{20} + \beta_{21}y_{1t-1} + \beta_{22}y_{2t-1} + \varepsilon_{2t} \end{aligned}$$

$$\begin{aligned} \text{where: } \beta_{11} &= \frac{\alpha_{10}\gamma_{21} + \gamma_{11}}{(1 - \alpha_{10}\alpha_{20})}, \beta_{12} \\ &= \frac{\alpha_{10}\gamma_{22} + \gamma_{12}}{(1 - \alpha_{10}\alpha_{20})}, \beta_{21} \\ &= \frac{\alpha_{20}\gamma_{11} + \gamma_{21}}{(1 - \alpha_{10}\alpha_{20})}, \end{aligned}$$

$$\begin{aligned} \beta_{22} &= \frac{\alpha_{20}\gamma_{12} + \gamma_{22}}{(1 - \alpha_{10}\alpha_{20})}, \varepsilon_{1t} \\ &= \frac{\alpha_{10}\mu_{2t} + \mu_{1t}}{(1 - \alpha_{10}\alpha_{20})}, \text{ and } \varepsilon_{2t} \\ &= \frac{\alpha_{20}\mu_{1t} + \mu_{2t}}{(1 - \alpha_{10}\alpha_{20})}. \end{aligned}$$

In the reduced form VAR model, each variable is regressed on its past values and the past values of the other variables in the system (Freeman et al., 1989). The reduced form VAR model can include additional lags of the variables ( $P$  of them):

$$\begin{aligned} y_{1t} &= \beta_{10} + \sum_{i=1}^P \beta_{1i}y_{1t-i} \\ &\quad + \sum_{i=1}^P \beta_{1(p+i)}y_{2t-i} + \varepsilon_{1t} \\ y_{2t} &= \beta_{20} + \sum_{i=1}^P \beta_{2i}y_{1t-i} \\ &\quad + \sum_{i=1}^P \beta_{2(p+i)}y_{2t-i} + \varepsilon_{2t} \end{aligned} \quad (4)$$

This can be extended even further to allow for additional endogenous variables  $Y_{kt}$ ;  $\Omega$ one additional equation is required for each additional endogenous variable. Exogenous variables can also be included (this does not require additional equations):

$$\begin{aligned} y_{1t} &= \beta_{10} + \sum_{i=1}^P \beta_{1i}y_{1t-i} \\ &\quad + \sum_{i=1}^P \beta_{1(p+i)}y_{2t-i} + \\ &\quad + \sum_{i=1}^K \kappa_{1(k)}x_{k,t} + \varepsilon_{1t} \\ y_{2t} &= \beta_{20} + \sum_{i=1}^P \beta_{2i}y_{1t-i} \\ &\quad + \sum_{i=1}^P \beta_{2(p+i)}y_{2t-i} \\ &\quad + \sum_{i=1}^K \kappa_{2(k)}x_{k,t} + \varepsilon_{2t} \end{aligned} \quad (5)$$

Compared with the SVAR model, an advantage of the reduced form VAR model is that the system of equations can be estimated (by OLS or maximum likelihood estimation) without making any restricting assumptions. The disadvantage is that the parameters in the reduced form model do not tell us anything about the causal contemporaneous relationships between the endogenous variables ( $\alpha_{10}$  and  $\alpha_{20}$ ). In fact, the parameters do not tell us anything *directly* about the non-contemporaneous causal relationships (the  $\gamma_{1t}$ s and  $\gamma_{2t}$ s). These cannot be calculated from the estimated parameters (the  $\beta$ s and  $\varepsilon_t$ s), unless we can make some identifying restriction – more on this to come.

The reduced form VAR does allow us to estimate how one endogenous variable will respond to a random shock to another endogenous variable. This response is not causal but predictive. This is achieved by transforming the reduced form VAR to what is known as the vector moving-average (VMA) representation. For a VAR with  $K$  endogenous variables and  $P$  lags, this is:

$$\begin{aligned}
 y_t - \mu_t &= \sum_{i=0}^{\infty} \Phi_i \varepsilon_{t-i} \\
 y_t &\equiv \begin{pmatrix} y_{1t} \\ \vdots \\ y_{Kt} \end{pmatrix} \quad \mu_t \equiv \begin{pmatrix} \mu_1 \\ \vdots \\ \mu_K \end{pmatrix} \\
 \varepsilon_t &\equiv \begin{pmatrix} \varepsilon_{1t} \\ \vdots \\ \varepsilon_{Kt} \end{pmatrix} \quad \Sigma_{\varepsilon_t} \equiv \begin{pmatrix} \sigma_{11}^2 & \cdots & \sigma_{1K}^2 \\ \vdots & \ddots & \vdots \\ \sigma_{K1}^2 & \cdots & \sigma_{KK}^2 \end{pmatrix}, \\
 \Phi_i &\equiv \begin{cases} I_k & \text{if } i = 0 \\ \sum_{j=1}^i \Phi_{i-j} \beta_j & \text{if } i > 0 \end{cases}
 \end{aligned} \tag{6}$$

where  $\beta_j$  is a  $K \times K$  matrix of parameters for the  $j$ th lag of  $y_t$ , and  $\beta_j = 0 \forall j > p$ .

The  $\Phi_i$  (which is  $K \times K$ ) tells us how the endogenous variables respond to a one-time, unit increase in the innovations – the  $\varepsilon_t$ . Specifically, the  $j, k$  element of  $\Phi_1$  gives the magnitude of the effect of a one-time, unit increase (an impulse) in the innovation of the  $k$ th endogenous variable on the  $j$ th endogenous variable after 1 periods. For example, the 1, 2 element of  $\Phi_1$  gives the magnitude of the effect of an impulse in  $\varepsilon_{2t-1}$  on  $Y_{1t}$  after 1 periods. The plot of the effects (the elements of the  $\Phi_i$ ) over time is called an impulse-response function (IRF). For example, plotting the magnitudes of the 1, 2 elements of  $\Phi_1, \Phi_2, \Phi_3 \dots$  plots the response of  $Y_{1t}$  to a one-unit impulse in  $\varepsilon_{2t}$ . This gives us a visual representation of the response of  $Y_{1t}$  to changes in  $Y_{2t}$ .

Note the variance–covariance matrix for the innovations ( $\Sigma_{\varepsilon_t}$ ) is not diagonal. In other words, the innovations correlate. This means that the elements of the  $\Phi_i$  cannot be given a causal interpretation. To do so, we would have to interpret the elements of the  $\Phi_i$  as the responses to an impulse in the innovation of one endogenous variable *holding all else*

*constant*. The correlation in the innovations means that all else is not necessarily held constant. In (6), the innovation in one endogenous variable may correlate with the innovation in another.

To provide an empirical example of a reduced form VAR model, we examine monthly prime ministerial (PM) satisfaction ratings, unemployment rates and vote intention data from the UK during the period June 1997 to May 2006 (Pickup, 2010). We are interested in how PM satisfaction and unemployment predict vote intention, taking into account that PM satisfaction and vote intention are likely endogenous to each other. To do this we estimate a reduced form VAR(1) model with PM satisfaction and vote intention as endogenous variables and unemployment rates as exogenous.<sup>6</sup> The unemployment variable is the three-month change in the unemployment rate (lagged by two months).<sup>7</sup> To account for electoral cycle effects, we include an independent trend for each electoral cycle and cycle specific intercepts. The parameter estimates from the model are presented in Table 34.1.

The parameter on lagged PM satisfaction in the vote equation is statistically significant (a 0.05 significance level is used throughout the chapter). PM satisfaction predicts vote intention. However, the reverse is not true. We also see that the unemployment-rate parameter is statistically significant in the PM satisfaction equation but not in the vote intention equation. An increase in the unemployment rate of one percentage point is predicted to cause a decrease in PM satisfaction of almost nine percentage points. While there is no evidence that vote intention responds directly to a change in the unemployment rate, the fact that PM satisfaction predicts vote intention suggests an indirect effect. However, with a reduced form model, we cannot make any causal claims regarding this effect.

**Table 34.1 PM satisfaction, vote intention and unemployment, Britain 1997–2006**

Equation		Parameter estimates
PMsat	PMsat <sub>t-1</sub>	0.739 (0.076)**
	Vote <sub>t-1</sub>	0.243 (0.165)
	Trend 1	-0.086 (0.048)
	Trend 2	-0.022 (0.064)
	Trend 3	-0.496 (0.379)
	Cycle 2	-4.054 (1.705)*
	Cycle 3	-2.889 (2.980)
	Unemployment	-8.703 (2.979)**
	Constant	3.836 (6.312)
	Vote	PMsat <sub>t-1</sub>
Vote <sub>t-1</sub>		0.204 (0.110)
Trend 1		-0.048 (0.032)
Trend 2		-0.170 (0.043)**
Trend 3		0.057 (0.253)
Cycle 2		0.659 (1.139)
Cycle 3		-5.385 (1.991)**
Unemployment		0.194 (1.990)
Constant		30.866 (4.217)**
<i>T</i>		101

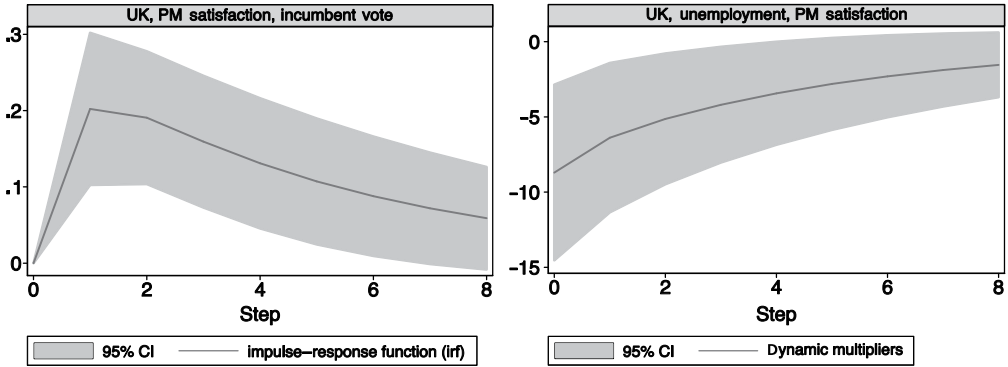

\*  $p < 0.05$ ; \*\*  $p < 0.01$ ; standard errors in parentheses.

With the parameter estimates from the reduced form VAR model in hand, we can plot the impulse–response function. This is a plot of the predicted change in one endogenous variable due to an impulse in the error (innovation) term of the other endogenous variable. This impulse occurs for only one period, after which it returns to zero. As a result, the response to the impulse will decay over time. The left pane of Figure 34.1 shows the impulse–response functions when PM satisfaction is the impulse variable and vote intention is the response variable. Each step is a month, so we see how the response to an impulse in PM satisfaction decays over eight months. Note that the response at time zero is zero. This is because we do not estimate contemporaneous effects/responses in the reduced form model. The right pane of Figure 34.1 is a dynamic multiplier function. This is the effect of a temporary one-unit increase in the unemployment rate on PM satisfaction.

We can see how the effect is initially negative and then decays over an eight-month period.

The advantage of the reduced form VAR is that it is identified, so the parameters can be estimated. The disadvantage is that the parameters of the original structural VAR cannot be calculated from the parameter estimates of the reduced form VAR without making some sort of identifying assumptions. These identifying restrictions amount to making some sort of causal assumptions. Without these assumptions, we are limited to what is known as Granger causality:  $Y_{1t}$  Granger causes  $Y_{2t}$  if past values of  $Y_{1t}$  and  $Y_{2t}$  can better predict the behaviour of  $Y_{2t}$  than past values of  $Y_{2t}$  alone. Put another way, does any individual lag or any combination of lags of  $Y_{1t}$  predict  $Y_{2t}$ , after we control for past values of  $Y_{2t}$ ?

Consider the reduced form VAR as it is expressed in (5). We test Granger causality by defining the null hypothesis that  $Y_{1t}$  does

Graphs by irfname, impulse variable and response variable

Graphs by irfname, impulse variable and response variable

**Figure 34.1 Impulse response and dynamic multiplier functions**

not Granger cause  $Y_{2t}$  as:  $\beta_{2(1)} = \beta_{2(2)} = \dots = \beta_{2(P)} = 0$ . The alternative is that  $Y_{1t}$  does Granger cause  $Y_{2t}$  if:  $\beta_{2(1)} \neq 0, \beta_{2(2)} \neq 0, \dots,$  or  $\beta_{2(P)} \neq 0$ .

If we are willing to make causal assumptions in order to place identifying restrictions, we may be able to ‘back out’ the parameters of the structural form of the model from the reduced form VAR. These SVAR parameters have a causal interpretation. There are two types of assumptions typically made. Depending on the type of assumptions, we call the analysis a short-run SVAR or a long-run SVAR.

**SVAR**

We begin with the short-run SVAR. The reduced form VAR with  $K$  endogenous variables and a lag order of  $P$  can be rewritten in matrix notation as:

$$y_t = b_0 + \beta_1 y_{t-1} + \beta_2 y_{t-2} + \dots + \beta_P y_{t-P} + \varepsilon_t$$

$$y_t = \begin{pmatrix} y_{1t} \\ \vdots \\ y_{Kt} \end{pmatrix}; \quad b_0 = \begin{pmatrix} b_{0,1} \\ \vdots \\ b_{0,K} \end{pmatrix};$$

$$\varepsilon_t = \begin{pmatrix} \varepsilon_{1t} \\ \vdots \\ \varepsilon_{Kt} \end{pmatrix}$$

$$\beta_p = \begin{pmatrix} \beta_{p,1,1} & \dots & \beta_{p,1,K} \\ \vdots & \ddots & \vdots \\ \beta_{p,K,1} & \dots & \beta_{p,K,K} \end{pmatrix}$$

Multiplying both sides by  $K \times K$  matrix  $A$ , this can then be rewritten as:

$$A(y_t - b_0 - \beta_1 y_{t-1} - \beta_2 y_{t-2} - \dots - \beta_P y_{t-P}) = A\varepsilon_t.$$

We can then define a new set of innovations  $e_t$  and  $K \times K$  matrix  $B$ , such that:

$$Be_t \equiv A\varepsilon_t.$$

The VAR can then be written as:

$$A(y_t - b_0 - \beta_1 y_{t-1} - \beta_2 y_{t-2} - \dots - \beta_P y_{t-P}) = Be_t$$

It can be shown that there is a set of values for the elements of  $A$  and  $B$ , such that the  $e_t$  are not correlated across equations. This means  $B^{-1}A$  orthogonalize the innovations  $\varepsilon_t$ . Defining  $P^{-1} = B^{-1}A$ , the VMA

representation of the reduced form VAR can be rewritten:

$$y_t - \mu_t = \sum_{i=0}^{\infty} \Phi_i \varepsilon_t = \sum_{i=0}^{\infty} \Phi_i P P^{-1} \varepsilon_t = \sum_{i=0}^{\infty} \Theta_i e_t$$

$$\Theta_i = \Phi_i P e_t = P^{-1} \varepsilon_t$$

Note that because the innovations are orthogonal, the elements of  $\Theta_i$  give the causal effects of the endogenous variables on each other.

Unfortunately, just as the SVAR is not identified, neither is  $P^{-1}$ . We proceed by placing enough restrictions on  $A$  and  $B$ , so that  $P^{-1}$  is identified. The parameters in  $B$  are the variances of the error terms. The parameters in  $A$  are the (negative of the) contemporaneous effects of the endogenous variables. Placing restrictions on  $A$  then means making assumptions about the contemporaneous causal relationships. The  $i, j$  th element of  $A$  determines how  $Y_{it}$  is contemporaneously caused by  $Y_{jt}$  – i.e., the contemporaneous causal effect of  $Y_{jt}$  on  $Y_{it}$ . A restriction could be that the contemporaneous causal effect of  $Y_{jt}$  on  $Y_{it}$  is 0.<sup>8</sup> It is important to note that any restrictions that identify  $A$  and  $B$  will correspond to restrictions that would have identified the original SVAR model.

Using this procedure means first estimating the reduced form VAR, then estimating causal effects by placing identifying restrictions on  $A$  and  $B$ , so that we can estimate the other elements of these matrices. The estimates of these other elements of  $A$  are estimates of the contemporaneous causal effects not assumed to be known (e.g., to be zero), and the estimated  $A$  and  $B$  give us the  $\Theta_i$ , and therefore the orthogonalized impulse–response functions.

In our previous example, we might assume that the contemporaneous effect of vote intention on PM satisfaction is zero and estimate the contemporaneous effect of PM satisfaction on vote intention. The estimated causal effect is 0.296 (standard error: 0.060). The result is statistically significant and suggests that an increase of one percentage point in PM satisfaction causes an immediate increase of 0.3 percentage points in vote intention for the incumbent government.

With the estimates for  $A$  and  $B$ , we can plot the structural impulse–response function (Figure 34.2). Comparing this to Figure 34.1, we see we now have an estimate for the contemporaneous effect of PM satisfaction on

Graphs by irfname, impulse variable and response variable

**Figure 34.2** Structural impulse response function

vote intention. Unlike the estimates from the reduced form model, this is an estimate of the causal effect. The units on the y axis have also changed. The constraints we placed on  $A$  and  $B$  had the effect of standardizing the variables. The impulse is now a change of one standard deviation in PM satisfaction and the response is measured in standard deviations of vote intention.

An alternative set of identifying restrictions are called long-run restrictions. Recall that the short-run SVAR can be written as follows:

$$A(y_t - b_0 - \beta_1 y_{t-1} - \beta_2 y_{t-2} - \dots - \beta_p y_{t-p}) = B e_t$$

This can also be written using the lag operator  $L^p$  (for example,  $L^p y_t = y_{t-p}$ ):

$$A(I - b_0 L - \beta_1 L^1 - \beta_2 L^2 - \dots - \beta_p L^p) y_t = B e_t$$

This allows us to rewrite the VAR:

$$y_t = C e_t$$

$$C \equiv \frac{A^{-1} B}{(I - b_0 L - \beta_1 L^1 - \beta_2 L^2 - \dots - \beta_p L^p)}$$

The SVAR can now be identified by placing restrictions on the matrix  $C$ . These restrictions can be interpreted as assumptions about the long-run causal relations between endogenous variables. Setting  $C_{ij} = 0$  can be interpreted as assuming the long-running response of variable  $i$  to the shocks driving variable  $j$  is zero.<sup>9</sup> The estimated parameters of  $C$  give us the long-run causal relationships between the endogenous variables. In this form, nothing is assumed about the short-run effects.<sup>10</sup>

The long-run SVAR makes assumptions about the long-run effects of the variables and system of equations. An alternative set of assumptions regarding the long-run relationship between variables motivates the VEC model, to which we turn next.

## VEC MODELS

To motivate vector error-correction models (VECMs), we begin with a review of cointegration. Up until now, we have assumed the variables are  $I(0)$  stationary (see Linn and Webb, Chapter 32, this *Handbook*), at least once we control for deterministic trends and periodicity. Say  $Y_t$  and  $X_t$  are  $I(1)$  non-stationary processes and that there is a  $\beta$  such that the linear combination of  $Y_t$  and  $X_t$ ,  $z_t = y_t - \alpha - \beta x_t$ , is a stationary process. If so, we say that  $Y_t$  and  $X_t$  are cointegrated and call  $\beta$  the cointegration parameter.<sup>11</sup> A common notation to indicate cointegration is  $(Y_t, X_t)' \sim CI(d, b)$ , where  $d$  indicates the order of integration for  $Y_t$  and  $X_t$  and  $d - b$  indicates the order of integration for  $z_t = y_t - \alpha - \beta x_t$ . For example, if  $Y_t$  and  $X_t$  are both  $I(1)$  and are cointegrated, such that  $Z_t$  is  $I(0)$ , then we could denote this as  $(Y_t, X_t)' \sim CI(1, 1)$ . If the two  $I(1)$  processes are cointegrated,  $\beta$  tells us the long-run relationship between  $Y_t$  and  $X_t$  - we will return to this later. If the two  $I(1)$  processes are not cointegrated, then there is no long-run relationship between  $Y_t$  and  $X_t$ , and  $y_t = \hat{\alpha} + \beta x_t + \hat{\varepsilon}_t$  is a spurious regression (although, note we could still estimate the short-run relationship with  $\Delta y_t = \beta \Delta x_t + \Delta \varepsilon_t$ ).

Certain combinations of variables cannot cointegrate. If  $z_t = y_t - \alpha - \beta x_t$  is a cointegrating relationship,  $Y_t$  and  $X_t$  must be of the same order of integration and  $Z_t$  must be of a lower order of integration. It does not make sense to claim that  $Y_t \sim I(0)$ ,  $X_t \sim I(1)$  and  $Z_t \sim I(0)$ ; an  $I(0)$  variable and an  $I(1)$  variable cannot combine to produce a  $I(0)$  variable. Nor does it make sense to claim that  $Y_t \sim I(2)$ ,  $X_t \sim I(1)$  and  $Z_t \sim I(0)$ . However, it is also possible to have the following situation:

$$z_t^* = y_t - \alpha - \beta_1 w_t - \beta_2 x_t$$

$$Y_t \sim I(2), X_t \sim I(1), W_t \sim I(2)$$

If  $Y_t$  and  $W_t$  are cointegrated, such that  $z_t = y_t - \alpha - \beta_1 z_t$  is  $I(1)$  (i.e.,  $(Y_t, W_t)' \sim CI(2,1)$ ) and  $Z_t$  and  $X_t$  are cointegrated, such that  $z_t^* = z_t - \beta_2 x_t$  is  $I(0)$  (i.e.,  $(Z_t, X_t)' \sim CI(1,1)$ ), then:

$$z_t^* = z_t - \beta_2 x_t = y_t - \alpha - \beta_1 w_t - \beta_2 x_t$$

is  $I(0)$ . This is called multi-cointegration. The requirement that the processes on the right-hand side must combine in a logical way to produce the process on the left-hand side is called balance. Balance is a somewhat advanced topic that we will not cover here (Banerjee et al., 2003).

We are now in a position to discuss the VECM:  $I(1)$  data can be modelled by first differencing it. However, this only allows us to look at short-run relationships. Cointegration allows us to expand the type of dynamic models that can be estimated for  $I(1)$  data beyond using first differences. If a cointegrating process  $Z_t$  is stationary, it can be included in time series models. Such models include error-correction models (also known as equilibrium-correction models (Hendry 2003)).

A standard VECM is just a VAR model that has been transformed. Starting with the SVAR with  $K = 2$  endogenous variables and a lag-order of  $P = 1$ :

$$\begin{aligned} y_{1,t} &= \alpha_1 + \alpha_{1,0}y_{2,t} + \gamma_{1,1}y_{1,t-1} \\ &\quad + \gamma_{1,2}y_{2,t-1} + \mu_{1,t} \\ y_{2,t} &= \alpha_2 + \alpha_{2,0}y_{1,t} + \gamma_{2,1}y_{1,t-1} \\ &\quad + \gamma_{2,2}y_{2,t-1} + \mu_{2,t} \end{aligned} \tag{6}$$

Subtract  $y_{1,t-1}$  from each side of the first equation and  $y_{2,t-1}$  from each side of the second equation:

$$\begin{aligned} y_{1,t} - y_{1,t-1} &= \alpha_1 + \alpha_{1,0}y_{2,t} \\ &\quad + \gamma_{1,1}y_{1,t-1} - y_{1,t-1} \\ &\quad + \gamma_{1,2}y_{2,t-1} + \mu_{1,t} \end{aligned}$$

$$\begin{aligned} y_{2,t} - y_{2,t-1} &= \alpha_2 + \alpha_{2,0}y_{1,t} \\ &\quad + \gamma_{2,1}y_{1,t-1} + \gamma_{2,2}y_{2,t-1} \\ &\quad - y_{2,t-1} + \mu_{2,t}, \end{aligned}$$

which can be rewritten as:

$$\begin{aligned} \Delta y_{1,t} &= \alpha_1 + (\gamma_{1,1} - 1)y_{1,t-1} \\ &\quad + \alpha_{1,0}y_{2,t} + \gamma_{1,2}y_{2,t-1} + \mu_{1,t} \\ \Delta y_{2,t} &= \alpha_2 + (\gamma_{2,2} - 1)y_{2,t-1} \\ &\quad + \alpha_{2,0}y_{1,t} + \gamma_{2,1}y_{1,t-1} + \mu_{2,t} \end{aligned}$$

Add and subtract  $\alpha_{1,0}y_{2,t-1}$  on the right-hand side of the first equation and add and subtract  $\alpha_{2,0}y_{1,t-1}$  on the right-hand side of the second equation:

$$\begin{aligned} \Delta y_{1,t} &= \alpha_1 + (\gamma_{1,1} - 1)y_{1,t-1} + \alpha_{1,0}y_{2,t} - \alpha_{1,0}y_{2,t-1} \\ &\quad + \alpha_{1,0}y_{2,t-1} + \gamma_{1,2}y_{2,t-1} + \mu_{1,t} \\ \Delta y_{2,t} &= \alpha_2 + (\gamma_{2,2} - 1)y_{2,t-1} + \alpha_{2,0}y_{1,t} - \alpha_{2,0}y_{1,t-1} \\ &\quad + \alpha_{2,0}y_{1,t-1} + \gamma_{2,1}y_{1,t-1} + \mu_{2,t} \end{aligned}$$

Note

$$\begin{aligned} \alpha_{k,0}y_{k,t} - \alpha_{k,0}y_{k,t-1} &= \alpha_{k,0}\Delta y_{k,t} \\ &\quad \text{and } \alpha_{k,0}y_{k,t-1} + \gamma_{k,1}y_{k,t-1} \\ &= (\alpha_{k,0} + \gamma_{k,1})y_{k,t-1} : \end{aligned}$$

$$\begin{aligned} \Delta y_{1,t} &= \alpha_1 + (\gamma_{1,1} - 1)y_{1,t-1} + \alpha_{1,0}\Delta y_{2,t} \\ &\quad + (\alpha_{1,0} + \gamma_{1,2})y_{2,t-1} + \mu_{1,t} \\ \Delta y_{2,t} &= \alpha_2 + (\gamma_{2,2} - 1)y_{2,t-1} + \alpha_{2,0}\Delta y_{1,t} \\ &\quad + (\alpha_{2,0} + \gamma_{2,1})y_{1,t-1} + \mu_{2,t} \end{aligned}$$

We then use  $(\alpha_{k,0} + \gamma_{k,1})$

$$\begin{aligned} &= \frac{(\gamma_{k,k} - 1)(\alpha_{k,0} + \gamma_{k,1})}{(\gamma_{k,k} - 1)} \\ &= -\frac{(\gamma_{k,k} - 1)(\alpha_{k,0} + \gamma_{k,1})}{(1 - \gamma_{k,k})} : \end{aligned}$$

$$\begin{aligned} \Delta y_{1,t} &= \alpha_1 + (\gamma_{1,1} - 1)y_{1,t-1} + \alpha_{1,0}\Delta y_{2,t} \\ &\quad - \frac{(\gamma_{1,1} - 1)(\alpha_{1,0} + \gamma_{1,2})}{(\gamma_{1,1} - 1)}y_{2,t-1} + \mu_{1,t} \\ \Delta y_{2,t} &= \alpha_2 + (\gamma_{2,2} - 1)y_{2,t-1} + \alpha_{2,0}\Delta y_{1,t} \\ &\quad - \frac{(\gamma_{2,2} - 1)(\alpha_{2,0} + \gamma_{2,1})}{(\gamma_{2,2} - 1)}y_{1,t-1} + \mu_{2,t} \end{aligned}$$

$$\begin{aligned} \Delta y_{1,t} &= \alpha_1 + \gamma_1 [y_{1,t-1} - \kappa_1 y_{2,t-1}] \\ &\quad + \kappa_{1,2,0}\Delta y_{2,t} + \mu_{1,t} \\ \Delta y_{2,t} &= \alpha_2 + \gamma_2 [y_{1,t-1} - \kappa_1 y_{2,t-1}] \\ &\quad + \kappa_{2,1,0}\Delta y_{1,t} + \mu_{2,t} \end{aligned} \tag{8}$$

Collect terms multiplied by  $(\gamma_{kk} - 1)$ :

$$\begin{aligned} \Delta y_{1,t} &= \alpha_1 + (\gamma_{1,1} - 1) \left[ y_{1,t-1} - \frac{(\alpha_{1,0} + \gamma_{1,2})}{(\gamma_{1,1} - 1)} y_{2,t-1} \right] \\ &\quad + \alpha_{1,0}\Delta y_{2,t} + \mu_{1,t} \\ \Delta y_{2,t} &= \alpha_2 + (\gamma_{2,2} - 1) \left[ y_{2,t-1} - \frac{(\alpha_{2,0} + \gamma_{2,1})}{(\gamma_{2,2} - 1)} y_{1,t-1} \right] \\ &\quad + \alpha_{2,0}\Delta y_{1,t} + \mu_{2,t} \end{aligned}$$

This can be written as:

$$\begin{aligned} \Delta y_{1,t} &= \alpha_1 + \gamma_1 [y_{1,t-1} - \kappa_{1,1}y_{2,t-1}] \\ &\quad + \kappa_{1,2,0}\Delta y_{2,t} + \mu_{1,t} \\ \Delta y_{2,t} &= \alpha_2 + \gamma_2 [y_{2,t-1} - \kappa_{2,1}y_{1,t-1}] \\ &\quad + \kappa_{2,1,0}\Delta y_{1,t} + \mu_{2,t} \end{aligned} \tag{7}$$

where  $\gamma_k = (\gamma_{k,k} - 1), \kappa_{k,1}$

$$= \frac{(\alpha_{k,0} + \gamma_{k,1})}{(1 - \gamma_{k,k})} \text{ and } \kappa_{k,2,0} = \alpha_{k,0}$$

The terms in the square brackets represent the cointegrating relationships between the endogenous variables (note that one could assume the  $\alpha_k$  to be equal and bring it into the cointegrating relationship). It can be shown that for any two  $I(1)$  variables, there can be at most one cointegrating relationship. Therefore, if  $Y_t$  and  $X_t$  are  $I(1)$  and cointegrated,  $[y_{1,t-1} - \kappa_{1,1}y_{2,t-1}] = [y_{2,t-1} - \kappa_{2,1}y_{1,t-1}]$  and (7) can be rewritten as:

If  $Y_{1,t}$  and  $Y_{2,t}$  are  $I(1)$  and cointegrated, the cointegrating relationship  $[y_{1,t-1} - \kappa_1 y_{2,t-1}]$  is  $I(0)$  stationary and the remaining terms are  $I(0)$  stationary. Therefore, all terms in the ECM are  $I(0)$  stationary.

It is not necessary that the variables in a VECM are  $I(1)$  and cointegrated: they can also be all  $I(0)$ . If this is the case, then the  $\kappa_{k,1}$  in (7) are the long-run effects of a change in one endogenous variable on the other, and the  $\kappa_{k,1,0}$  are the short-run effects. If the data are  $I(1)$  and cointegrated, the  $\kappa_{k,1,0}$  continue to be the short-run effect but  $\kappa_1$  in (8) is the cointegrating parameter. This still represents a long-run relationship between the variables but it is of a different nature than the long-run relationship between stationary variables.

If  $y_{1,t-1} - \kappa_1 y_{2,t-1}$  is the cointegrating relationship, the estimates of  $\gamma_1$  and  $\gamma_2$  indicate how quickly  $\Delta Y_t$  and  $\Delta X_t$  respectively respond to  $Y_t$  and  $X_t$  being out of equilibrium. These are the rate of adjustment coefficients. If  $Y_t$  and  $X_t$  are out of equilibrium with each other (i.e.,  $y_{1,t-1} - \kappa_1 y_{2,t-1}$  is not equal to zero), then  $Y_t$  will change such that  $|\gamma_1| \times 100\%$  of the adjustment necessary to bring them into equilibrium occurs in the next time point. Then,  $|\gamma_1| \times 100\%$  of the remaining adjustment occurs in the next time point after that and so on. Similarly,  $X_t$  will change such that  $|\gamma_2| \times 100\%$  of the adjustment necessary to bring them into equilibrium occurs in the next time point and so on.<sup>12</sup>

Equation (8) is the VECM of order  $P - 1 = 0$ . A higher order VECM includes additional lags of the first differences of the variables. For example, a first order VECM would be:

$$\begin{aligned} \Delta y_{1,t} &= \alpha_1 + \gamma_1 [y_{1,t-1} - \kappa_1 y_{2,t-1}] \\ &\quad + \kappa_{1,2,0} \Delta y_{2,t} + \kappa_{1,1,1} \Delta y_{1,t-1} \\ &\quad + \kappa_{1,2,1} \Delta y_{2,t-1} + \mu_{1,t} \\ \Delta y_{2,t} &= \alpha_2 + \gamma_2 [y_{1,t-1} - \kappa_1 y_{2,t-1}] \\ &\quad + \kappa_{2,1,0} \Delta y_{1,t} + \kappa_{2,1,1} \Delta y_{1,t-1} \\ &\quad + \kappa_{2,2,1} \Delta y_{2,t-1} + \mu_{2,t} \end{aligned}$$

This is a structural VECM(1) model. The issue of deciding how many lags of the differenced endogenous variables should be included is one of choosing a lag length that ensures the resulting residuals contain no serial correlation. Generalizing to a structural VECM( $P - 1$ ), where  $P$  denotes the order of the corresponding VAR:

$$\begin{aligned} \Delta y_{1,t} &= \gamma_1 [z_{t-1}] + \sum_{i=0}^{P-1} \kappa_{1,1,i} \Delta y_{t-i} \\ &\quad + \sum_{i=0}^{P-1} \kappa_{1,2,i} \Delta x_{t-i} + \varepsilon_{1,t} \\ \Delta y_{2,t} &= \gamma_2 [z_{t-1}] + \sum_{i=0}^{P-1} \kappa_{2,1,i} \Delta y_{t-i} \\ &\quad + \sum_{i=1}^{P-1} \kappa_{2,2,i} \Delta x_{t-i} + \varepsilon_{2,t} \end{aligned} \tag{9}$$

$$z_{t-1} \equiv y_{t-1} - \lambda_1 - \kappa_{1,1} x_{t-1}$$

A VECM is isomorphic with a VAR model. Specifically, the VECM(1) with a single lag of the first difference of the dependent variables is isomorphic to a VAR(2), and just as with any VAR, this can be transformed into the reduced form:

$$\begin{aligned} \Delta y_{1,t} &= \Gamma_{1,0,1} [z_{t-1}] + \Gamma_{1,1,1} \Delta y_{t-1} \\ &\quad + \Gamma_{1,2,1} \Delta x_{t-1} + \varepsilon_{1,t} \\ \Delta y_{2,t} &= \Gamma_{2,0,1} [z_{t-1}] + \Gamma_{2,1,1} \Delta y_{t-1} \\ &\quad + \Gamma_{2,2,1} \Delta x_{t-1} + \varepsilon_{2,t} \end{aligned} \tag{10}$$

$$z_{t-1} \equiv y_{t-1} - \lambda_1 - \kappa_{1,1} x_{t-1} \rightarrow$$

Generalizing to the reduced form VECM( $P - 1$ ):

$$\begin{aligned} \Delta y_{1,t} &= \Gamma_{1,0,1} [z_{t-1}] + \sum_{i=1}^{P-1} \Gamma_{1,1,i} \Delta y_{t-i} \\ &\quad + \sum_{i=1}^{P-1} \Gamma_{1,2,i} \Delta x_{t-i} + \varepsilon_{1,t} \\ \Delta y_{2,t} &= \Gamma_{2,0,1} [z_{t-1}] + \sum_{i=1}^{P-1} \Gamma_{2,1,i} \Delta y_{t-i} \\ &\quad + \sum_{i=1}^{P-1} \Gamma_{2,2,i} \Delta x_{t-i} + \varepsilon_{2,t} \\ z_{t-1} &\equiv y_{t-1} - \lambda_1 - \kappa_{1,1} x_{t-1} \end{aligned}$$

Note that the reduced form does not include contemporaneous values of the endogenous variables on the left-hand side.

The constants in the VECM equations can be included within or outside the cointegrating relationship. Further, a trend can be included inside or outside the cointegrating equation.

$$\begin{aligned} \Delta y_{1,t} &= \Gamma_{1,0,1} [z_{t-1}] + \sum_{i=1}^{P-1} \Gamma_{1,1,i} \Delta y_{t-i} \\ &\quad + \sum_{i=1}^{P-1} \Gamma_{1,2,i} \Delta x_{t-i} + \gamma + \tau t + \varepsilon_{1,t} \\ \Delta y_{2,t} &= \Gamma_{2,0,1} [z_{t-1}] + \sum_{i=1}^{P-1} \Gamma_{2,1,i} \Delta y_{t-i} \\ &\quad + \sum_{i=1}^{P-1} \Gamma_{2,2,i} \Delta x_{t-i} + \gamma + \tau t + \varepsilon_{2,t} \\ z_{t-1} &\equiv y_{t-1} - \lambda_1 - \rho t - \kappa_{1,1} x_{t-1} \end{aligned}$$

The constant inside the cointegrating equation allows the cointegrating variables to be stationary around the constant. The constant outside the cointegrating equation adds a linear time trend in the levels of the data. The trend within the cointegrating equation allows the cointegrating variables to be stationary around a trend. The trend outside the cointegrating equation allows for quadratic trends in the levels of the variables.

The VECM with two endogenous variables examined so far can be extended to include additional endogenous variables. If

these are  $I(1)$ , they can be included in the cointegrating relationship. For example,  $[y_{1t-1} - \kappa_1 y_{2t-1} - \kappa_2 y_{3t-1}]$ . It is important to determine if the endogenous variables are cointegrated, and if we have more than two endogenous variables, we *may* have more than one cointegrating relationship. Both cointegration and the number of cointegrating equations can be tested with the Johansen rank test (Johansen, 1995).

For our next example, we will use data from an article by Moore and Lanoue (2003). They use a vector error-correction model to look at the relationship between hostility sent ( $HS_t$ ) from the United States to other countries, hostility received ( $HR_t$ ) by the United States from other countries and the popularity of the US president ( $PP_t$ ). Hostility sent and received is measured on the basis of coded news reports of foreign policy behaviour – news reports are given a score ranging from cooperative foreign policy behaviour to conflictual foreign policy behaviour. The data used by Moore and Lanoue (2003) are quarterly means of these scores, from 1953–78. The popularity of the US president is based on the proportion of poll respondents indicating they approved of the performance of the president, aggregated quarterly.

We have three potentially endogenous variables. Using the Johansen rank test, Moore and Lanoue (2003) determined that the data are cointegrated with one cointegrating equation and the appropriate model is a VECM(1):

$$\begin{aligned} \Delta HS_t &= \hat{\gamma}_{11}^* [\hat{z}_{1,t-1}] + \hat{\Gamma}_{1,1,1} \Delta HS_{t-1} \\ &\quad + \hat{\Gamma}_{1,2,1} \Delta HR_{t-1} + \hat{\Gamma}_{1,3,1} \Delta PP_{t-1} + \hat{\epsilon}_{1,t} \\ \Delta HR_t &= \hat{\gamma}_{21}^* [\hat{z}_{1,t-1}] + \hat{\Gamma}_{2,1,1} \Delta HS_{t-1} \\ &\quad + \hat{\Gamma}_{2,2,1} \Delta HR_{t-1} + \hat{\Gamma}_{2,3,1} \Delta PP_{t-1} + \hat{\epsilon}_{2,t} \\ \Delta PP_t &= \hat{\gamma}_{31}^* [\hat{z}_{1,t-1}] + \hat{\Gamma}_{3,1,1} \Delta HS_{t-1} \\ &\quad + \hat{\Gamma}_{3,2,1} \Delta HR_{t-1} + \hat{\Gamma}_{3,3,1} \Delta PP_{t-1} + \hat{\epsilon}_{3,t} \\ \hat{z}_{1,t-1} &\equiv \hat{\kappa}_{1,1} HS_{t-1} + \hat{\kappa}_{1,2} HR_{t-1} + \hat{\kappa}_{1,3} PP_{t-1} + \hat{\lambda}_1 \end{aligned}$$

The estimated parameters from this model are presented in Table 34.2. The coefficients on the lag of the first difference of the variables are the short-run responses of the dependent variable to these variables. The only statistically significant short-run response (other than a variable’s response to its own change in a previous quarter) is that of presidential approval to hostility sent to other countries (positive effect). Note that as with the reduced form VAR, these ‘responses’ are not causal in the traditional sense; they are predictive.

The  $CI_{t-1}$  indicates the cointegrating relationship, which is also calculated and reported. The coefficients on  $CI_{t-1}$  are the (rate of) adjustment coefficients. Each endogenous variable does adjust to being out of equilibrium (the adjustment coefficients are statistically significant) but not particularly quickly. Approval responds the quickest, moving to close 13% of the gap each period.

Looking to the cointegrating relationship, we have restricted the coefficient on the first variable (hostility sent) to be one – this is a necessary but innocuous identifying restriction. The effect of presidential popularity in the cointegrating relationship is not statistically significant at the 0.05 significance level. The coefficient on hostility received is statistically significant in the cointegrating relationship.

To understand the cointegrating relationship, consider the impact of a change in hostility received, such that it moves out of equilibrium with hostility sent. The expected value for the cointegrating equation is zero. The coefficient on hostility received is negative and the coefficient on hostility sent is positive (1).

$$CI_{t-1} = HS_t - 5.33HR_t + 0.36PP_t + 44.93$$

This means that when hostility received increases so that it is out of equilibrium with hostility sent, the cointegrating equations will

**Table 34.2 Hostility sent, hostility received and presidential popularity, United States 1953–78**

Equation		Parameter estimates

### Cointegrating equation

	Parameter estimates
$HS_t$	1 (Fixed)
$HR_t$	-5.32854 (1.264653)**
$PP_t$	0.356464 (0.211377)
Constant	44.93087

produce negative values (below equilibrium). The adjustment coefficient for the cointegrating equation in the hostility-sent equation is negative, which means that when the cointegrating equation produces a negative value, hostility sent responds by increasing (starting in the next period). Putting all this together, when hostility received increases so that it is too high relative to hostility sent (moving the two out of equilibrium), hostility sent increases to close the gap.

The adjustment coefficient in the hostility-received equation is positive and so if hostility received increases so that it is too high relative to hostility sent (the cointegrating

relationship produces negative values), hostility received decreases (starting in the next period). The adjustment coefficient in the presidential-approval equation is negative and so presidential approval increases when the cointegrating relationship produces negative values – if hostility received is too high relative to hostility sent.

### THE STATE-SPACE APPROACH

We now turn to the state-space approach to dynamic systems of equations. Those that are

familiar with the ARMA or ARIMA (Autoregressive Integrated Moving Average) model will have (perhaps unknowingly) already seen a state-space model. The ARMA model is sometimes written as follows:

$$y_t = \alpha_0 + \sum_{i=1}^p \alpha_i y_{t-i} + \sum_{j=1}^q \theta_j \xi_{t-j} + \xi_t$$

$$\xi_t \sim NID(0, \sigma_\xi^2)$$

But it is also commonly written in two components:

$$y_t = \beta_0 + a_t$$

$$a_t = \sum_{i=1}^p \alpha_i a_{t-i} + \sum_{j=1}^q \theta_j \xi_{t-j} + \xi_t$$

The first equation is called the structural (or observation or measurement) component and the second is the disturbance (or state) component. This is a state-space model and it is the representation often used for the purposes of ARMA/ARIMA model estimation and interpretation of the estimation results.

The model can also be written in matrix form. Take the ARMA(1,1), for example, which can be written as

$$y_t = (1 \quad 1 \quad 0) \begin{pmatrix} \beta_0 \\ a_{1,t} \\ a_{2,t} \end{pmatrix}$$

Observation equation

$$\begin{pmatrix} \beta_0 \\ a_{1,t} \\ a_{2,t} \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \alpha_1 & 1 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} \beta_0 \\ a_{1,t-1} \\ a_{2,t-1} \end{pmatrix} + \begin{pmatrix} 0 \\ 1 \\ \theta_1 \end{pmatrix} \xi_t$$

State equation

or

$$y_t = \beta_0 + \mathbf{Z}a_t \quad \text{Observation equation}$$

$$a_t = \mathbf{T}a_{t-1} + R\xi_t \quad \text{State equation}$$

$$a_t = \begin{pmatrix} \beta_0 \\ a_{1,t} \\ a_{2,t} \end{pmatrix}, \mathbf{Z} = (1 \quad 1 \quad 0),$$

where

$$\mathbf{T} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \alpha_1 & 1 \\ 0 & 0 & 0 \end{pmatrix} \text{ and } R = \begin{pmatrix} 0 \\ 1 \\ \theta_1 \end{pmatrix}.$$

To understand the etymology of the name ‘state-space’, consider the current ARMA example. The state equation contains two state variables:  $a_{1t}$  and  $a_{2t}$  ( $\beta_0$  can also be thought of as a state that does not vary). These describe the *state* of the system we are observing. If we are observing public opinion, then this is the state of public opinion.

The *space* is a mathematical abstraction; it is the mathematical space in which different ‘positions’ represent different states of the system. For example, in Figure 34.3, the perpendicular axes define a space within which each point represents the values of  $a_{1t}$  and  $a_{2t}$ . Each pair of values, and therefore each point in the space, defines a state. We measure and therefore observe ( $y_t$ ), and it is a function of this state.

Figure 34.3 Two-dimensional space

The state-space approach to modelling time series is a more flexible way to solve problems of non-stationarity (e.g.,  $I(1)$  processes and deterministic trends) and measurement error than classical approaches (Durbin and Koopman, 2001). It is a powerful method for filtering and smoothing time series and forecasting (Commandeur and Koopman, 2007).<sup>13</sup> Most importantly for our discussion, it is easily extended to the multivariate case and it subsumes almost all classical linear time-series models – i.e., most classical models can be expressed in state-space form.

We begin by generalizing beyond the ARMA model. The state-space approach relates observations on one or more variables to unobserved (read latent) *states* by an *observation* equation:

$$y_t = \mathbf{Z}_t a_t + \mathbf{G}_t \varepsilon_t, \quad \varepsilon_t \sim NID(0, \boldsymbol{\sigma}_\varepsilon^2)$$

Observation equation

where  $y_t$  is an  $P \times 1$  vector of observed endogenous variables, in which  $P$  denotes the number of observed variables;  $\mathbf{Z}_t$  is an  $P \times M$  design matrix;  $a_t$  is an unobserved  $M \times 1$  state vector, in which  $M$  denotes the number of states; and  $\varepsilon_t$  is a  $P \times 1$  vector of observation errors with zero means and variances defined by the  $P \times P$  diagonal matrix  $\boldsymbol{\sigma}_\varepsilon^2$  – meaning the errors from the different observed variables do not correlate. Diagonal elements of  $\mathbf{G}_t$  are used to determine which vectors of  $y_t$  have stochastic error terms (set to one) and which are deterministic (set to zero). The state equation is

$$a_t = \mathbf{T}_t a_{t-1} + \mathbf{R}_t \xi_t, \quad \xi_t \sim NID(0, \boldsymbol{\sigma}_\xi^2)$$

State equation

where  $\mathbf{T}_t$  is an  $M \times M$  transition matrix that determines how values of the state vectors  $a_t$  relate to past values  $a_{t-1}$ ;  $\xi_t$  is a  $M \times 1$  vector of state disturbances, with zero means and

variances defined by the  $M \times M$  matrix  $\boldsymbol{\sigma}_\xi^2$ . The observation and state disturbances are assumed to be serially and mutually independent. Diagonal elements of  $\mathbf{R}_t$  are used to determine which states have stochastic error terms (set to one) and which are deterministic (set to zero). It is straightforward to include exogenous covariates in the observation and/or state equations.

The exogenous coefficients in the model can themselves be modelled by a state equation (allowing them to vary over time). For example, see Matthews and Pickup (2019). It is more common to specify a model with time invariant coefficients:

$$y_t = \mathbf{Z} a_t + \beta x_t + G \varepsilon_t, \quad \varepsilon_t \sim NID(0, \boldsymbol{\sigma}_\varepsilon^2)$$

$$a_t = \mathbf{T} a_{t-1} + \lambda \omega_t + R \xi_t, \quad \xi_t \sim NID(0, \boldsymbol{\sigma}_\xi^2)$$

The  $\beta x_t$  and  $\lambda \omega_t$  are exogenous variables within the observation and state equations, respectively.

The state-space form is used to derive the likelihood of the observed endogenous variables, conditional on their own past values and any exogenous variables. Expressing the model in state-space form allows us to use something called a Kalman filter to derive the prediction error form of the likelihood function. The Kalman filter is a set of *recursive* algorithms applied to the observed data to predict current values of the unobserved states and endogenous variables from past values (and exogenous variables). Recursive means the algorithm is first applied to the data at  $t = 1$  (e.g.,  $y_1$ ), then the algorithm is applied to the output and the data at  $t = 2$ , and the algorithm is then applied to the output and the data at  $t = 3$ , and so on.

The purpose of the filter is to obtain *optimal* predictions of the state vector(s) at  $t$  considering the observations  $\{y_1, y_2, \dots$

$y_{t-1}$  } – denoted  $a_{t|t-1}$ . Optimal is defined as the smallest prediction error:  $y_t - Za_{t|t-1}$ ; or  $y_t - Za_{t|t-1} - \beta x_t$ , if exogenous covariates are included.

Assuming a single state equation, so that the transition matrix  $T$  is a scalar, and a single observation equation, and excluding covariates, the Kalman filter algorithm is:

$$a_{t|t-1} = T \left[ a_{t-1|t-2} + K_{t-1} (y_{t-1} - Za_{t-1|t-2}) \right]$$

Predicted state at  $t$  is equal to the predicted state at  $t - 1$ , adjusted by the prediction error of the predicted state at  $t - 1$ , all multiplied by the transition scalar  $T$

The key to the Kalman filter is the ‘Kalman gain’:  $K_{t-1}$ . It determines how much the past prediction error influences the current predicted state. For simplicity, we shall assume the design matrix  $Z = 1$ :

$$a_{t|t-1} = T \left[ a_{t-1|t-2} + K_{t-1} (y_{t-1} - a_{t-1|t-2}) \right]$$

The Kalman gain is calculated as a compromise between the uncertainty in the state estimate based on  $\{y_1, y_2, \dots, y_{t-2}\}$  (i.e.,  $a_{t-1|t-2}$ ) and the uncertainty in the observation  $y_{t-1}$ . If the uncertainty in the observation  $y_{t-1}$  is very large relative to that in the predicted state  $a_{t-1|t-2}$ , we do not want  $y_{t-1}$  to influence subsequent predicted states very much. This is achieved by having  $K_{t-1} \rightarrow 0$ , such that the predicted state becomes

$$a_{t|t-1} = T \left[ a_{t-1|t-2} \right]$$

If the uncertainty in the predicted state  $a_{t-1|t-2}$  is very large relative to that in the observation  $y_{t-1}$ , we want  $y_{t-1}$  to have a large influence, such that the subsequent predicted state  $a_{t|t-1}$  is entirely informed by  $y_{t-1}$ . This is achieved by having  $K_{t-1} \rightarrow 1$ , such that the predicted state becomes:

$$a_{t|t-1} = T \left[ y_{t-1} \right]$$

To achieve these goals, the Kalman gain is defined as:

$$K_{t-1} = \frac{P_{t-1}}{F_{t-1}}$$

If we define the prediction error,  $v_t = y_t - Za_{t|t-1}$ , then  $F_{t-1}$  is the variance of the prior prediction error,  $var(v_{t-1})$ , and  $P_{t-1}$  is the error variance of the prior predicted state,  $a_{t-1|t-2}$ . Therefore,  $K_{t-1}$  is the proportion of the prior prediction error that can be attributed to uncertainty in the prior predicted state. The remaining error is due to the error in our measurement of  $y_{t-1}$ . If the entire prediction error is a result of uncertainty in the predicted state (at  $t - 1$ ), we do not want the predicted state to influence our subsequent predictions,  $K_{t-1} = 1$ . If no part of the prediction error is a result of uncertainty in the predicted state (at  $t - 1$ ), it must come from uncertainty in the observed value ( $y_{t-1}$ ). We do not want the observed value to influence our subsequent prediction,  $K_{t-1} = 0$ .

The means by which  $F_{t-1}$  and  $P_{t-1}$  are calculated and the proof that they give the optimal value for  $K_{t-1}$  is beyond this chapter, but they are functions of the state-space model parameters (Harvey, 1993).<sup>14</sup> These can be estimated by expressing the log-likelihood function for the observed data in terms of the prediction errors ( $v_t$ ) and

their variances ( $F_t$ ) and maximizing this function:

$$\log(L_d) = -\frac{T}{2} \log(2\pi) - \frac{1}{2} \sum_{t=d+1}^T \left( \log(F_t) + \frac{v_t}{F_t} \right)$$

where  $v_t$  and  $F_t$  are functions of the data and the unknown state-space model parameters and  $d$  is the number of *initial elements* for the state. An initial element is the value of the state prior to the first observation. These are required because the Kalman filter is recursive. The recursive nature means that the estimate of the current state always refers to the previous state. Because we need to start the Kalman algorithm somewhere, some assumptions need to be made about the first value of the state(s) to be entered into the algorithm – the initial element(s).<sup>15</sup>

The maximization of the log likelihood simultaneously minimizes the prediction errors,  $v_t$ , and their variances,  $F_t$ . Therefore, estimation of the state-space parameters through maximization of this log likelihood gives us the optimal predictions. This highlights a difference between the estimation of state-space models and classical time-series models. Classical models (using OLS or maximum likelihood estimation (MLE)) minimize the observation errors,  $\hat{\epsilon}_t$ , and their variances,  $\sigma_{\hat{\epsilon}_t}^2$ .

In addition to allowing us to write a likelihood function, the Kalman filter gives us both filtered and predicted values for the state(s):

$$\frac{a_{t|t-1}}{\text{Predicted state : } a_{t|t-1}} = \frac{T \left[ a_{t-1|t-2} + K_{t-1} (y_{t-1} - Z a_{t-1|t-2}) \right]}{\text{Filtered state } a_{t-1}}$$

The predicted state,  $a_{t|t-1}$ , is the optimal prediction of  $a_t$  based on  $\{y_1, y_2, \dots, y_{t-1}\}$ . The

filtered state,  $a_t$ , is the optimal estimate of  $a_t$  based on  $\{y_1, y_2, \dots, y_t\}$ . Each filtered state is a compromise between a prediction of the current state based on past information and the current observation:

$$a_t = a_{t|t-1} + K_t (y_t - Z a_{t|t-1})$$

The compromise is based on how much (un)certainty exists in each.

We can gain an intuition as to why  $a_t$  is a filtered state if we consider the following simple state-space model:

$$y_t = a_t + \epsilon_t, \quad \epsilon_t \sim NID(0, \sigma_\epsilon^2)$$

$$a_t = T a_{t-1} + \xi_t, \quad \xi_t \sim NID(0, \sigma_\xi^2)$$

We can interpret the  $\xi_t$  component as a random disturbance in the state process that we are interested in ( $a_t$ ) and  $\epsilon_t$  as random measurement error in our indirect observations of that state ( $y_t$ ). Our estimate of the filtered state,  $a_t$ , is our estimate of the observed value of  $y_t$ , with the random measurement error removed (or filtered).

In addition to predicted and filtered states, we can calculate *smoothed states*. Smoothed states are obtained by taking the output of the Kalman filter (the filtered states) and applying a similar algorithm backwards through time. This produces estimates of the states at a given time  $t$  based on all observations:  $\{y_1, y_2, \dots, y_T\}$ .

As suggested by the notation that we have been using for the state-space models, it is relatively easy to apply this approach to multivariate models. As examples, we will look at how to specify two classic models in state-space form: the reduced form VAR and the SVAR. We will then examine two models that are specific to the state-space approach: dynamic seemingly unrelated time-series equation and dynamic-factor models.

The reduced form VAR(1) model with two endogenous variables can be expressed in state-space form as follows:

**Table 34.3 PM satisfaction, vote intention and unemployment, Britain 1997–2006**

Equation		Parameter estimates
<i>PMs</i> $a_{PM,t}$	$a_{PM,t}$	1 (Fixed)

Unemployment		0.063 (2.021)
Constant		29.038 (4.533)**
VAR( $a_{V,t}$ )		7.088 (1.014)**
COV ( $a_{PM,t}$ , $a_{V,t}$ )		5.089 (1.219)**
$T$		101

\*  $p < 0.05$ ; \*\*  $p < 0.01$ ; standard errors in parentheses.

$$\begin{pmatrix} y_{1,t} \\ y_{2,t} \end{pmatrix} = \begin{pmatrix} a_{1,1,t} \\ a_{1,2,t} \end{pmatrix}$$

$$\begin{pmatrix} a_{1,1,t} \\ a_{1,2,t} \end{pmatrix}; = \begin{pmatrix} \alpha_{1,1} & \alpha_{1,2} \\ \alpha_{2,1} & \alpha_{2,2} \end{pmatrix} \begin{pmatrix} a_{2,1,t} \\ a_{2,2,t} \end{pmatrix}$$

$$+ \begin{pmatrix} \lambda_1 \\ \lambda_2 \end{pmatrix} + \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \xi_t,$$

$$\xi_t \sim NID \left( \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} \sigma_{\xi_{1,1}}^2 & \sigma_{\xi_{1,2}}^2 \\ \sigma_{\xi_{2,1}}^2 & \sigma_{\xi_{2,2}}^2 \end{pmatrix} \right)$$

$$\begin{pmatrix} a_{2,1,t} \\ a_{2,2,t} \end{pmatrix} = \begin{pmatrix} a_{1,1,t-1} \\ a_{1,2,t-1} \end{pmatrix}$$

We return to our British vote intention example, in which  $Y_{1t}$  = PM satisfaction and  $Y_{2t}$  = vote intention. We also include unemployment as an exogenous variable in the state equation. Estimation of the state-space model produces the results presented in Table 34.3. The results (both parameter estimates and standard errors) are very similar to those from the reduced form VAR results presented in Table 34.2. Increases in the unemployment rate have a negative effect on PM satisfaction and that, in turn, predicts a reduction in vote intention for the incumbent government.

We can also represent a structural VAR(1) model with two endogenous variables in state-space form.

$$\begin{pmatrix} y_{1,t} \\ y_{2,t} \end{pmatrix} = \begin{pmatrix} \mu_{1,1,t} \\ \mu_{1,2,t} \end{pmatrix}$$

$$\begin{pmatrix} \mu_{1,1,t} \\ \mu_{1,2,t} \end{pmatrix}; = \begin{pmatrix} 0 & \alpha_{1,0} \\ \alpha_{2,0} & 0 \end{pmatrix} \begin{pmatrix} \mu_{1,1,t-1} \\ \mu_{1,2,t-1} \end{pmatrix};$$

$$+ \begin{pmatrix} \alpha_{1,1} & \alpha_{1,2} \\ \alpha_{2,1} & \alpha_{2,2} \end{pmatrix} \begin{pmatrix} \mu_{2,1,t} \\ \mu_{2,2,t} \end{pmatrix}$$

$$+ \begin{pmatrix} \lambda_1 \\ \lambda_2 \end{pmatrix} + \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \xi_t,$$

$$\xi_t \sim NID \left( \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} \sigma_{\xi_{1,1}}^2 & 0 \\ 0 & \sigma_{\xi_{2,2}}^2 \end{pmatrix} \right)$$

$$\begin{pmatrix} \mu_{2,1,t} \\ \mu_{2,2,t} \end{pmatrix} = \begin{pmatrix} \mu_{1,1,t-1} \\ \mu_{1,2,t-1} \end{pmatrix}$$

In order for this to be identified for the purposes of estimation, an assumption must be made. To make the assumption about the contemporaneous causal order that we made previously – that satisfaction contemporaneously causes vote intention but not the reverse – we restrict  $\alpha_{2,0} = 0$ . We also restrict the variance–covariance matrix for  $\xi_t$  to be diagonal. Estimation of this model gives us the contemporaneous causal effect of PM satisfaction on vote  $\alpha_{1,0} = 0.299$  ( $p$  value  $< 0.001$ ). An increase in PM satisfaction of one percentage point causes vote intention for the incumbent government to immediately increase by 0.3 of a percentage point. This is equivalent to the results from the structural VAR(1) model estimated previously. We could also calculate the long-run effect, if we like.

Next we examine a dynamic seemingly unrelated regression equation in state-space form.

$$\begin{pmatrix} y_{1,t} \\ \vdots \\ y_{K,t-1} \end{pmatrix} = \begin{pmatrix} a_{1,t} \\ \vdots \\ a_{K,t-1} \end{pmatrix} + \begin{pmatrix} \beta_1 \\ \vdots \\ \beta_k \end{pmatrix} \begin{pmatrix} x_{1,t} \\ \vdots \\ x_{k,t} \end{pmatrix}$$

$$\begin{pmatrix} a_{1,t} \\ \vdots \\ a_{K,t} \end{pmatrix} = \begin{pmatrix} \alpha_1 \\ \vdots \\ \alpha_k \end{pmatrix} \begin{pmatrix} a_{1,t-1} \\ \vdots \\ a_{K,t-1} \end{pmatrix} + \begin{pmatrix} \lambda_1 \\ \vdots \\ \lambda_k \end{pmatrix}$$

$$+ \begin{pmatrix} 1 & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & 1 \end{pmatrix} \begin{pmatrix} \xi_{1,t} \\ \vdots \\ \xi_{K,t} \end{pmatrix},$$

$$\xi_t \sim NID \left( 0, \begin{pmatrix} \sigma_{\xi_{1,1}}^2 & \dots & \sigma_{\xi_{1,k}}^2 \\ \vdots & \ddots & \vdots \\ \sigma_{\xi_{k,1}}^2 & \dots & \sigma_{\xi_{k,k}}^2 \end{pmatrix} \right)$$

This model includes  $K$  observation equations. They represent autoregressive processes that are independent of each other, except the errors are modelled as correlated. In doing so, this model relates multiple observed time processes through their error term.

As an example, we examine 114 weekly estimates of party support (measured through vote intention polls) for the Conservatives, Labour and Liberal Democrats in Britain after the General Election in 2010. We include the lag of inflation (measured as the year-over-year change in the CPI) as a covariate in the observation equation. Note that by including the exogenous variables in the observation equation, we are assuming that inflation has no effect beyond the immediate short-run effect. To see this, plug the state equation into the observation equation:

$$y_t = Ta_{t-1} + \lambda + R\xi_t + \beta x_t$$

and note that by the definition of the observation equation,

$$a_{t-1} = y_{t-1} - \beta x_{t-1}$$

Plugging this into the above and tidying things up a bit:

$$y_t = Ty_{t-1} + \lambda + \beta x_t - T\beta x_{t-1} + R\xi_t$$

The long-run effect of  $x_t$  is calculated as  $\frac{\beta - T\beta}{1 - T} = \beta$ . The long-run effect is the short-run effect. If we place inflation in the state equation, it would have a long-run effect of:  $\frac{\beta}{1 - T}$ .

The estimated parameters from the model are presented in Table 34.4. Before

interpreting the results, we note that the transition coefficient in the Conservative support state equation ( $a_{C,t}$ ) is indistinguishable from one. The transition coefficients for Labour and Liberal Democrat support are also very close to one. This suggests that these states may be unit root processes. Unlike MLE or OLS estimates of classical models, this is not actually a problem for the estimator. The estimator for a state-space model is not biased by a unit root process. However, it suggests that we could gain efficiency by fixing these parameters to one and removing the constant from the observation equations. The constant can be removed under these circumstances because the initial value for the unit root

process acts as the constant. This explains the enormous standard error on the constant in the conservative support observation equation. Making these changes, we re-estimate the model parameters (Table 34.5).

We can see that the estimated errors have negative covariance. The increase in support for one party reduces support for another party. This effect is biggest for Labour and the Liberal Democrats: the left and centre (-left) parties. This is as we might expect. Turning to the effects of inflation, we see that increases in inflation reduce support for the Conservative party, increase support for the Labour Party and have no direct effect on support for the Liberal Democrats. A one-percentage point increase in inflation causes a 0.7-percentage point reduction in support for the Conservatives and a 0.6-percentage point increase in support for Labour. While statistically significant, these are not large effects. Because of the

relationship between Labour and Liberal Democrat support and Conservative and Liberal Democrat support, inflation does have a small indirect effect on Liberal Democrat support. Because the Labour–Liberal Democrat relationship is stronger, the indirect effect is negative.

Finally, we explore the dynamic-factor model. This is like a factor analysis where the observed variables are time series. Intuitively, the observed time series are observable measures of one or more underlying latent processes. These latent processes can be modelled as dynamic processes (autoregressive, random walk, trending deterministically, etc). As a state-space model, the latent processes are modelled as states and the observed time series as observations (Jackman, 2005; Pickup and Johnston, 2008). As an example, let us say we wish to model the proportion of individuals intending to vote for the Conservatives

in the next UK general election. The underlying state is the percentage of British voters that would vote for the Conservative party if an election were held tomorrow. Through public-opinion polls, we have multiple observations at multiple time points (weeks). We use 95 weeks of data starting the week of the 2017 UK general election. There are 279 polls from 11 polling houses during this period.

$$\begin{pmatrix} y_{1,t} \\ \vdots \\ y_{K,t-1} \end{pmatrix} = a_t + \delta_k + \varepsilon_t, \quad \varepsilon_t \sim NID(0, \sigma_{\varepsilon,t}^2)$$

$$a_t = \alpha_t a_{t-1} + \lambda_k + \xi_t, \quad \xi_t \sim NID(0, \sigma_{\xi}^2)$$

Each  $y_{kt}$  represents the observed measure of  $a_t$  from polling house  $k$  at time  $t$ . The observed measure is the proportion of individuals in the poll indicating they would vote for the Conservatives. This measure of Conservative-party support from polling house  $k$  at time  $t$  equals the latent support for the Conservative party at time  $t$  ( $a_t$ ) plus the systematic measurement error (bias) for polling house  $k$  ( $\delta_k$ ) and random measurement error ( $\varepsilon_t$ ). This measurement error has a variance that varies over time. Specifically, it is a function of sample size and the observed support:  $\sigma_{\varepsilon,t}^2 = \frac{y_{kt}(1-y_{kt})}{N}$ .

The latent support is modelled as first-order autoregressive.

If we allow all  $k$  observation equations to have a biased term ( $\delta_k$ ), the model is not identified. We can estimate the systematic bias of one house relative to another but we need to choose a house as the reference point for the estimation of the bias. We have chosen the pollster YouGov as the reference. Estimation of the model produces the bias terms (Table 34.6). We see that the house biases range from a systematic one-percentage point overestimation of support

**Table 34.6 Systematic polling house biases**

Poll house	Bias (percentage points)
1	Reference
2	-1.80 (0.37)
3	-1.04 (0.36)
4	-1.62 (0.26)
5	-2.57 (0.27)
6	0.55 (0.73)
7	-0.15 (0.37)
8	0.93 (0.94)
9	-0.76 (0.21)
10	0.66 (0.21)
11	0.0022 (0.55)

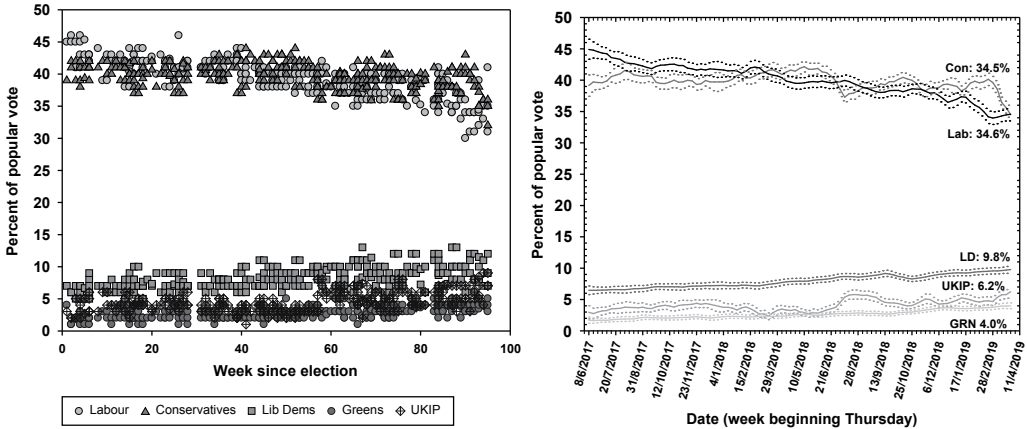

Standard errors in parentheses.

(relative to YouGov) for the Conservatives to a 2.5-percentage point underestimation.

We can next estimate the smoothed state ( $a_t$ ) and its root-mean-squared error. This is the estimate of public opinion with random measurement error filtered out. To produce the estimates, we anchored the systematic bias on the average of all pollsters. We then plotted the estimated smoothed state with 95% confidence interval and compared it to the original poll results. Figure 34.4 does this for the Conservative party, Labour, the Liberal Democrats, UKIP, and the Green party.<sup>16</sup> We can see that the estimated smoothed states contain far less variance than the original poll data.

The estimated root-mean-squared errors are small so it is difficult to see, but these confidence intervals do vary over time. This is an important difference between state-space and most classical time series models. In classical models, there is typically a single root-mean-squared-error term and so the confidence intervals are of a constant width over time. When a state-space model is used for forecasting, the time varying root-mean-squared errors also allow the confidence intervals of the estimated forecast to increase as the forecasts move further away from the

**Figure 34.4 Smooth states for vote intention**

last observed data point. This provides a more accurate estimate of the uncertainty in the forecast. A final distinction between the state-space approach and classical estimators is the way non-stationary processes are modelled. Classical estimators require us to detect  $I(1)$  processes in advance and adjust the model accordingly (typically by first differencing the variables). As  $I(1)$  processes do not bias state-space estimates, we can detect them in the model estimates and model as  $I(1)$  if necessary.

Overall, we can see that state-space models are a very flexible way of expressing and estimating dynamic systems of equations. The greatest drawback currently is that programs/packages/commands for estimating them are still very limited and are often very complex. For example, a missing data problem required the last model to be estimated as a Bayesian model in WinBUGS.

**Notes**

- 1 The estimator will also be inconsistent (Greene, 2012: 225).
- 2 However, it should be noted that modelling the third type of data generating process (including the past value of  $Y_t$ ) will always lead to a violation of strict exogeneity.

- 3 By encompass, we mean that the data model contains at least as many lags of the dependent and independent variables as the DGP.
- 4 It is helpful to keep in mind the difference between a structural equation and simultaneous equation model. In a structural model, the structure is based on prior theoretical ideas/assumptions about how the variables are expected to be causally related. If the prior theoretical assumptions are valid, a structural model allows us to come to conclusions regarding causal relationships. In a simultaneous equation model, where the form is not assumed to reflect the actual causal relationships between the variables, we should not give the estimated parameters a causal interpretation.
- 5 Since  $y_{2t}$  is a function of  $y_{1t}$  and therefore  $\mu_{1t}$ .
- 6 The lag order of the VAR was determined using the following lag-order selection statistics: final prediction error, Akaike's information criterion, Schwarz's Bayesian information criterion (SBIC), Hannan and Quinn information criterion (HQIC) and a likelihood-ratio test.
- 7 This is done because unemployment rates are reported for a three-month period with a two-month lag.
- 8 For a SVAR with  $K$  endogenous variables,  $\frac{2K^2 - K(K+1)}{2}$  restrictions must be placed on the parameters of  $A$  and  $B$ . This is a necessary but not sufficient condition.
- 9 For a SVAR with  $K$  endogenous variables,  $\frac{K^2 - K(K+1)}{2}$  restrictions must be placed on the parameters of  $C$ . This is a necessary but not sufficient condition.

- 10 Caution: the restrictions necessary to identify a SVAR are often difficult to justify theoretically. As social scientists, we very much want to give a causal interpretation to our analysis, BUT the discussion of our results should always include the appropriate caveat: 'The orthogonalized/structural impulse response function can only be given a causal interpretation to the extent that our identifying restrictions are correct'. On the upside, SVARs allow us to make identifying restrictions that are less arbitrary than those implicitly assumed in univariate time-series models. In addition to providing the appropriate caveat, it is also good practice to test different plausible identifying restrictions and note if this results in major differences.
- 11 Assuming we have determined that  $y_t$  and  $x_t$  are each integrated  $I(1)$  processes (e.g., using the Dickey–Fuller test), the Engle–Granger test of cointegration is as follows. As the cointegration parameter  $\beta$  is unknown, we first have to estimate  $\beta$ . We can estimate  $y_t = \alpha + \beta x_t + \mu_t$  (with or without  $\alpha$  or other deterministic terms like a trend) and calculate  $\hat{z}_t = \hat{\mu}_t = y_t - \hat{\alpha} - \hat{\beta}x_t$ . After estimating  $\beta$  we apply the Dickey–Fuller test to  $\hat{z}_t$ , in order to determine if it is  $I(0)$ . This requires different critical values than the usual Dickey–Fuller test; a higher threshold is necessary to take into account that the  $\beta$  is estimated and not known ahead of time (these can be looked up; MacKinnon, 2010). If we can reject a unit-root process for  $\hat{z}_t$ , then  $y_t$  and  $x_t$  are cointegrated.
- 12 Note that when we use a single equation ECM, we assume that only  $y_t$  responds when it and  $x_t$  are out of equilibrium (we are assuming that  $x_t$  is weakly exogenous). The VECM allows us to relax this assumption.
- 13 It can be also used to include time varying coefficients (Matthews and Pickup, 2019) and for non-linear dynamic models (Durbin and Koopman, 2001).
- 14 It can be shown that as  $t \rightarrow \infty$ ,  $F_t$  and  $P_t$  converge to constant values so does  $K_t$ ; when this happens, the filter is said to be in a steady state.
- 15 If the state is a stationary process, there are different techniques for specifying the initial element(s) and the corresponding standard error(s) – for example, we might assume the process was in equilibrium before our first observation of it. If the state is a non-stationary process, it is common to use *diffuse* initial elements. They are diffuse if they are estimated from the observed data and the random distributions used to represent our prior beliefs about them have an infinite variance (we know nothing about it).
- 16 Support for each party is estimated in a separate model but this could have all been done in a single model. This would allow us to relate the parameters for each party to each other (e.g., through the random error term).

# Duration Analysis

Kentaro Fukumoto

## INTRODUCTION

Political scientists sometimes study time to an event such as the end of a legislator's career, cabinet termination, and a war's conclusion. Duration analysis (sometimes called survival analysis or event history analysis) is a particular class of modeling for time to event.

The first section, which focuses on single duration without considering censoring, emphasizes that this class of analyses models not just *a single time point* when an event happens, but the *duration* where a unit is at risk of the event. By considering this way and comparing with conventional models, it will be more natural to derive seemingly weird distribution functions, in particular by way of hazard and not by way of the mean of event time like usual linear models. I represent non-parametric, parametric, and semi-parametric models in terms of both continuous and discrete time, discuss proportionality, and

explain frailty models. I also translate some technical terms specific to duration analysis into more general statistical terms.

The second section introduces parallel durations and explains competing risks, right censoring, and split population models. I emphasize that *censoring is another event* in which scholars have no interest. I also clarify independence assumptions scholars usually implicitly make and elaborate on how we can relax such assumptions by using frailties, seemingly unrelated regressions, and copula functions.

The third section considers serial durations and deals with left/interval truncation/censoring, time varying covariates, repeated events, and multi-state models. I call attention to whether durations are (conditionally) independent and, if not, how dependence among durations are modeled. The discussion of this section will also underscore how useful it is to analyze not *a point of time* but the *duration*.

This chapter explains duration analysis in unconventionally way, while it aims to shed light on the motivation as to why we model duration as we do and the assumption behind the scene and encourage readers to develop new models, in particular those which take into consideration dependence among multiple durations. Readers who are unfamiliar with duration analysis may refer to textbooks such as Box-Steffensmeier and Jones (2004) for ordinary guidance.

**SINGLE DURATION**

**Non-Parametric Model**

Suppose that  $T_i$  is a real random variable of the time when an event happens to unit  $i \in \mathcal{I} \equiv \{1, 2, \dots, \bar{i}\}$  and the cumulative distribution function (CDF) of  $T_i$  is denoted by  $F_i(t) \equiv Pr(T_i \leq t)$  for a real number  $t$ . We make the following two basic assumptions:

**Assumption 1** (Positive Time).

$$T_i > 0.$$

**Assumption 2** (Independence Across Units).

$$T_i \perp\!\!\!\perp T_{i'} \text{ if } i \neq i'.$$

For identification, we had better assume  $\lim_{t \rightarrow \infty} F_i(t) = 1$ , that is, the event certainly happens someday.

**Discrete time framework**

Suppose that there are fixed cutoff points  $t_j$ 's where  $j$  is a positive integer,  $t_j$  is a positive real number such that  $t_{j-1} < t_j$ , and  $t_0 \equiv 0$ . They might be located at regular intervals (e.g.,  $t_j \equiv j$  in years). Denote the  $j$ -th interval by  $\mathcal{T}_j \equiv (t_{j-1}, t_j]$ .

A conventional model pays attention to a discrete event time variable  $J_i$  which is the positive integer such that  $T_i \in \mathcal{T}_{J_i}$  (e.g.,  $J_i \equiv [T_i]$ ). It follows:

$$\begin{aligned} Pr(J_i = j) &= Pr(T_i \in \mathcal{T}_j) \\ &= F_i(t_j) - F_i(t_{j-1}) \\ &\equiv \Delta F_{ij}. \end{aligned} \tag{1}$$

A duration model focuses not just on a single event time  $J_i$  but on a series of event indicators  $E_i$  where an event indicator is defined as:

$$E_{ij} \equiv \begin{cases} 0 & \text{if } j < J_i \quad \left( \begin{array}{l} \text{the event will} \\ \text{occur after } \mathcal{T}_j \end{array} \right), \\ 1 & \text{if } j = J_i \quad \left( \begin{array}{l} \text{the event does} \\ \text{occur during } \mathcal{T}_j \end{array} \right), \end{cases}$$

for  $j \in \mathcal{J}_i \equiv \{1, 2, \dots, J_i\}$ , and the vector of event indicators is defined as  $E_i \equiv (E_{i1}, E_{i2}, \dots, E_{iJ_i})$ . Define the survivor function as:

$$\begin{aligned} S_i(t) &\equiv Pr(T_i > t) \\ &= 1 - F_i(t), \end{aligned} \tag{2}$$

which is called the complementary cumulative distribution function in the more general statistical literature. For  $j \geq 2$ , denote  $\mathcal{J}_{< j} \equiv \{1, 2, \dots, j - 1\}$  and  $\mathcal{J}_{< 1} \equiv \emptyset$ . It follows:

$$\begin{aligned} Pr(E_{ij} = 1 \mid \forall j' \in \mathcal{J}_{< j}, E_{ij'} = 0) &= Pr(T_i \in \mathcal{T}_j \mid t_{j-1} < T_i) \\ &= \frac{\Delta F_{ij}}{S_i(t_{j-1})} \quad (\because \text{Equations 1 and 2}) \\ &\equiv \Delta H_{ij}, \end{aligned} \tag{3}$$

which is called the discrete hazard rate, and, thus:

$$\begin{aligned} Pr(E_{ij} = 0 \mid \forall j' \in \mathcal{J}_{< j}, E_{ij'} = 0) &= 1 - \Delta H_{ij} \\ &= \frac{S_i(t_j)}{S_i(t_{j-1})}. \end{aligned} \tag{4}$$

Therefore,

$$\begin{aligned}
 \Pr(E_i) &= \Pr(\forall j' \in \mathcal{J}_{<J_i}, E_{ij'} = 0, E_{iJ_i} = 1) \\
 &= \left\{ \prod_{j=1}^{J_i-1} \Pr(E_{ij} = 0 \mid \forall j' \in \mathcal{J}_{<J_i}, E_{ij'} = 0) \right\} \\
 &\quad \Pr(E_{iJ_i} = 1 \mid \forall j' < J_i, E_{ij'} = 0) \\
 &= \left\{ \prod_{j \in \mathcal{J}_i} (1 - \Delta H_{ij}) \right\} \frac{\Delta H_{iJ_i}}{1 - \Delta H_{iJ_i}} \quad (5) \\
 &\quad (\because \text{Equations 3 and 4}) \\
 &= \exp \left\{ \underbrace{\sum_{j \in \mathcal{J}_i} \log(1 - \Delta H_{ij})}_{\text{duration}} \right\} \underbrace{\frac{\Delta H_{iJ_i}}{1 - \Delta H_{iJ_i}}}_{\text{event}},
 \end{aligned}$$

where  $\prod_{j=1}^0 = 1$ .

It is easy to show that Equations 1 and 5 are equal to each other. That is, the conventional and duration models approach the same object from different points of view. On the one hand, Equation 1 expresses the probability that an event happens during  $(t_{J_{i-1}}, t_{J_i}]$ . On the other hand, Equation 5 implies the probability that an event *does not* happen during  $(0, t_{J_{i-1}}]$  and *does* happen during  $(t_{J_{i-1}}, t_{J_i}]$ . Thus, a quantity of natural interest for duration model is not so much  $\Delta F_j$  as  $\Delta H_j$ .

Analysts might have an intrinsic interest in  $\Delta H_j$  rather than  $\Delta F_j$ . For instance, if  $J_i$  is the number of terms lawmaker  $i$  serves,  $\Delta H_{ij}$  represents the probability to be re-elected at time  $j$  given that the lawmaker survived the previous elections up to  $j - 1$ . Theoretically, scholars may expect that senior members are more likely to be reelected than junior ones, that is,  $\Delta H_j > \Delta H_{j'}$  for  $j > j'$ , while  $\Delta F_j = S_{j-1} \Delta H_j$  can be smaller than  $\Delta F_{j'} = S_{j'-1} \Delta H_{j'}$  because of  $S_{j-1} \leq S_{j'-1}$ .

### Continuous time framework

Suppose that  $F_i(t)$  is left differentiable and denote its left derivative by  $f_i(t)$ . A conventional model will analyze

$$p(T_i = t) = f_i(t). \quad (6)$$

A duration model focuses not just on a *point* of time  $T_i$ , but on the *duration* of time  $\mathcal{T}_i \equiv (0, T_i]$ . Define the hazard rate by:

$$\frac{f_i(t)}{S_i(t)} \equiv h_i(t), \quad (7)$$

which is equivalent to the inverse of the Mills ratio in more general statistical literature. Let  $\Delta t_{.j} \equiv t_{.j} - t_{.j-1}$ . It follows that:

$$\begin{aligned}
 &\lim_{\Delta t_{.j} \downarrow 0} \frac{\Delta H_{ij}}{\Delta t_{.j}} \\
 &= \lim_{\Delta t_{.j} \downarrow 0} \frac{F_i(t_{.j}) - F_i(t_{.j} - \Delta t_{.j})}{\Delta t_{.j}} \frac{1}{S_i(t_{.j} - \Delta t_{.j})} \\
 &= \frac{f_i(t_{.j})}{S_i(t_{.j})} \quad (8) \\
 &= h_i(t_{.j}).
 \end{aligned}$$

Denote  $\Delta t \equiv \max_j \Delta t_{.j}$ ; It follows that:

$$\begin{aligned}
 p(\mathcal{T}_i) &\equiv \lim_{\Delta t \downarrow 0} \frac{1}{\Delta t_{J_i}} \Pr(E_i) \\
 &= \lim_{\Delta t \downarrow 0} \exp \left\{ \sum_{j \in \mathcal{J}_i} \frac{\log(1 - \Delta H_{ij})}{\Delta t_{.j}} \Delta t_{.j} \right\} \\
 &\quad \frac{\Delta H_{iJ_i}}{\Delta t_{.J_i} (1 - \Delta H_{iJ_i})} \quad (\because \text{Equation 5}) \\
 &= \exp \left[ \int_0^{T_i} \frac{d \log \{S_i(t)\}}{dt} dt \right] h_i(T_i) \\
 &\quad (\because \text{Equations 4 and 8, } \lim_{\Delta t \downarrow 0} (1 - \Delta H_{iJ_i}) = 1) \\
 &= \underbrace{\exp\{-H_i(\mathcal{T}_i)\}}_{\text{duration}} \underbrace{h_i(T_i)}_{\text{event}},
 \end{aligned} \quad (9)$$

where the cumulative hazard rate is defined as

$$H_i(\mathcal{T}) \equiv \int_{\mathcal{T}} h_i(t) dt, \quad (10)$$

for any set of positive values of  $t$ ,  $\mathcal{T} \subseteq \{t \mid t > 0\}$ .<sup>1</sup>

It is a good exercise to show that Equations 6 and 9 are equal to each other. On the one hand, Equation 6 deals with the probability density that an event happens at  $T_i$ . On the other, Equation 9 implies the probability density that an event *does not* happen during  $(0, T_i)$  and *does* happen at  $T_i$ . Thus, a quantity of natural interest for the duration model is not so much  $f(t)$  as  $h(t)$ .

Obviously, Equation 9 looks similar to its discrete time framework version, Equation 5. Since information on event timing is coarsened in the discrete time framework, estimation is less efficient than in the continuous time framework. Nonetheless, if we can observe not  $T_i$  but  $J_i$ , or if  $F_i(t)$  is not left differentiable (e.g., the event can happen only at finite time points), only the discrete time framework is available.

**Parametric Model**

**Accelerated failure time model**

Conventional models would characterize  $F_i(t)$  only by a vector of sufficient statistics,  $\psi_i \equiv (\psi_i^{(1)}, \psi_i^{(2)}, \dots, \psi_i^{(A)})$ , that is,  $F_i(t) = F(t|\psi_i)$ . A typical example is the log normal distribution:

$$F_{\text{Log Normal}}(t|\psi_i) \equiv \Phi(z_i), \tag{11}$$

where  $\Phi(\cdot)$  is the CDF of the standard normal distribution,  $z_i$  is the standardized logged time such that

$$z_i \equiv z(t|\mu_i, \sigma) \equiv \frac{\log(t) - \mu_i}{\sigma}, \tag{12}$$

$\mu_i$  and  $\sigma > 0$  are location and scale parameters, respectively, and  $\psi_i = (\mu_i, \sigma)$ . Instead, we may use the log logistic distribution  $F_{\text{Log Logistic}}(t|\psi_i) \equiv \Lambda(z_i) \equiv 1/\{1 + \exp(-z_i)\}$ .

Furthermore, scholars are usually interested in the distribution of  $T_i$  conditioned on a row vector of covariates  $x_i \equiv (x_i^{(1)}, x_i^{(2)}, \dots, x_i^{(B)})$  by modeling  $\psi_i^{(a)} = \psi^{(a)}(x_i, \beta) = g^{-1}(x_i\beta)$  where  $\beta$  is a column vector of coefficient parameters not indexed by  $i$  and  $g(\cdot)$  is a link function. (For ease of presentation, I do not annotate transposition of a vector because it

is obvious in the context.) If  $\psi_i = (\mu_i, \sigma)$ , one may model

$$\mu_i = x_i\beta, \tag{13}$$

where the identity link function  $g_{\text{identity}}(\mu) \equiv \mu$  is used. Thus,  $F_i(t) = F(t|x_i, \theta)$  where  $\theta = (\beta, \sigma)$  is a vector of unit invariant extended parameters and variation in  $F_i(t)$  is explained by unit variant  $x_i$  only. If we use Equations 12 and 13, we can rewrite them as

$$\log(T_i) = x_i\beta + \sigma Z_i, \tag{14}$$

where  $\sigma Z_i$  works as an error term and, in the case of log normal model (Equation 11), follows normal distribution with mean 0 and variance  $\sigma^2$ . This representation is called the accelerated failure time model because, if the  $b$ -th coefficient is positive ( $\beta^{(b)} > 0$ ), ‘failure time’  $T$  increases in (or is ‘accelerated’ by) the  $b$ -th covariate,  $x^{(b)}$ . In general, this model is called log linear regression, which most scholars are familiar with.

We can estimate  $\theta$  by maximizing the likelihood: in the case of the discrete time framework,

$$l(\theta|J, x) \propto \prod_{i \in \mathcal{I}} \Delta F_{J_i}(x_i, \theta) \tag{:: Assumption 2 and Equation 1},$$

where  $J \equiv (J_1, J_2, \dots, J_T)$  and  $x \equiv (x_1, x_2, \dots, x_T)$ , and in the case of the continuous time framework,

$$l(\theta|T, x) \propto \prod_{i \in \mathcal{I}} f(T_i|x_i, \theta) \tag{:: Assumption 2 and Equation 6},$$

where  $T \equiv (T_1, T_2, \dots, T_T)$ . Note that, in the discrete time framework, unlike ordered logit or probit models, cutoff points ( $t_j$ 's) are not parameters to be estimated but known values.

**Hazard model**

For a while, we consider the continuous time framework. According to Equations 2, 4, and 9, it holds

$$S_i(t) = \exp\{-H_i(\mathcal{T})\}, \tag{15}$$

where  $\mathcal{T} \equiv (0, t]$ . Thus, thanks to Equation 9, the likelihood of unit  $i$  is proportional to

$$f(T_i | \psi_i) = \exp\{-H(T_i | \psi_i)\}h(T_i | \psi_i).$$

Accordingly, the duration model would specify  $H(\mathcal{T} | \psi_i)$  or  $h(t | \psi_i)$  instead of  $F(t | \psi_i)$ . The most popular distribution is Weibull:

$$\begin{aligned} H_{\text{Weibull}}(T | \psi_i) &\equiv \exp(z_i) \\ &= \mu_i^* t^{\sigma^*}, \end{aligned} \tag{16}$$

where  $\mu_i^* \equiv \exp(-\mu_i / \sigma)$  and  $\sigma^* \equiv 1/\sigma^2$ . Accordingly, the hazard rate is

$$\begin{aligned} H_{\text{Weibull}}(t | \psi_i) &= \frac{dH_{\text{Weibull}}(\mathcal{T} | \psi_i)}{dt} \\ &= \sigma \mu_i^* t^{\sigma^* - 1}, \end{aligned} \tag{17}$$

If  $\sigma^* > 1$  (or  $\sigma^* < 1$ ), the hazard rate  $h(\cdot)$  increases (or decreases) in  $t$ . For example, parliament dissolution becomes more likely as the term approaches expiration. If  $\sigma^* = 1$ , Weibull distribution is reduced to exponential distribution and the hazard rate is constant over  $t$ :

$$h_{\text{exponential}}(t | \psi_i) = \mu_i^*. \tag{18}$$

Usually, we condition on  $x_i$  by way of Equation 13. Thus, we estimate  $\theta$  by maximizing the likelihood:

$$\begin{aligned} l(\theta | \mathcal{T}, x) &\propto \prod_{i \in \mathcal{I}} p(\mathcal{T}_i | x_i, \theta) \\ &\quad (\because \text{Assumption 2}) \\ &= \prod_{i \in \mathcal{I}} \underbrace{\exp\{-h(\mathcal{T}_i | x_i, \theta)\}}_{\text{duration}} \underbrace{h(\mathcal{T}_i | x_i, \theta)}_{\text{event}}, \\ &\quad (\because \text{Equation 9}) \end{aligned}$$

where  $\mathcal{T} \equiv (\mathcal{T}_1, \dots, \mathcal{T}_T)$ . Off-the-shelf statistical software often reports estimates of  $\beta^* \equiv -\beta/\sigma$  and  $\sigma^*$  instead of  $\beta$  and  $\sigma$ . If  $\beta^{*(b)} > 0$ , the hazard rate  $h(\cdot)$  increases in  $x^{(b)}$ , which implies  $T$  decreases in  $x^{(b)}$

( $\because \beta^{(b)} < 0$ ). However, some analysts might be interested in the effect of  $x$  not on  $h(\cdot)$  but on  $T$  and, for them, the package result can be misleading. They would prefer an accelerated failure time representation of the same model (Equation 14) where  $Z_i$  looks like a scaled error term and follows type 1 extreme value (namely, Gumbel maximum) distribution:

$$\begin{aligned} Z_i &\sim \Xi(z_i) \\ &\equiv 1 - \exp\{-\exp(z_i)\} \\ &= F_{\text{Weibull}}(t | \psi_i) \\ &\quad (\because \text{Equations 2, 15, and 16}). \end{aligned} \tag{19}$$

### Cox model

The most popular method of duration analysis is the Cox model because it only has to specify the hazard rate up to the ‘baseline hazard’. In this sense, this model is called semi-parametric.

For  $t \in \mathcal{T}_i$ , an event indicator in the continuous time framework is defined as

$$E_i(t) \equiv \begin{cases} 0 & \text{if } t < T_i \\ \text{(the event will occur after } t), \\ 1 & \text{if } t = T_i \\ \text{(the event does occur at } t). \end{cases}$$

Define the ‘risk set’ as the set of units whose events have not happened before  $t$  (in the continuous time framework) or  $t_{j-1}$  (in the discrete time framework) and, thus, which are still at risk of the event at  $t$  or during  $\mathcal{T}_j$ :

$$\begin{aligned} \mathcal{I}(t) &\equiv \{i | t \in \mathcal{T}_i\}, \\ \mathcal{I}_j &\equiv \{i | j \in \mathcal{J}_i\}. \end{aligned} \tag{20}$$

We make two assumptions.

**Assumption 3** (Proportional Hazard):

$$h_i(t) = h_0(t)\psi_i.$$

We call  $h_0(t)$  the baseline hazard, which is constant across unit  $i$ 's.

**Assumption 4** (No Tied Events):

$$T_i \neq T_{i'} \text{ if } i \neq i'.$$

Thus, for any  $i$ ,  $\sum_{i' \in \mathcal{I}(T_i)} E_{i'}(T_i) = 1$  and, for sufficiently small  $\Delta t_{i,j}$ , it follows  $\sum_{i' \in \mathcal{I}_{i,j}} E_{i'} = 1$ .

If  $i \in \mathcal{I}_j$ , we calculate the probability that unit  $i$  has an event during  $\mathcal{T}_j$  conditioned that one unit in the risk set  $\mathcal{I}_j$  has an event during  $\mathcal{T}_j$ :

$$\begin{aligned} & \Pr(E_{ij} = 1 \mid \sum_{i' \in \mathcal{I}_j} E_{i'} = 1) \\ = & \Pr(E_{ij} = 1, \forall i' \in \mathcal{I}_j \setminus \{i\}, E_{i'} = 0) / \\ & \sum_{i' \in \mathcal{I}_j} \Pr(E_{i'} = 1, \forall i'' \in \mathcal{I}_j \setminus \{i'\}, E_{i''} = 0) \\ & (\because i \in \mathcal{I}_j) \\ = & \left\{ \Pr(E_{ij} = 1 \mid E_{ij} \leq 1) \right. \\ & \left. \prod_{i' \in \mathcal{I}_j \setminus \{i\}} \Pr(E_{i'} = 0 \mid E_{i'} \leq 1) \right\} \\ & / \left\{ \sum_{i' \in \mathcal{I}_j} \Pr(E_{i'} = 1 \mid E_{i'} \leq 1) \right. \\ & \left. \prod_{i'' \in \mathcal{I}_j \setminus \{i'\}} \Pr(E_{i''} = 0 \mid E_{i''} \leq 1) \right\} \\ & (\because \text{Assumption 2 and Equation 20,} \end{aligned}$$

dividing numerator and denominator (21)

$$\begin{aligned} & \text{by } \prod_{i' \in \mathcal{I}_j} \Pr(E_{i'} \leq 1), i \in \mathcal{I}_j \\ = & \left\{ \Delta H_{ij} \prod_{i' \in \mathcal{I}_j \setminus \{i\}} (1 - \Delta H_{i'}) \right\} / \\ & \left\{ \sum_{i' \in \mathcal{I}_j} \Delta H_{i'} \prod_{i'' \in \mathcal{I}_j \setminus \{i'\}} (1 - \Delta H_{i''}) \right\} \\ & (\because \text{Equations 3 and 4}) \\ = & \frac{\Delta H_{ij}}{1 - \Delta H_{ij}} / \sum_{i' \in \mathcal{I}_j} \frac{\Delta H_{i'}}{1 - \Delta H_{i'}} \\ & (\because \text{dividing numerator and denominator by} \\ & \prod_{i' \in \mathcal{I}_j} (1 - \Delta H_{i'}), i \in \mathcal{I}_j). \end{aligned}$$

(Note that  $\Delta H_{ij}/(1 - \Delta H_{ij})$  is odds of an event.) It follows that, if  $i \in \mathcal{I}(t)$ ,  $t \in \mathcal{T}_j$ ,

$$\begin{aligned} & \Pr\{E_i(t) = 1 \mid \sum_{i' \in \mathcal{I}(t)} E_{i'}(t) = 1\} \\ = & \lim_{\Delta t_j \downarrow 0} \Pr(E_{ij} = 1 \mid \sum_{i' \in \mathcal{I}_j} E_{i'} = 1) \quad (\because t \in \mathcal{T}_j) \\ = & \lim_{\Delta t_j \downarrow 0} \frac{\Delta H_{ij}}{\Delta t_j (1 - \Delta H_{ij})} / \\ & \sum_{i' \in \mathcal{I}_j} \frac{\Delta H_{i'}}{\Delta t_j (1 - \Delta H_{i'})} \quad (22) \\ & (\because \text{Equation 21, } i \in \mathcal{I}_j) \\ = & h_i(t) / \sum_{i' \in \mathcal{I}(t)} h_{i'}(t) \\ & (\because \text{Equation 8, } \lim_{\Delta t_j \downarrow 0} (1 - \Delta H_{i'}) = 1) \\ = & \frac{\psi_i}{\sum_{i' \in \mathcal{I}(t)} \psi_{i'}} \quad (\because \text{Assumption 3}). \end{aligned}$$

Thus, we cancel out the baseline hazard and do not have to estimate it. This equation may also remind us of multinomial or conditional logit models derived by assuming that random utility follows the type 1 extreme value distribution (Equation 19). If we model  $\psi_i = \exp(x_i \beta^*)$ , where  $x_i$  does not contain the constant term, we define the partial likelihood function as

$$\begin{aligned} & l^{\text{partial}}(\beta^* \mid \mathcal{I}(T), \mathbf{x}) \\ \propto & \prod_{i \in \mathcal{I}} \Pr \left\{ E_i(T_i) = 1 \mid \sum_{i' \in \mathcal{I}(T_i)} E_{i'}(T_i) = 1 \right\} \\ = & \prod_{i \in \mathcal{I}} \frac{\exp(\mathbf{x}_i \beta^*)}{\sum_{i' \in \mathcal{I}(T_i)} \exp(\mathbf{x}_{i'} \beta^*)} \\ & \text{event} \\ & (\because \text{Equation 22}), \end{aligned} \quad (23)$$

where  $\mathcal{I}(T) \equiv (\mathcal{I}(T_1), \mathcal{I}(T_2), \dots, \mathcal{I}(T_T))$ . Equation 23 uses information of risk sets at event time  $\mathcal{I}(T)$  alone, not sets of duration  $\mathcal{I}$ , and lacks a duration term unlike Equations 5 and 9. Luckily, even though we do not specify the baseline hazard, by maximizing

Equation 23, we obtain an estimate of  $\beta^*$  which has the same properties (such as consistency under the regularity conditions) as a maximum likelihood estimate.

We may relax Assumptions 3 and 4. As for Assumption 4, I refer readers to other textbooks (for example Box-Steffensmeier and Jones, 2004: 53–9). Below, we elaborate on Assumption 3.

**Proportionality**

Suppose that we arbitrarily choose a baseline value such as zero ( $x_i = x_0 \equiv (0, 0, \dots, 0)$ ). The corresponding hazard rate is called the baseline hazard and denoted by  $h_0(t) \equiv h(t|x_0, \theta)$ . If we can factor

$$h(t | x_i, \theta) = h_0(t)\psi(x_i, \theta), \tag{24}$$

it is called a proportional hazard rate. It is easy to see that Assumption 3 is a general case of Equation 24. If we use Equation 13, Weibull distribution is a proportional hazard model where  $h_{0, \text{Weibull}}(t | \theta) = \sigma^* t^{\sigma^* - 1}$  and

$$\begin{aligned} \psi(x_i, \theta) &= \mu_i^* \equiv \exp(-\mu_i / \sigma) \\ &= \exp(-x_i \beta / \sigma) = \exp(x_i \beta^*). \end{aligned} \tag{25}$$

Log normal (Equation 11) and logistic models are not proportional hazard models because  $h(t|x_i, \theta)/h(t|x_0, \theta)$  is not constant over  $t$ .

In fact, though, we sometimes doubt Assumption 3 (or Equation 24). For instance, prior political experience affects a legislator’s reelection hazard at an earlier stage, though it does not at a later stage. There are a few tests to check proportionality (for example, Park and Hendry, 2015). If tests imply non-proportionality, we should replace Equation 24 by

$$h(t | x_i, \theta) = h_0(t)\psi(x_i, t, \theta), \tag{26}$$

and specify  $\psi(x_i, t, \theta)$ . The most popular way is usage of interaction term:  $\psi(x_i, t, \theta) = \exp(x_i \beta + t x_i \gamma)$ .

**Frailty**

Scholars may suspect that  $\mu_i = \mu(x_i, \beta)$  is misspecified and there remains an omitted random variable or ‘frailty’  $W_i$  and, instead, assume that  $\mu_i = \mu(x_i, W_i, \beta)$ .<sup>3</sup> Suppose that we can specify  $h_i(t) = h(t|\psi_i) = h(t|x_i, W_i, \beta, \sigma)$  where  $\psi_i = (\mu_i, \sigma)$ . If  $W_i$  is unobserved, we only have to assume that  $W_i$  follows a certain distribution  $m(w|v)$  in order to integrate out  $w_i$ , obtain the marginal distribution,

$$\begin{aligned} p(\mathcal{T} | x_i, \theta) &= \int \exp\{-H(\mathcal{T} | x_i, w, \beta, \sigma)\} \\ &h(t | x_i, w, \beta, \sigma) m(w | v) dw, \end{aligned} \tag{27}$$

according to Equation 9, and estimate  $\theta = (\beta, \sigma, v)$ . In particular, if we can factor

$$h(t | x_i, W, \beta, \sigma) = W^* h(t | x_i, w_0, \beta, \sigma), \tag{28}$$

where  $W^*$  is a function of  $W$ , it follows that  $H(\mathcal{T}|x_i, W, \beta, \sigma) = W^* H(\mathcal{T}|x_i, w_0, \beta, \sigma)$ . This is called multiplicative frailty. For instance, in the case of the proportional hazard model (Equations 24 and 25), where we replace  $x_i$  by  $x'_i = (x_i, w_i)$  and Equation 13 by  $\mu_i = x_i \beta + W_i$  (where  $W_i$  might be called random effect), if  $W_i^* = \exp(-W_i / \sigma)$  and  $w_0 = 0$ , Equation 28 holds where  $h(t | x_i, w_0, \beta, \sigma) = h_0(t | \sigma) \exp(x_i \beta^*)$ .

Furthermore, if we assume  $W_i^*$  follows the gamma distribution with mean 1 and variance  $v$ ,  $m(w|v) = \Gamma(w^* | 1, v)$ , it follows that

$$S_{\text{gamma}}(t | x_i, \theta) = \{1 + v H(\mathcal{T} | x_i, w_0, \beta, \sigma)\}^{-\frac{1}{v}}. \tag{29}$$

If  $W_i^*$  follows the inverse-Gaussian distribution with mean 1 and variance  $v$ , it follows that

$$\begin{aligned} S_{\text{inv.Gauss}}(t | x_i, \theta) \\ = \exp\left(\frac{1}{v} [1 - \{1 + 2v H(\mathcal{T} | x_i, w_0, \beta, \sigma)\}^{\frac{1}{2}}]\right). \end{aligned} \tag{30}$$

If we give up using duration analysis jargon and apply general statistical terminology,

frailty models are a class of compound probability (or continuous mixture) distributions where  $W$  is the latent random variable or nuisance,  $p(\mathcal{T}|w, \cdot)$  is a conditional distribution,  $m(w|\cdot)$  is a mixing (or weight) distribution, and  $p(\mathcal{T}|\cdot)$  is an unconditional distribution which results by compounding  $p(\mathcal{T}|w, \cdot)$  with  $m(w|\cdot)$ . Thus, frailty models address heterogeneity and/or overdispersion, enabling robust inference.

Another look at frailty models is multi-level or hierarchical models:

$$T_i \sim f(t|x_i, W_i, \beta, \sigma),$$

$$W_i \sim m(w|\nu),$$

where we now replace a single frailty variable  $W_i$  by a vector of multiple frailties  $W_i$ . This representation makes it easy to construct more complicated models in a flexible manner. For instance, we may assume two components of  $W_i$  follow the gamma distribution with mean  $\nu_{\text{mean}}$  and variance  $\nu_{\text{variance}}$ :

$$W_i^{(1)} = W_{y(i)}^{(1)} \sim \Gamma(w^{(1)} | \nu_{\text{mean},y}^{(1)}, \nu_{\text{variance}}^{(1)}),$$

$$W_i^{(2)} \sim \Gamma(w^{(2)} | \nu_{\text{mean},i}^{(2)}, \nu_{\text{variance}}^{(2)}),$$
(31)

where  $y(i)$  indicate the group unit  $i$  belongs to. We call  $W_{y(i)}^{(1)}$  shared frailty. This is a kind of random effect (or coefficient) model. We may nest  $W_i^{(2)}$  in  $W_{y(i)}^{(1)}$  ('nested frailties'):  $\nu_{\text{mean},i}^{(2)} = W_{y(i)}^{(1)}$ . Or we may model  $W_i^{(2)}$  by covariates:  $\nu_{\text{mean},i}^{(2)} = \exp(x_i^{\text{frailty}} \beta^{\text{frailty}})$ . We can estimate parameters by using Markov Chain Monte Carlo (MCMC). Homola and Gill (Nd) elaborate on this topic.

### Discrete time framework

We may model

$$\Delta H_{ij} = \Delta H_{\cdot j}(\mathbf{x}_i, \theta)$$

$$= g^{-1}\{d(j|\tau) + \mathbf{x}_i \beta\},$$
(32)

where  $\theta \equiv (\tau, \beta)$  and  $d(j|\tau)$  is a time dependency function such as  $\bar{\nu}$ -th polynomial  $\left(\sum_{\nu=0}^{\bar{\nu}} \tau^{(\nu)} j^\nu\right)$ ,

and  $x_i$  does not contain the constant term. Since  $0 \leq \Delta H_{ij} \leq 1$ , the canonical link functions are logit  $g_{\text{logit}}(\pi) \equiv \Lambda^{-1}(\pi) = \log\{\pi/(1-\pi)\}$  and probit  $g_{\text{probit}}(\pi) \equiv \Phi^{-1}(\pi)$ . Nonetheless, if we employ the complementary log-log (cloglog) link function  $g_{\text{cloglog}}(\pi) \equiv \Xi^{-1}(\pi) = \log\{-\log(1-\pi)\}$  and specify  $d(j|\tau) = \log\{H_0(\mathcal{T}_j|\tau)\}$ , it is equivalent to assume that the corresponding hazard function in the continuous time framework is  $h_i(t|\theta) = h_0(t|\tau) \exp(x_i \beta)$  (it is a good exercise to prove the equivalence). For instance, if we employ  $d_{\text{Cox}}(j|\tau) \equiv \tau^{(j)} \equiv \log\{H_0(\mathcal{T}_j)\}$ , the model corresponds to the Cox model. However, choice among these link functions does not matter so much (Beck et al., 1998).

The likelihood is proportional to

$$l(\theta | E, \mathbf{x}) \propto \prod_{i \in \mathcal{I}} \Pr(E_i | x_i, \theta)$$

(∵ Assumption 2)

$$= \prod_{i \in \mathcal{I}} \left[ \underbrace{\prod_{j \in \mathcal{J}_i} \{1 - \Delta H_{\cdot j}(\mathbf{x}_i, \theta)\}}_{\text{duration}} \right] \underbrace{\frac{\Delta H_{\cdot j_i}(\mathbf{x}_i, \theta)}{1 - \Delta H_{\cdot j_i}(\mathbf{x}_i, \theta)}}_{\text{event}}$$

(∵ Equation 5),

where  $E \equiv (E_1, E_2, \dots, E_{\bar{T}})$ . This representation reminds us of time series cross section data with a binary dependent variable (BTSCS), where time index is  $j$ , unit of observation is  $ij$ , and the binary dependent variable is  $E_{ij}$  (Beck et al., 1998). That is, analysis of BTSCS data can be interpreted as a duration model in the discrete time framework. As the above argument shows, how to model time dependency function  $d(j|\tau)$  determines how the discrete hazard rate changes over time  $t_j$ 's. If analysts of BTSCS data do not include  $j$  as covariates ( $d_{\text{exponential}}(j|\tau) \equiv \tau^{(0)}$ ), they implicitly assume that  $T_i$  follows exponential distribution – that is, the hazard rate is constant over time  $t$  (Equation 18), which may be inappropriate.

### PARALLEL DURATIONS

Suppose that there are  $\bar{r}$  types of events (and the corresponding durations) or ‘competing risks’  $r \in \mathcal{R} \equiv \{0, 1, 2, \dots, \bar{r} - 1\}$  for every unit and, once an event happens, we cannot observe the other later events. For instance, a cabinet will end with an event among resignation ( $r = 1$ ), vote of non-confidence ( $r = 2$ ), or electoral defeat ( $r = 3$ ). Denote the latent continuous time of event due to risk  $r$  by  $T_i^{(r)}$ . By abusing notation, redefine  $T_i$  as the earliest event time ( $T_i \equiv \min_r T_i^{(r)}$ ) and let  $R_i \in \mathcal{R}$  denote the risk which incurs the earliest event, supposing no tied earliest events ( $\{r \mid r \in \mathcal{R}, T_i^{(r)} = T_i\} = \{R_i\}$  is a singleton set). We observe  $T_i$  and  $R_i$  but not  $T_i^{(r)}$  for  $r \neq R_i$ .

If  $R_i = r$ , duration  $T_i^{(r)} \equiv (0, T_i^{(r)}]$  is observed, and event  $r$  is observed at time  $T_i = T_i^{(r)}$ . If  $R_i \neq r$ ,  $T_i^{(r)}$  is said to be ‘censored’ at time  $T_i = T_i^{(R_i)}$  (or  $T_i^{(r)} > T_i$  is missing in terms of ordinary statistical vocabulary) and we do not observe event  $r$ . Sometimes we say  $T_i^{(r)}$  is ‘right’ censored because we usually locate  $T_i^{(r)}$  to the right of  $T_i$  on the horizontal axis  $t$ . We know that event  $r$  will happen after  $T_i$  (i.e.,  $T_i^{(r)} > T_i$ ), though we do not know exactly when it will happen ( $T_i^{(r)}$ ).

Denote the set of risks in which researchers have no interest by  $\mathcal{R}^0 \subsetneq \mathcal{R}$ . In the example of cabinet termination, the literature does not care about the case where a cabinet technically ends due to the constitutional term of the parliament ( $r = 0 \in \mathcal{R}^0$ ). In the case of  $R_i = r \in \mathcal{R}^0$ , even though duration  $T_i^{(r)}$  and event  $r$  are observed, we call (not just duration  $T_i^{(r)}$  for  $r' \neq r$  but also) unit  $i$  censored at time  $T_i = T_i^{(r)}$ . Let  $\mathcal{R}^+ \equiv \mathcal{R} \setminus \mathcal{R}^0$  (note  $\mathcal{R}^+ \neq \emptyset$ ). In simple duration models, we have substantive interest in a particular event  $r \in \mathcal{R}$  alone ( $\mathcal{R}^+ = \{r\}$ ). In typical competing risks models, however, we define  $\mathcal{R}^0 = \{0\}$ , where I call  $r = 0$  the ‘censoring’ event. In a special case, the censoring event time is constant:  $\Pr(T_i^{(0)} = t_i^{(0)}) = 1$ . The usual situation is that a researcher stops to observe duration at predetermined time  $t_i^{(0)} = t^{(0)}$ , where

the censoring event refers to the end of observation. I emphasize that *censoring is another event* in which scholars have no interest.

### Independent Durations

We make two assumptions.

**Assumption 5** (Stochastic Independence of Parallel Durations):

$$T_i^{(r)} \perp\!\!\!\perp T_i^{(r')} \text{ if } r \neq r'.$$

This is usually called independence of competing risks. In particular, if, for all  $r \in \mathcal{R}^+$  and all  $r' \in \mathcal{R}^0$ , Assumption 5 holds, we call the situation non-informative censoring (or, more generally, missing at random).

**Assumption 6** (Parametric Independence of Parallel Durations):

$$f_i^{(r)}(t) = p(T_i^{(r)} = t \mid x_i, \theta^{(r)}),$$

where  $\theta^{(r)}$  and  $\theta^{(r')}$  share no parameter in the case of  $r \neq r'$ .

Namely, we parametrize the distribution of  $T_i^{(r)}$  across  $r$ 's separately. We redefine  $\theta \equiv (\theta^{(0)}, \theta^{(1)}, \dots, \theta^{(\bar{r}-1)})$ .<sup>4</sup>

### Discrete time framework

Denote the latent discrete time of event due to risk  $r$  by  $J_i^{(r)}$  (where  $T_i^{(r)} \in \mathcal{T}_{J_i^{(r)}}$ ). By abusing notation, redefine  $J_i$  as the earliest event time ( $J_i \equiv \min_r J_i^{(r)}$ ), supposing no tied earliest events ( $J_i^{(r)} > J_i$  for  $r \neq R_i$ ). We observe  $J_i$  but not  $J_i^{(r)}$  for  $r \neq R_i$ . For  $j \in \mathcal{J}_r$ , define the event  $r$  indicator as

$$E_{ij}^{(r)} \equiv \begin{cases} 0 & \text{if } j < J_i^{(r)} & \left( \begin{array}{l} \text{event } r \text{ will} \\ \text{occur after } \mathcal{T}_{j} \end{array} \right), \\ 1 & \text{if } j = J_i^{(r)} & \left( \begin{array}{l} \text{event } r \text{ does} \\ \text{occur during } \mathcal{T}_{j} \end{array} \right), \end{cases}$$

and the vector of event  $r$  indicators as  $E_i^{(r)} \equiv (E_{i1}^{(r)}, E_{i2}^{(r)}, \dots, E_{iJ_i}^{(r)})$ . It follows that:

$$\begin{aligned} \Pr(E_i, R_i) &= \prod_{r \in \mathcal{R}} \Pr(E_i^{(r)}) \quad (\text{Assumption 5}) \\ &= \left\{ \prod_{r \in \mathcal{R}} \prod_{j \in \mathcal{J}_i} (1 - \Delta H_{ij}^{(r)}) \right\} \left( \frac{\Delta H_{i i_i}^{(R_i)}}{1 - \Delta H_{i i_i}^{(R_i)}} \right) \quad (33) \\ & (\because \text{Equation 5, } E_{ij}^{(r)} = 0 \text{ except } E_{i i_i}^{(R_i)} = 1). \end{aligned}$$

Therefore, the likelihood is:

$$\begin{aligned} l(\theta | E, R, x) &\propto \prod_{i \in \mathcal{I}} \Pr(E_i, R_i | x_i, \theta) \quad (\because \text{Assumption 2}) \\ &= \prod_{i \in \mathcal{I}} \left[ \underbrace{\prod_{r \in \mathcal{R}} \prod_{j \in \mathcal{J}_i} \{1 - \Delta H_{ij}^{(r)}(x_i, \theta^{(r)})\}}_{\text{duration}} \right] \quad (34) \\ &\quad \frac{\Delta H_{i i_i}^{(R_i)}(x_i, \theta^{(R_i)})}{\underbrace{1 - \Delta H_{i i_i}^{(R_i)}(x_i, \theta^{(R_i)})}_{\text{event}}} \\ & (\because \text{Equations 32 and 33}), \end{aligned}$$

where  $R \equiv (R_1, R_2, \dots, R_T)$ . Equation 34 indicates the probability that *no* event happens during  $(0, t_{J_i-1}]$  and *only* event  $R_i$  happens during  $(t_{J_i-1}, t_{J_i}]$ . Furthermore,

$$\begin{aligned} l(\theta^{(r)} | E, R, x) &\propto \prod_{i \in \mathcal{I}} \left[ \prod_{j \in \mathcal{J}_i} \{1 - \Delta H_{ij}^{(r)}(x_i, \theta^{(r)})\} \right] \quad (35) \\ &\quad \left\{ \frac{\Delta H_{i i_i}^{(R_i)}(x_i, \theta^{(R_i)})}{1 - \Delta H_{i i_i}^{(R_i)}(x_i, \theta^{(R_i)})} \right\}^{I(R_i=r)}, \end{aligned}$$

where  $I(\cdot)$  is an indicator function of whether the argument holds. Thus, thanks to Assumption 6, we only have to maximize Equation 35 so as to estimate  $\theta^{(r)}$  where  $r \in \mathcal{R}^+$ .

**Continuous time framework**

In the same spirit of Equation 9, we define and derive

$$\begin{aligned} p(\mathcal{T}_i, R_i) &\equiv \lim_{\Delta t \downarrow 0} \frac{1}{\Delta t_{J_i}} \Pr(E_i, R_i) \\ &= \lim_{\Delta t \downarrow 0} \left[ \prod_{r \in \mathcal{R}} \exp \left\{ \sum_{j \in \mathcal{J}_i} \frac{\log(1 - \Delta H_{ij}^{(r)})}{\Delta t_{j_i}} \Delta t_{j_i} \right\} \right] \quad (36) \\ &\quad \frac{\Delta H_{i i_i}^{(R_i)}}{\Delta t_{j_i} (1 - \Delta H_{i i_i}^{(R_i)})} \quad (\because \text{Equation 33}) \\ &= \left[ \prod_{r \in \mathcal{R}} \exp \{-H_i^{(r)}(\mathcal{T}_i)\} \right] h_i^{(R_i)}(\mathcal{T}_i). \end{aligned}$$

Therefore, the likelihood is:

$$\begin{aligned} l(\theta | \mathcal{T}, R, x) &\propto \prod_{i \in \mathcal{I}} p(\mathcal{T}_i, R_i | x_i, \theta) \\ & (\because \text{Assumption 2}) \\ &= \prod_{i \in \mathcal{I}} \left[ \underbrace{\prod_{r \in \mathcal{R}} \exp \{-H_i^{(r)}(\mathcal{T}_i | x_i, \theta^{(r)})\}}_{\text{duration}} \right] \quad (37) \\ &\quad \underbrace{\{h_i^{(R_i)}(\mathcal{T}_i | x_i, \theta^{(R_i)})\}}_{\text{event}} \\ & (\because \text{Equation 36}). \end{aligned}$$

Equation 37 implies the probability density that *no* event happens during  $(0, \mathcal{T}_i)$  and *only* event  $R_i$  happens at  $\mathcal{T}_i$ . Instead, by applying Equations 7 and 15 to Equation 37, we obtain its standard representation:

$$\begin{aligned} l(\theta | \mathcal{T}, R, x) &\propto \prod_{i \in \mathcal{I}} \prod_{r \in \mathcal{R}} \{S^{(r)}(\mathcal{T}_i | x_i, \theta^{(r)})\}^{I(R_i \neq r)} \\ &\quad \{f^{(r)}(\mathcal{T}_i | x_i, \theta^{(r)})\}^{I(R_i=r)}, \quad (38) \end{aligned}$$

which means the probability density that event  $r \neq R_i$  will happen after  $\mathcal{T}_i$  and event  $R_i$  happens at  $\mathcal{T}_i$ .

Furthermore,

$$\begin{aligned} l(\theta^{(r)} | \mathcal{T}, R, x) &\propto \prod_{i \in \mathcal{I}} \exp \{-H_i^{(r)}(\mathcal{T}_i | x_i, \theta^{(r)})\} \\ &\quad \{h_i^{(R_i)}(\mathcal{T}_i | x_i, \theta^{(R_i)})\}^{I(R_i=r)}. \quad (39) \end{aligned}$$

Accordingly, in practice, ready-made statistical software users only have to conduct

duration analysis for each risk  $r \in \mathcal{R}^+$  separately where, in the case of  $R_i \neq r$ , they regard such unit  $i$ 's as censored. This is the most famous advantage of duration analysis. Conventional models would call  $S^{(r)}(t|\cdot) = \int_t^\infty f^{(r)}(t'|\cdot) dt'$  truncated distribution (and call this model Torbit if  $T_i^{(r)}$  follows log normal distribution in the accelerated failure time model), though it is more straight-forward to model the likelihood in terms of hazard.

**Split population**

Some units may never be at risk of interest  $r \in \mathcal{R}^+$  and, thus, duration  $T_i^{(r)}$  does not exist and  $R_i \neq r$ , though observers do not know whether unit  $i$  is such a unit in the case of  $R_i \neq r$ . For instance, if a prime minister has no willingness to dissolve the parliament, all legislators serve till the end of their term – but not vice versa.

Here I introduce an extended split population model. Suppose that there are  $\bar{q}$  (choice) sets of risks at which a unit is,  $\mathcal{R}^{(q)}$ 's, such that  $q \in \mathcal{Q} \equiv \{1, 2, \dots, \bar{q}\}, \mathcal{R}^{(q)} \subseteq \mathcal{R}, \mathcal{R}^{(q)} \neq \emptyset$ , for  $q \neq q', \mathcal{R}^{(q)} \neq \mathcal{R}^{(q')}$ ,<sup>5</sup> let  $\mathcal{R}_i$  denote the set of risks at which unit  $i$  is:  $\mathcal{R}_i \in \{\mathcal{R}^{(q)} \mid q \in \mathcal{Q}\}$ , and denote  $\rho_i^{(q)} \equiv \Pr(\mathcal{R}_i = \mathcal{R}^{(q)})$ . Note that, if  $R_i \notin \mathcal{R}^{(q)}, \rho_i^{(q)} = 0$ . Then, the likelihood is

$$l(\theta \mid \mathcal{T}, R, x) \propto \prod_{i \in \mathcal{I}} p(\mathcal{T}_i, R_i \mid x_i, \theta)$$

$$= \prod_{i \in \mathcal{I}} \left[ \sum_{q \in \mathcal{Q}} \rho_i^{(q)} \underbrace{\prod_{r \in \mathcal{R}^{(q)}} \exp\{-H^{(r)}(\mathcal{T}_i | x_i, \theta^{(r)})\}}_{\text{duration}} \right]$$

$$\underbrace{h^{(R_i)}(\mathcal{T}_i | x_i, \theta^{(R_i)})}_{\text{event}}$$

Since this equation involves summation, in general, we cannot factor it like Equation 37 and estimate each  $\theta^{(r)}$  separately like Equation 39. Nonetheless, if  $r \in \bigcap_{q \in \mathcal{Q}} \mathcal{R}^{(q)}$ , we can factor  $l(\theta \mid \mathcal{T}, R, x) = l(\theta^{(r)} \mid \mathcal{T}, R, x) l(\theta^{(-r)} \mid \mathcal{T}, R, x)$  and estimate  $\theta^{(r)}$  alone, where  $\theta^{(-r)} = (\theta^{(0)}, \theta^{(1)}, \dots, \theta^{(r-1)}, \theta^{(r+1)}, \dots, \theta^{(\bar{r}-1)}, \rho)$ ,  $\rho = (\rho^{(1)}, \rho^{(2)}, \dots,$

$\rho^{(\bar{q})}$ ) and  $\rho^{(q)} = (\rho_1^{(q)}, \rho_2^{(q)}, \dots, \rho_i^{(q)})$ . We may model  $\rho_i^{(q)} = g^{-1}(x_i \beta^{(q)})$  if we have substantive interest in  $\rho_i^{(q)}$  and/or improve estimation (for example, Fukumoto and Masuyama, 2015). To my knowledge, the only setup in practical use is  $\bar{q} = 2, r = 0$  is the ‘censoring’ event,  $\mathcal{R} = \mathcal{R}^{(1)} = \{0, 1\}$  and  $\mathcal{R}^{(2)} = \{0\}$ . Since  $0 \in \bigcap_{q \in \mathcal{Q}} \mathcal{R}^{(q)}$ , we can factor  $l(\theta \mid \mathcal{T}, R, x) = l(\theta^{(0)} \mid \mathcal{T}, R, x) l(\theta^{(1)}, \rho \mid \mathcal{T}, R, x)$  and, thus, estimate either  $\theta^{(0)}$  or  $(\theta^{(1)}, \rho)$  alone.

**Dependent Parallel Durations**

In fact, however, violation of Assumptions 5 and 6 is not uncommon. How to deal with such a situation (e.g., dependent competing risks and informative censoring) is an important research agenda. Below, I sketch the frontier and promising directions. For ease of presentation, I suppose that, for all  $i, \mathcal{R}_i = \mathcal{R}$  unless otherwise noted.

**Stochastic dependence**

Sometimes we have to doubt Assumption 5. In the running example of cabinet duration, if cabinet  $i$  expects a vote of non-confidence ( $r = 2$ ) is likely, it tends to resign ( $r = 1$ ) pre-emptively:  $F(T_i^{(1)} = t \mid T_i^{(2)} = t_{\text{early}}) > F(T_i^{(1)} = t \mid T_i^{(2)} = t_{\text{late}})$  if  $t_{\text{early}} < t_{\text{late}}$ . In this case, we should give up Assumption 5 and instead model the joint survivor function of  $T_i \equiv (T_i^{(0)}, T_i^{(1)}, \dots, T_i^{(\bar{r}-1)})$  which is denoted by  $S_i^{\bar{r}}(t) \equiv \Pr(\forall r \in \mathcal{R}, T_i^{(r)} \geq t)$ . Note that we cannot factor  $p(\mathcal{T}_i, R_i)$  into terms for each risk as in Equation 36 because they are not independent any more. Instead, we will utilize

$$p(\mathcal{T}_i, R_i) = - \frac{\partial S_i^{\bar{r}}(t)}{\partial t^{(R_i)}} \Bigg|_{t=T_i} \tag{40}$$

$$\equiv - \frac{\partial}{\partial t^{(R_i)}} \Pr(\forall r \in \mathcal{R}, T_i^{(r)} \geq t^{(r)}) \Bigg|_{\forall r \in \mathcal{R}, t^{(r)}=T_i}$$

We introduce three approaches to model  $S_i^{\bar{r}}(t \mid x_i, \theta)$  below.

**Frailty**

The first approach is frailty models. We assume stochastic independence of parallel durations conditional on a vector of frailties,  $W_i$ , which follows  $m(w|v)$ :

$$T_i^{(r)} \perp\!\!\!\perp T_i^{(r')} \mid w_i \text{ if } r \neq r'. \quad (41)$$

The likelihood is

$$\begin{aligned} l(\theta \mid \mathcal{T}, R, x) &\propto \prod_{i \in \mathcal{I}} p(T_i, R_i \mid x_i, \theta) \quad (\because \text{Assumption 2}) \\ &\propto \prod_{i \in \mathcal{I}} \int p(T_i, R_i \mid x_i, w, \theta) m(w \mid v) dw \\ &\propto \prod_{i \in \mathcal{I}} \int \underbrace{\left\{ \prod_{r \in \mathcal{R}} S^{(r)}(T_i \mid x_i, w, \theta^{(r)}) \right\}}_{\text{duration}} \underbrace{h^{(R_i)}(T_i \mid x_i, w, \theta^{(R_i)})}_{\text{event}} m(w \mid v) dw \\ &(\because \text{Equations 38 and 41}), \end{aligned} \quad (42)$$

where  $v$  now controls dependency among parallel durations and  $\theta = (\theta^{(0)}, \dots, \theta^{(\bar{r}-1)}, v)$ .

A ‘generalized dependent risks’ model (Gordon, 2002) assumes that  $W_i = (W_i^{(0)}, W_i^{(1)}, \dots, W_i^{(\bar{r}-1)})$  follows a multivariate normal distribution and a multiplicative frailty model (Equation 28) holds for every risk:  $h^{(r)}(t \mid x_i, W_i, \theta^{(r)}) = W_i^{(r)*} h^{(r)}(t \mid x_i, w_0^{(r)}, \theta^{(r)})$ .<sup>6</sup> A drawback of this model is that it has no closed form and, thus, should be calculated by multi-dimensional numerical integration or MCMC. It is computationally intensive and, in particular for not a small number of  $\bar{r}$ , challenging.

A simpler frailty model is that hazard rates of all risks share the same frailty  $W_i^{(r)} = W_i$ . It leads to positive dependency among  $T_i^{(r)}$ ’s across  $r$ ’s within unit  $i$ . Equation 42 leads to

$$\begin{aligned} \prod_{i \in \mathcal{I}} \int \underbrace{\left\{ \prod_{r \in \mathcal{R}} \{S^{(r)}(T_i \mid x_i, w_0, \theta^{(r)})\}^{w^*} \right\}}_{\text{duration}} \underbrace{w^* h^{(R_i)}(T_i \mid x_i, w_0, \theta^{(R_i)})}_{\text{event}} m(w \mid v) dw, \end{aligned} \quad (43)$$

where we only have to integrate out a single frailty  $W_i$ . For instance, if we assume  $m(w|v) = \Gamma(w^*|L, v)$ , according to Equations 29 and 40, Equation 43 can be expressed in closed form:

$$\prod_{i \in \mathcal{I}} \underbrace{\left\{ 1 + v \sum_{r \in \mathcal{R}} H^{(r)}(T_i \mid x_i, w_0, \theta^{(r)}) \right\}^{\frac{1}{v}-1}}_{\text{duration}} \underbrace{h^{(R_i)}(T_i \mid x_i, w_0, \theta^{(R_i)})}_{\text{event}}.$$

**Seemingly unrelated regression**

The second approach is a seemingly unrelated regression which assumes that  $S^{\bar{r}}(t \mid x_i, \theta)$  is equal to a well-defined multivariate distribution function. In the case of  $\bar{r} = 2$ , besides the bivariate normal, one of such distributions is a bivariate Weibull:

$$\begin{aligned} S_{\text{Weibull}}^2(t \mid x_i, \theta) &= \left\{ \prod_{r=0}^1 S_{\text{Weibull}}(t \mid x_i, \theta^{(r)}) \right\} \\ &\left\{ 1 + v \prod_{r=0}^1 F_{\text{Weibull}}(t \mid x_i, \theta^{(r)}) \right\} \end{aligned} \quad (44)$$

(for the univariate Weibull, recall Equation 19). According to Equations 40 and 44, the likelihood is

$$\begin{aligned} l(\theta \mid \mathcal{T}, R, x) &\propto \prod_{i \in \mathcal{I}} \underbrace{\left\{ \prod_{r=0}^1 S_{\text{Weibull}}(T_i \mid x_i, \theta^{(r)}) \right\}}_{\text{duration}} \\ &\underbrace{1 + v F_{\text{Weibull}}(T_i \mid x_i, \theta^{(1-R_i)})}_{\text{duration}} \\ &\underbrace{\left\{ 1 - 2 S_{\text{Weibull}}(T_i \mid x_i, \theta^{(R_i)}) \right\}}_{\text{duration}} \\ &\times \underbrace{h_{\text{Weibull}}(T_i \mid x_i, \theta^{(R_i)})}_{\text{event}}, \end{aligned}$$

which can be expressed in closed form and is easy to calculate.

**Copula**

The third approach, copula modeling, provides a more easy-to-compute, general, and

flexible platform.<sup>7</sup> According to Sklar’s Theorem,  $F^{\bar{r}}(t | x_i, \theta) \equiv \Pr(\forall r \in \mathcal{R}, T_i^{(r)} \leq t)$  and  $S^{\bar{r}}(t | x_i, \theta)$  can be uniquely expressed by a copula  $C(u)$  and a survivor copula  $\tilde{C}(\tilde{u})$ , functions of  $u^{(r)}$ ’s and  $\tilde{u}^{(r)}$ ’s, respectively:

$$\begin{aligned}
 F^{\bar{r}}(t | x_i, \theta) &= C(u), \\
 u &\equiv (u^{(0)}, \dots, u^{(\bar{r}-1)}), \\
 u^{(r)} &\equiv F^{(r)}(t | x_i, \theta^{(r)}), \\
 S^{\bar{r}}(t | x_i, \theta) &= \tilde{C}(\tilde{u}), \\
 \tilde{u} &\equiv (\tilde{u}^{(0)}, \dots, \tilde{u}^{(\bar{r}-1)}), \\
 \tilde{u}^{(r)} &\equiv S^{(r)}(t | x_i, \theta^{(r)}) = 1 - u^{(r)}.
 \end{aligned}$$

Below, we only consider cases of  $\bar{r} = 2$ . It follows  $\tilde{C}(\tilde{u}) = 1 + C(u) - \sum_{r=0}^1 u^{(r)}$ .

There are numerous copula functions developed. Here, we only name a few. An example is the Farlie–Gumbel–Morgenstern (FGM) copula:

$$C_{\text{FGM}}(u | v) \equiv \left\{ \prod_{r=0}^1 u^{(r)} \right\} \left\{ 1 + v \prod_{r=0}^1 (1 - u^{(r)}) \right\}.$$

The most useful class is Archimedean copulas, where there is a generator function  $a(u)$  such that

$$C_{\text{Archi}}\{u | a(\cdot)\} \equiv a^{-1} \left\{ \sum_{r=0}^1 a(u^{(r)}) \right\}.$$

For instance, the generator function of Gumbel copula is  $a_{\text{Gumbel}}(u | v) \equiv \{-\log(u)\}^v$ .

The first merit of copula is ease to compute. Equation 40 turns into

$$\begin{aligned}
 & - \frac{\partial S_i^{\bar{r}}(t)}{\partial t^{(R_i)}} \Big|_{t=T_i} \\
 &= 1 - \underbrace{\frac{\partial \tilde{C}(\tilde{u}_i)}{\partial \tilde{u}^{(R_i)}} \Big|_{\forall r \in \mathcal{R}, \tilde{u}^{(r)} = S_i^{(r)}(T_i)}}_{\text{duration}} S_i^{(R_i)}(T_i) \\
 & \quad \underbrace{h_i^{(R_i)}(T_i)}_{\text{event}}.
 \end{aligned}$$

Seemingly, this is weird, though the first derivative of many copulas has the analytical

solution and, thus, is easy to calculate. For instance,

$$\begin{aligned}
 & \frac{\partial C_{\text{FGM}}(u | v)}{\partial u^{(r)}} \\
 &= u^{(1-r)} \left\{ 1 + v(1 - u^{(1-r)})(1 - 2u^{(r)}) \right\}, \\
 & \frac{\partial C_{\text{Archi}}\{u | a(\cdot)\}}{\partial u^{(r)}} \\
 &= \frac{\partial a(u')}{\partial u'} \Big|_{u'=u^{(r)}} / \frac{\partial a(u'')}{\partial u''} \Big|_{u''=C_{\text{Archi}}\{u | a(\cdot)\}}.
 \end{aligned}$$

The second advantage is that some copulas are general enough to incorporate other approaches. For example, it turns out that one type of bivariate Weibull (Equation 44) is equivalent to FGM copula where the marginal distribution is the univariate Weibull (Equation 19):

$$\begin{aligned}
 & S_{\text{Weibull}}^2(t | x_i, \theta) \\
 &= C_{\text{FGM}} \left\{ \begin{aligned} & S_{\text{Weibull}}(t | x_i, \theta^{(0)}), \\ & S_{\text{Weibull}}(t | x_i, \theta^{(1)}) | v \end{aligned} \right\}. \tag{45}
 \end{aligned}$$

The third strength of copula is flexibility or modularity: any survivor copula  $\tilde{C}(\tilde{u})$  can connect any marginal distributions  $S^{(r)}(t)$ . For instance, scholars may replace FGM copula by Gumbel copula in Equation 45:

$$\begin{aligned}
 & S_{\text{Weibull Alt}}^2(t | x_i, \theta) \\
 &= C_{\text{Archi}} \left\{ \begin{aligned} & S_{\text{Weibull}}(t | x_i, \theta^{(0)}), \\ & S_{\text{Weibull}}(t | x_i, \theta^{(1)}) | a_{\text{Gumbel}}(\cdot | v) \end{aligned} \right\},
 \end{aligned}$$

which is another, often-mentioned type of bivariate Weibull. Or we can substitute log normal (Equation 11) with marginal Weibull in Equation 45:

$$\begin{aligned}
 & S^2(t | x_i, \theta) \\
 &= C_{\text{FGM}} \left\{ \begin{aligned} & S_{\text{Log Normal}}(t | x_i, \theta^{(0)}), \\ & S_{\text{Log Normal}}(t | x_i, \theta^{(1)}) | v \end{aligned} \right\}.
 \end{aligned}$$

**Parametric dependence**

Sometimes, Assumption 6 is violated. For instance, if lawmakers foresee electoral defeat ( $r = 1$ ), they will strategically retire ( $r = 2$ ). Then, scholars may suppose the following systematically dependent competing risks model (Fukumoto, 2009):

$$\begin{aligned} &h^{(1)}(t \mid x_i, \theta^{(1)}) \\ &= h_0^{(1)}(t \mid \sigma^{(1)}) \exp(x_i^{(1)} \beta^{*(1)}), \\ &h^{(2)}(t \mid x_i, \theta^{(2)}) \\ &= h_0^{(2)}(t \mid \sigma^{(2)}) \exp(x_i^{(2)} \beta^{*(2)} + \nu x_i^{(1)} \beta^{*(1)}). \end{aligned}$$

If  $\beta^{*(1)}$ ,  $\nu > 0$ , it follows that  $x_i^{(1)}$  (e.g., prior vote share margin) increases  $h^{(2)}(\cdot)$  as it increases  $h^{(1)}(\cdot)$ . Note that  $\theta^{(1)} = (\sigma^{(1)}, \beta^{*(1)})$  and  $\theta^{(2)} = (\sigma^{(2)}, \beta^{*(1)}, \beta^{*(2)}, \nu)$  share  $\beta^{*(1)}$ . Thus, we cannot estimate  $\theta^{(1)}$  by maximizing Equation 39 because  $\beta^{*(1)}$  is included in  $\theta^{(2)}$  as well. Instead, we have to estimate  $\theta$  by maximizing Equation 37 if Assumption 5 holds. For identification, exclusion restriction is necessary (i.e., at least one covariate in  $x_i^{(1)}$ , which is now a vector, is excluded from  $x_i^{(2)}$ ).

Another approach toward systematic dependence is the simultaneous equations model. For details, see Hays and Kachi (2015).

**SERIAL DURATIONS**

Finally, I consider multiple serial latent durations. I begin with laying out a general format, whose special cases are repeated events and multi-stage models.

**Left Truncation and Time Varying Covariates**

Suppose that each unit has multiple durations at each risk and denote the latent continuous event time of unit  $i$ 's  $k$ -th duration (or, simply, unit  $ik$ ) at risk  $r$  by  $T_{ik}^{(r)}$  where  $k$  is a positive integer and  $T_{ik}^{(r)}$  follows  $F_i^{(rk)}(t)$ . For example, the  $k$ -th duration may refer to the  $k$ -th term of

a legislator in a parliamentary system. The observable event time of unit  $ik$  is denoted by  $T_{ik} \equiv \min_{r \in \mathcal{R}} T_{ik}^{(r)}$ . Let  $T_{i0} \equiv 0$ . Denote the risk which incurs the earliest event at  $T_{ik}$  as  $R_{ik} \in \mathcal{R}$ , supposing no tied earliest events ( $\{r \mid r \in \mathcal{R}, T_{ik}^{(r)} = T_{ik}\} = \{R_{ik}\}$  is a singleton set). We also suppose that, only if  $T_{i,k-1} < T_{ik}$ , we can observe unit  $ik$ 's duration for the period  $\mathcal{T}_{ik} \equiv (T_{i,k-1}, T_{ik}]$ . Unless  $k = 1$ , we call unit  $ik$ 's duration 'left truncated' because we cannot observe the duration for the period  $(0, T_{i,k-1}]$ .

In order to focus on serial, not parallel, durations, we make Assumption 5 within the  $k$ -th durations.

**Assumption 7** (Serial Duration Version of Stochastic Independence of Parallel Durations):

$$T_{ik}^{(r)} \perp\!\!\!\perp T_{ik}^{(r')} \text{ if } r \neq r'.$$

Denote the set of such  $k$ 's for unit  $i$  that we actually observe  $\mathcal{T}_{ik}$  by  $\mathcal{K}_i \subseteq \{k \mid T_{i,k-1} < T_{ik}\}$ . For any  $k$ , denote the history of observed  $k$ 's up to  $k$  by  $\mathcal{K}_{i,<k} \equiv \{k' \mid k' \in \mathcal{K}_i, k' < k\}$ . For now, suppose that  $\mathcal{K}_i$  is a set of consecutive integers from  $\min \mathcal{K}_i \equiv \underline{k}_i$  to  $\max \mathcal{K}_i \equiv \bar{k}_i$ . If  $\underline{k}_i > 1$ , we call unit  $i$  left truncated. For instance, if researchers study lawmakers' careers only after the Second World War, they will overlook the first few terms of old lawmakers.

**Discrete time framework**

Denote the latent discrete event time of unit  $ik$  at risk  $r$  by  $J_{ik}^{(r)}$  (where  $T_{ik}^{(r)} \in \mathcal{T}_{J_{ik}^{(r)}}$ ). The observable event time of unit  $ik$  is denoted by  $J_{ik} \equiv \min_{r \in \mathcal{R}} J_{ik}^{(r)}$ . Let  $J_{i0} \equiv 0$ . We suppose no tied earliest events ( $J_{ik}^{(r)} > J_{ik}$  for  $r \neq R_{ik}$ ). We also suppose that, only if  $J_{i,k-1} < J_{ik}$ , we can observe unit  $ik$ 's duration for the period  $\mathcal{J}_{ik} \equiv \{J_{i,k-1} + 1, J_{i,k-1} + 2, \dots, J_{ik}\}$ . For  $j \in \mathcal{J}_{ik}$ , redefine the event  $r$  indicator as

$$E_{ij}^{(r)} \equiv \begin{cases} 0 & \text{if } j < J_{ik}^{(r)} \\ & \text{(event } r \text{ of the } k\text{-th duration} \\ & \text{will occur after } \mathcal{T}_{.j}), \\ 1 & \text{if } j = J_{ik}^{(r)}. \\ & \text{(event } r \text{ of the } k\text{-th duration} \\ & \text{does occur during } \mathcal{T}_{.j}), \end{cases}$$

and  $E_{ij} \equiv E_{ij}^{(R_{ik})}$ . Denote the vector of unit  $ik$ 's event  $r$  indicators by  $E_{ik}^{(r)} \equiv (E_{i,J_{i,k-1}+1}^{(r)}, E_{i,J_{i,k-1}+2}^{(r)}, \dots, E_{i,k}^{(r)})$  and define  $E_{ik} \equiv (E_{i,J_{i,k-1}+1}, E_{i,J_{i,k-1}+2}, \dots, E_{i,k})$ . Redefine  $E_i \equiv (E_{i,k_1}, E_{i,k_1+1}, \dots, E_{i,k_1}^-)$  and define  $R_i \equiv (R_{i,k_1}, R_{i,k_1+1}, \dots, R_{i,k_1}^-)$ . For any  $k$ , denote the history of observed  $E_{ik}$ 's and  $R_{ik}$ 's up to  $k$  by  $E_{i,<k} \equiv (j_{i,k_1-1}, E_{i,k_1}, E_{i,k_1+1}, \dots, E_{i,k_1}^-)$  and  $R_{i,<k} \equiv (R_{i,k_1}, R_{i,k_1+1}, \dots, R_{i,k_1}^-)$ , where  $k_{i,<k} = \max \mathcal{K}_{i,<k}$ . Note that  $E_{i,<k}$  includes the starting point,  $j_{i,k_1-1}$ .

We derive the probability of  $E_i$  and  $R_i$  like Equation 33, though we now condition it on the starting point,  $j_{i,k_1-1}$ :

$$\begin{aligned} \Pr(E_i, R_i | j_{i,k_1-1}) &= \prod_{k \in \mathcal{K}_i} \Pr(E_{ik}, R_{ik} | E_{i,<k}, R_{i,<k}) \\ (\because \mathcal{K}_i \text{ is a set of consecutive integers}) \\ &= \prod_{k \in \mathcal{K}_i} \prod_{r \in \mathcal{R}} \Pr(E_{ik}^{(r)} | E_{i,<k}, R_{i,<k}) \\ (\because \text{Assumption 7}) \end{aligned} \tag{46}$$

$$\begin{aligned} &= \prod_{k \in \mathcal{K}_i} \left\{ \prod_{r \in \mathcal{R}} \prod_{j \in (J_{ik} \setminus J_{i,k-1})} (1 - \Delta H_{ij}^{(rk)} | E_{i,<k}, R_{i,<k}) \right\} \\ &\quad \frac{(\Delta H_{i,j_{i,k_1}}^{(R_{ik}^k)} | E_{i,<k}, R_{i,<k})}{(1 - \Delta H_{i,j_{i,k_1}}^{(R_{ik}^k)} | E_{i,<k}, R_{i,<k})} \text{ (c.f. Equation 33).} \end{aligned}$$

When we parametrize  $\Delta H_{ij}^{(rk)}$ , we may also introduce time varying covariates  $x_{ik}$  in the sense that it can be  $x_{ik} \neq x_{ik'}$  if  $k \neq k'$ . Thus, we model  $\Delta H_{ij}^{(rk)} = \Delta H_{ij}^{(rk)}(x_{ik}, \theta^{(rk)})$  instead of Equation 32. Redefine  $x_i \equiv (x_{i,k_1}, x_{i,k_1+1}, \dots, x_{i,k_1}^-)$ .

Therefore, the likelihood is

$$\begin{aligned} l(\theta | E, R, x, j_{i,k_1-1}) &\propto \prod_{i \in \mathcal{I}} \Pr(E_i, R_i | x_i, \theta, j_{i,k_1-1}, R_{i,<k}) \\ (\because \text{Assumption 2}) \\ &= \prod_{i \in \mathcal{I}} \prod_{k \in \mathcal{K}_i} \underbrace{\left[ \prod_{r \in \mathcal{R}} \prod_{j \in (J_{ik} \setminus J_{i,k-1})} \{1 - \Delta H_{ij}^{(rk)}\} \right]}_{\text{duration}} \tag{47} \\ &\quad \underbrace{\left[ x_{ik}, \theta^{(rk)} | E_{i,<k}, R_{i,<k} \right]}_{\text{duration}} \\ &\quad \times \underbrace{\frac{\Delta H_{i,j_{i,k_1}}^{(R_{ik}^k)}(x_{ik}, \theta^{(R_{ik}^k)} | E_{i,<k}, R_{i,<k})}{1 - \Delta H_{i,j_{i,k_1}}^{(R_{ik}^k)}(x_{ik}, \theta^{(R_{ik}^k)} | E_{i,<k}, R_{i,<k})}}_{\text{event}} \\ (\because \text{Equation 46}), \end{aligned}$$

where  $j_{i,k-1} \equiv (j_{1,k_1-1}, j_{2,k_2-1}, \dots, j_{\bar{i},k_{\bar{i}}-1})$ ,  $\theta^{(r)} \equiv (\theta^{(r1)}, \theta^{(r2)}, \dots, \theta^{(r\bar{k})})$ , and  $\bar{k} \equiv \max_i \bar{k}_i$ . Equation 47 implies the probability that, for all  $k \in \mathcal{K}_i$ , no event happens during  $(t_{J_{i,k-1}}, t_{J_{ik}}]$  (rather than  $(0, t_{J_{ik}}]$ ) and only event  $R_{ik}$  happens during  $(t_{J_{ik-1}}, t_{J_{ik}}]$ . The difficulty of serial durations arises from the dependence of the  $k$ -th duration ( $E_{ik}$  and  $R_{ik}$ ) on its history ( $E_{i,<k}$  and  $R_{i,<k}$ ). It is also clear that Equation 47 deals with panel data.

### Continuous time framework

Denote  $\mathcal{T}_i \equiv (\mathcal{T}_{i,k_1}, \mathcal{T}_{i,k_1+1}, \dots, \mathcal{T}_{i,k_1}^-)$ . For any  $k$ , denote the history of observed  $\mathcal{T}_{ik}$ 's up to  $k$  by  $\mathcal{T}_{i,<k} \equiv (t_{i,k_1-1}, \mathcal{T}_{i,k_1}, \mathcal{T}_{i,k_1+1}, \dots, \mathcal{T}_{i,k_1}^-)$ . Note that  $\mathcal{T}_{i,<k}$  includes the starting point,  $t_{i,k_1-1}$ . Because  $\mathcal{K}_i$  is a set of consecutive integers, it follows

$$\begin{aligned} &p(\mathcal{T}_i, R_i | t_{i,k_1-1}) \\ &= \prod_{k \in \mathcal{K}_i} p(\mathcal{T}_{ik}, R_{ik} | \mathcal{T}_{i,<k}, R_{i,<k}). \end{aligned} \tag{48}$$

We define  $p(\mathcal{T}_{ik}, R_{ik})$  in the same spirit of Equation 36, though we now condition  $p(\mathcal{T}_{ik}, R_{ik})$  on their history,  $\mathcal{T}_{i,<k}$  and  $R_{i,<k}$ :

$$\begin{aligned} &p(\mathcal{T}_{ik}, R_{ik} | \mathcal{T}_{i,<k}, R_{i,<k}) \\ &\equiv \lim_{\Delta t \downarrow 0} \frac{1}{\Delta t_{J_{ik}}} \Pr(E_{ik}, R_{ik} | E_{i,<k}, R_{i,<k}) \\ &= \lim_{\Delta t \downarrow 0} \left[ \prod_{r \in \mathcal{R}} \exp \left\{ \sum_{j \in (J_{ik} \setminus J_{i,k-1})} \frac{\log(1 - \Delta H_{ij}^{(rk)} | E_{i,<k}, R_{i,<k})}{\Delta t_j} \Delta t_j \right\} \right] \\ &\quad \frac{(\Delta H_{i,j_{i,k_1}}^{(R_{ik}^k)} | E_{i,<k}, R_{i,<k})}{\Delta t_{J_{ik}} (1 - \Delta H_{i,j_{i,k_1}}^{(R_{ik}^k)} | E_{i,<k}, R_{i,<k})} \tag{49} \\ (\because \text{Equation 46}) \\ &= \left[ \prod_{r \in \mathcal{R}} \exp \{ -H_i^{(rk)}(\mathcal{T}_{ik} | \mathcal{T}_{i,<k}, R_{i,<k}) \} \right] \\ &\quad h_i^{(R_{ik}^k)}(\mathcal{T}_{ik} | \mathcal{T}_{i,<k}, R_{i,<k}). \end{aligned}$$

We model  $h_i^{(rk)}(t | \mathcal{T}_{i,<k}, R_{i,<k}) = h^{(rk)}(t | \mathcal{T}_{i,<k}, R_{i,<k}, x_{ik}, \theta^{(rk)})$ . Redefine  $\mathcal{T} \equiv (\mathcal{T}_1, \mathcal{T}_2, \dots, \mathcal{T}_{\bar{i}})$  and  $R \equiv (R_1, R_2, \dots, R_{\bar{i}})$ . Let  $t_{i,k-1} \equiv (t_{1,k_1-1}, t_{2,k_2-1}, \dots, t_{\bar{i},k_{\bar{i}}-1})$ . The likelihood is

$$\begin{aligned}
 l(\theta | \mathcal{T}, \mathbf{R}, \mathbf{x}, \mathbf{t}_{\underline{k}-1}) &\propto \prod_{i \in \mathcal{I}} p(\mathcal{T}_i, \mathbf{R}_i | \mathbf{x}_i, \theta, \mathbf{t}_{i, \underline{k}_i-1}) \\
 &(\because \text{Assumption 2}) \\
 &= \prod_{i \in \mathcal{I}} \prod_{k \in \mathcal{K}_i} p(\mathcal{T}_{ik}, R_{ik} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k}, \mathbf{x}_{ik}, \theta) \\
 &(\because \text{Equation 48}) \\
 &= \prod_{i \in \mathcal{I}} \prod_{k \in \mathcal{K}_i} \left[ \prod_{r \in \mathcal{R}} \exp\{-H^{(rk)}\} \right] \\
 &\quad \underbrace{\hspace{10em}}_{\text{duration}} \\
 &\quad \left[ \underbrace{(\mathcal{T}_{ik} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k}, \mathbf{x}_{ik}, \theta^{(rk)})}_{\text{duration}} \right] \\
 &\quad \times \underbrace{\{h^{(R_{ik})}(T_{ik} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k}, \mathbf{x}_{ik}, \theta^{(R_{ik})})\}}_{\text{event}} \\
 &(\because \text{Equation 49}).
 \end{aligned}
 \tag{50}$$

Equation 50 implies the probability density that *no* event happens during  $(T_{i, k-1}, T_{ik})$  (rather than  $(0, T_{ik})$ ) and *only* event  $R_{ik}$  happens at  $T_{ik}$ . The difficulty of serial durations arises from the dependence of the  $k$ -th duration  $(\mathcal{T}_{ik}, R_{ik})$  on its history  $(\mathcal{T}_{i, < k}, \mathbf{R}_{i, < k})$ . Note that

$$\begin{aligned}
 &\exp\{-H_i^{(rk)}(\mathcal{T}_{ik} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k})\} \\
 &= \exp\left\{-\int_{T_{i, k-1}}^{T_{ik}} h_i^{(rk)}(t | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k}) dt\right\} \\
 &= \frac{S_i^{(rk)}(T_{ik} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k})}{S_i^{(rk)}(T_{i, k-1} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k})}.
 \end{aligned}$$

If we follow the standard representation like Equation 38 and only pay attention to the fact that event  $r \neq R_{ik}$  will happen after  $T_{ik}$ , it would not be straight-forward to see why we divide  $S_i^{(rk)}(T_{ik} | \cdot)$  by  $S_i^{(rk)}(T_{i, k-1} | \cdot)$ . I also emphasize that we only have to consider the univariate distribution of one random variable,  $T_{ik}$ , conditioned on  $T_{i, k-1}$ , not the bivariate distribution of two random variables,  $T_{ik}$  and  $T_{i, k-1}$ . This view is another merit of my focus on duration rather than a single event time point.

**Interval truncation**

If  $\mathcal{K}_i$  is not a set of consecutive integers, we can partition it into  $\bar{K}$  sets of consecutive

integers:  $\mathcal{K}_i = \bigcup_{K=1}^{\bar{K}} \mathcal{K}_i^{(K)}$  where  $\mathcal{K}_i^{(K)}$  is the  $K$ -th set of consecutive integers from  $\min \mathcal{K}_i^{(K)} \equiv \underline{k}_i^{(K)}$  to  $\max \mathcal{K}_i^{(K)} \equiv \bar{k}_i^{(K)} < \underline{k}_i^{(K+1)} - 1$ . Unit  $i$  is not observed between  $T_{i, \underline{k}_i^{(K)}}$  and  $T_{i, \underline{k}_i^{(K+1)}-1}$  and is said to be interval truncated. For instance, we may observe unit  $i$  for  $k = 1, 2, 4, 5$  but not  $k = 3$ , and this unit is interval truncated between  $T_{i2}$  and  $T_{i3}$ , where  $\mathcal{K}_i^{(1)} = \{1, 2\}$  and  $\mathcal{K}_i^{(2)} = \{4, 5\}$ . Let us redefine  $\mathcal{T}_{i, < k} \equiv (t_{i, \underline{k}-1}, \mathcal{T}_{i, \underline{k}_i^{(1)}}, \mathcal{T}_{i, \underline{k}_i^{(1)}+1}, \dots, \mathcal{T}_{i, \bar{k}_i^{(1)}}, \mathcal{T}_{i, \underline{k}_i^{(2)}}, \mathcal{T}_{i, \underline{k}_i^{(2)}+1}, \dots, \mathcal{T}_{i, \bar{k}_i^{(2)}}, \dots, \mathcal{T}_{i, \underline{k}_i^{(K)}}, \mathcal{T}_{i, \bar{k}_i^{(K)}+1}, \mathcal{T}_{i, \bar{k}_i^{(K)}, \dots, \mathcal{T}_{i, \underline{k}_i^{(K+1)}}, \dots, t_{i, \bar{k}_i^{(K)}})$ , where  $\mathbf{t}_{i, \underline{k}-1} \equiv (t_{i, \underline{k}_i^{(1)}}, t_{i, \underline{k}_i^{(1)}+1}, \dots, t_{i, \bar{k}_i^{(K)}})$  and  $\bar{k}_{i, < k} \in \mathcal{K}_i^{(K)}$ . We replace Equation 48 by

$$\begin{aligned}
 &p(\mathcal{T}_i, \mathbf{R}_i | \mathbf{t}_{i, \underline{k}-1}) \\
 &= \prod_{K=1}^{\bar{K}} \prod_{k \in \mathcal{K}_i^{(K)}} p(\mathcal{T}_{ik}, R_{ik} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k}) \\
 &= \prod_{k \in \mathcal{K}_i} p(\mathcal{T}_{ik}, R_{ik} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k}).
 \end{aligned}
 \tag{51}$$

**Left or interval censoring**

In some cases, even though  $T_{i, k-1} \geq T_{ik}$  and we do not observe  $T_{ik}$ , we may observe  $T_{i, k-1}$  and know  $T_{i, k-1} \geq T_{ik}$ . For instance, suppose that the  $k - 1 = 1$ -st duration is the time to delivery of a drug to a patient, and the  $k = 2$ -nd duration is the time to the patient’s death. When a doctor gives a drug to a patient at  $T_{i1}$ , the doctor may find the patient has already died ( $T_{i1} \geq T_{i2}$ ) but not know exactly when the patient died ( $T_{i2}$ ). In this case, unit  $ik$ ’s duration is said to be left censored. In particular, if we observe nothing before  $T_{i, k-1}$ , unit  $i$  is said to be left censored. If we observe not  $\mathcal{T}_{i, k-1}$  but  $\mathcal{T}_{ik}$ , for some  $k' < k - 1$ , unit  $i$  is said to be interval censored.

When unit  $ik'$  is left censored, we replace Equation 49 by

$$\begin{aligned}
 &\Pr(T_{ik} \leq T_{i, k-1} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k}) \\
 &= 1 - \Pr(T_{ik} > T_{i, k-1} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k}) \\
 &= 1 - \Pr(\forall r \in \mathcal{R}, T_{ik}^{(r)} > T_{i, k-1} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k}) \\
 &= 1 - \prod_{r \in \mathcal{R}} \Pr(T_{ik}^{(r)} > T_{i, k-1} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k}) \\
 &(\because \text{Assumption 7}) \\
 &= 1 - \prod_{r \in \mathcal{R}} S_i^{(rk)}(T_{i, k-1} | \mathcal{T}_{i, < k}, \mathbf{R}_{i, < k}).
 \end{aligned}
 \tag{52}$$

### Independent Serial Durations

In this subsection, we assume stochastic independence of serial durations across duration  $k$ 's within unit  $i$ .

**Assumption 8** (Stochastic Independence of Serial Durations):

$$T_{ik}^{(r)} \perp\!\!\!\perp T_{ik'}^{(r')} \text{ if } k \neq k',$$

where it can be either  $r = r'$  or  $r \neq r'$ .

It is straight-forward to derive  $h_i^{(rk)}(t | \mathcal{T}_{i,<k}, R_{i,<k}) = h_i^{(rk)}(t)$ . Accordingly, we do not have to condition the likelihood on the starting values.

In a simple (and, thus, often used) specification of the continuous time framework, we are interested in a certain risk  $r \in \mathcal{R}^+$  alone. Usually, we make the following assumptions: once an event due to risk  $r$  occurs at the end of  $k$ -th duration, we do not observe the succeeding unit  $i$ 's durations (if  $R_{ik} = r$ , it follows  $\bar{k}_i = k$  and  $R_{ik'} \neq r$  for  $k' < k$ ); hazard rates vary over  $k$  only through  $x_{ik}$  ( $h_i^{(rk)}(t) = h^{(r)}(t | x_{ik}, \theta^{(r)})$ ); and Assumption 6. Equation 50 is reduced to

$$\begin{aligned} & l(\theta^{(r)} | \mathcal{T}, R, x) \\ & \propto \prod_{i \in \mathcal{I}} \prod_{k \in \mathcal{K}_i} \exp\left\{-H^{(r)}(\mathcal{T}_{ik} | x_{ik}, \theta^{(r)})\right\} h^{(R_{ik})} \\ & \quad \left(T_{ik} | x_{ik}, \theta^{(R_{ik})}\right\}^{I(R_{ik}=r)}. \end{aligned}$$

In a popular specification of the discrete time framework, we substitute  $k$  with  $j$ . We also suppose that, for all units, the ‘censoring’ event ( $r = 0$ ) time for the  $k$ -th duration is constantly equal to the  $k$ -th fixed cutoff point:  $T_{ik}^{(0)} = t_{.k}$ . We model  $\Delta H_{ij}^{(rk)} = \Delta H^{(r)}(x_{ik}, \theta^{(r)})$ . Equation 47 is reduced to

$$\begin{aligned} & l(\theta^{(-0)} | E, R, x) \\ & \propto \prod_{i \in \mathcal{I}} \prod_{k \in \mathcal{K}_i} \left[ \prod_{r \in \mathcal{R} \setminus \{0\}} \{1 - \Delta H^{(r)}(x_{ik}, \theta^{(r)})\} \right] \\ & \quad \left\{ \frac{\Delta H^{(R_{ik})}(x_{ik}, \theta^{(R_{ik})})}{1 - \Delta H^{(R_{ik})}(x_{ik}, \theta^{(R_{ik})})} \right\}^{I(R_{ik} \neq 0)}. \end{aligned}$$

Moreover, let us assume that the hazard rate is proportional to the risk invariant baseline,  $h_i^{(rk)}(t): h_i^{(rk)}(t) = h_i^{(k)}(t) \exp(x_{ik} \beta^{*(rk)})$ . We apply the Cox model to  $\bar{r}$  durations in every duration  $k$  for every unit  $i$ . In Equation 22, we replace  $E_i(t)$  by  $E_{ik}^{(r)}$ ,  $i'$  by  $r'$ , and  $\mathcal{I}(t)$  by  $\mathcal{R}$  to obtain

$$\begin{aligned} & \Pr\left(E_{ik}^{(r)} = 1 \mid \sum_{r' \in \mathcal{R}} E_{ik}^{(r')} = 1\right) \\ & = \exp(x_{ik} \beta^{*(rk)}) / \sum_{r' \in \mathcal{R}} \exp(x_{ik} \beta^{*(r'k)}). \end{aligned}$$

By using Equations 23 and 47, it follows

$$\begin{aligned} & l^{\text{partial}}(\beta^* | R, x) \\ & \propto \prod_{i \in \mathcal{I}} \prod_{k \in \mathcal{K}_i} \Pr\left(E_{ik}^{(R_{ik})} = 1 \mid \sum_{r \in \mathcal{R}} E_{ik}^{(r)} = 1\right) \\ & = \prod_{i \in \mathcal{I}} \prod_{k \in \mathcal{K}_i} \exp(x_{ik} \beta^{*(R_{ik}k)}) / \sum_{r \in \mathcal{R}} \exp(x_{ik} \beta^{*(rk)}). \end{aligned}$$

where, conventionally, all elements of  $\beta^{(0k)}$  is set at zero for identification. It turns out that this is multinomial logit model of competing risks, and Assumption 7 is equivalent to the independence of irrelevant alternatives.

### Conditionally Independent Serial Durations

In this subsection, for ease of presentation, we suppose that  $\mathcal{K}_i$  is a set of consecutive integers and  $\underline{k}_i = 1$ .

### Repeated events

In some cases, repeated events are not independent of each other. For instance, once a unit has an event (e.g., electoral defeat), the unit may tend to have the event once more. Denote the number of events  $r$  unit  $i$  has before duration  $k \in \mathcal{K}_i$  by  $N_{ik}^{(r)}$ :

$$N_{ik}^{(r)} \equiv \sum_{k'=1}^{k-1} I(R_{ik'} = r),$$

where  $\sum_{k'=1}^0 \equiv 0$ .

Instead of Assumption 8, we assume stochastic independence of serial durations conditioned on the number of past events and the previous (i.e.,  $N_{ik}^{(r)}$ -th) event time  $T_{i,k_{ik}^{(r)}-1}$  where  $k_{ik}^{(r)} \equiv \min\{k' | N_{ik}^{(r')} = N_{ik}^{(r)}\}$ :

$$T_{ik}^{(r)} \perp\!\!\!\perp T_{ik'}^{(r')} | N_{ik}^{(r)}, T_{i,k_{ik}^{(r)}-1} \text{ if } k > k'. \quad (53)$$

It follows  $h_i^{(rk)}(t | \mathcal{T}_{i,<k}, R_{i,<k}) = h_i^{(rk)}(t | n_{ik}^{(r)}, t_{i,k_{ik}^{(r)}-1})$ . In the gap time (or inter-event time) specification, for  $t > t'$ ,  $h_i^{(rk)}(t | n, t') = h_i^{(rk)}(t - t' | n)$ , while, in the elapsed time (or clock time) specification,  $h_i^{(rk)}(t | n, t') = h_i^{(rk)}(t | n)$ , where we do not have to condition on  $T_{i,k_{ik}^{(r)}-1}$  in Equation 53. Either way, one way to model the hazard rate is  $h_i^{(rk)}(t | n) = h^{(rk)}(t | x_{ik}, \theta^{(rk|n)})$ . For instance, the first and second events have the same hazard rate functions ( $h^{(rk)}(t | x_{ik}, \theta^{(rk|)})$ ), though their parameters may differ ( $\theta^{(rk|0)} \neq \theta^{(rk|1)}$ ).

**Multi-state model**

Scholars may be interested in not just single but multiple risks. Often, the risk which incurred the previous non-censoring event is called ‘state’, ‘stage’, or ‘phase’ in which the unit is currently situated (Metzger and Jones, 2016). We denote it by  $R_{i,k_{ik}^{(+)}}^{(+)}$ , where  $k_{ik}^{(+)} \equiv \min\{k' | N_{ik}^{(+)} = N_{ik}^{(+)}\}$  and

$$N_{ik}^{(+)} \equiv \sum_{k'=1}^{k-1} I(R_{ik'} \in \mathcal{R}^+),$$

and suppose that the initial state is  $R_{i0} \in \mathcal{R}^+$ .

For example, suppose that  $\mathcal{R}^+ = \{‘war’, ‘crisis’, ‘peace’\}$ ,  $\mathcal{R}^0 = \{‘censoring’\}$  and  $R_{i0} = ‘peace’$ . If the  $k = 1$ -st duration ends with crisis ( $R_{i1} = ‘crisis’$ ), the state of the  $k = 2$ -nd duration is crisis ( $k_{i2}^{(+)} = 2, R_{i,k_{i2}^{(+)}-1} = R_{i1} = ‘crisis’$ ). Then, scholars would naturally expect that war in the  $k = 2$ -nd duration is more likely than in peacetime:  $h_i^{(war,2)}(t | R_{i,k_{i2}^{(+)}-1} = ‘crisis’) > h_i^{(war,2)}(t | R_{i,k_{i2}^{(+)}-1} = ‘peace’)$ .

Instead of Assumption 8, we assume stochastic independence of serial durations conditioned on the state:

$$T_{ik}^{(r)} \perp\!\!\!\perp T_{ik'}^{(r')} | R_{i,k_{ik}^{(+)}}-1 \text{ if } k > k'. \quad (54)$$

It follows  $h_i^{(rk)}(t | \mathcal{T}_{i,<k}, R_{i,<k}) = h_i^{(rk)}(t | R_{i,k_{ik}^{(+)}}-1)$ . We may model the hazard rate at state  $r$  by  $h_i^{(rk)}(t | r') = h^{(rk)}(t | x_{ik}, \theta^{(rk|r')})$ , where  $\theta^{(rk|r')}$  can be interpreted as a transition parameter vector from state  $r$  to  $r'$ . Further, we may condition on  $N_{ik}^{(+)}$  (or  $N_{ik}^{(r)}$ ) and  $T_{i,k_{ik}^{(+)}}-1$  as well.

We sometimes assume that a unit is not at risk(s) of the previous event(s). Let  $\mathcal{R}_{ik}$  denotes the (choice) set of risks at which unit  $ik$  is  $\langle \mathcal{R}_{ik} \neq \emptyset$ , and  $\mathcal{R}_{ik} \subseteq \mathcal{R} \setminus \{R_{i,k_{ik}^{(+)}}-1\}$  or  $\mathcal{R}_{ik} \subseteq \mathcal{R} \setminus \{R_{i,k_{ik}^{(+)}}-1 | k' \leq k\}$ . For example, if unit  $ik$  is at war ( $R_{i,k_{ik}^{(+)}}-1 = ‘war’$ ), it is not at risk of war any more ( $\mathcal{R}_{ik} = \{‘censoring’, ‘crisis’, ‘peace’\}$ ).

**Dependent Serial Durations**

We can apply the same methods to dependent serial durations as to dependent parallel durations in the previous section: frailty models, seemingly unrelated regressions, and copula functions. For instance, Chiba et al. (2015) examine the timing of government formation ( $T_{i1}$ ) and survival ( $T_{i2}$ ), respectively, and apply a copula model. Fukumoto (2015) studies the dependence between the duration ( $T_{i1}$ ) and outcome ( $T_{i2}$ ) of civil wars by coarsening  $T_{i2}$  into an ordered event variable and employing copula functions.

**CONCLUSION**

This chapter elaborates on duration analysis with emphasis on its duration nature rather than a point of event time. In particular, this chapter relaxes assumptions of independent multiple durations in tractable ways and explains advanced models in a systematic way. There remains, however, at least two assumptions I have still kept – the first two assumptions I make.

We may doubt even Assumption 1. For instance, if we study democratization or state formation, we may use calendar time as  $T_{ik}$ . It is not easy to nail down in which year  $t = 0$ . Rather, we may cease to assume Assumption 1 and  $t_0 = 0$  and instead may suppose that  $k$  can be a non-positive integer as well.

Another agenda is Assumption 2. An example against it is spatial correlation (Hays and Kachi, 2015, Hays et al., 2015): neighboring countries may introduce a new rule at similar timings. A shared frailty model (Equation 31) also implies that Assumption 2 does not hold. Darmofal (2009) takes spatial correlation into account by using frailty.

My hope is that readers will invent creative duration models by relaxing any assumption in a manageable way.

## Notes

- 1 For derivation of the continuous time framework from the discrete time one, see Alt et al. (2001).
- 2 Admittedly and confusingly, in the literature,  $\mu_i^*$  and  $\sigma^*$  are called 'scale' and shape parameters, respectively – though this chapter calls  $\sigma$  a scale parameter.
- 3 In early applications of this class of models,  $W_i$  refers to a hidden characteristic which makes patients frailer, that is, increases the hazard rate and shortens duration. This is why  $W_i$  is called frailty.
- 4 As for stochastic and parametric independence, see King (1989).
- 5 Admittedly and confusingly, this is different from 'risk set'  $\mathcal{I}(t)$  or  $\mathcal{I}_j$ .
- 6 Gordon (2002) assumes a proportional hazard model (Equations 24 and 25) and  $W_i^{*(r)} = \exp(W_i^{(r)})$ ,  $W_0^{(r)} = 0$  as well, though I don't think these assumptions are essential for this model.
- 7 See Trivedi and Zimmer (2007) for a concise introduction to copula. The appendix of Fukumoto (2015) gives a more handy explanation.

# Multilevel Analysis

Marco Steenbergen

In *Man, the State, and War*, Waltz (1959) outlines three different levels of analysis that help us understand war: individuals, states, and international systems. In international relations, political science, and public administration, it is common that a phenomenon can be approached at different levels. Rather than settling on one of those levels, it would be of considerable interest to bring them together into a single data-analytic framework. This is precisely what multilevel analysis offers.

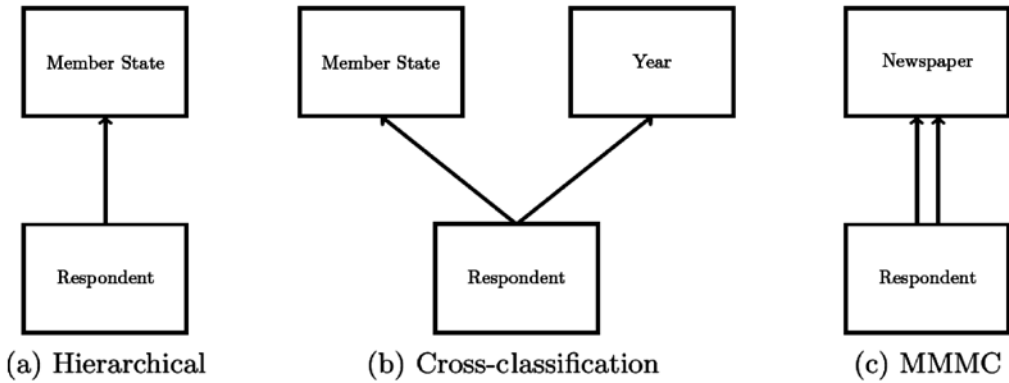

Over the past three decades, statisticians have made major breakthroughs in the analysis of multilevel data structures. Where such analysis was once limited to continuous outcomes and balanced data, it is now possible to analyze unbalanced data for categorical and limited dependent variables, as well as continuous outcomes. This chapter provides an overview of what is all now possible with multilevel data and how this can serve students of international relations, political science, and public administration.

## WHAT ARE MULTILEVEL DATA?

Multilevel data arise when we have multiple units of analysis, which stand in a (partial) hierarchy with each other and where the outcome variable varies across all units. To take the Waltz (1959) example, there are three units that form a clear hierarchy: individuals reside in states, which in turn are part of international systems. The units are called levels and a multilevel data structure consists of at least two levels.

It is possible to identify three canonical multilevel-data structures. To understand those structures, we employ the following example. Imagine we are interested in public support of the EU, analyzing Eurobarometer survey data. At first, we consider a single survey year. This yields a classical **hierarchical data structure**: we have respondents nested in EU member states. The structure is shown in panel (a) of Figure 36.1. This classification diagram (Browne et al., 2001) shows the respondents as the level-one units in the bottom box. The

**Figure 36.1** Three canonical multilevel-data structures

Source: Browne et al. (2001).

EU member states are the level-two units in the top box. An arrow points from the level-one to the level-two units to emphasize that the former is nested in the latter.

A second canonical data structure arises when we take the repeated nature of the Eurobarometer survey into account. In this example, we would bring this aspect in to explore both spatial and temporal variation in EU support. We would still treat respondents as the level-one units. It is less clear what the nesting structure of member states and years should be and, hence, we treat them equivalently. Quite literally, the second level of the data hierarchy comes about by crossing the member states with years, for example, Belgium 2016, Belgium 2017, etc. The resulting **cross-classification** is depicted as a classification diagram in panel (b) of Figure 36.1.

In the hierarchical and cross-classified data structures, it is assumed that a level-one unit may belong to only one level-two unit of a particular type. **Multiple membership and multiple classification (MMMC)** structures relax this assumption (Browne et al., 2001). Imagine that we would like to assess the effect of print media on EU support. The working assumption is that some newspapers are far more supportive of the EU in their discourse than others. We can characterize newspaper readership as a hierarchy between

the respondent and a newspaper, in the sense that a subset of respondents can be identified who read a particular newspaper and are subject to its influence. But what do we do with respondents who read multiple newspapers and can be influenced by all? The MMMC structure allows for this possibility, as is visible from the double arrows in the classification diagram in panel (c) of Figure 36.1.

We can combine the different canonical data structures. For instance, we could combine the MMMC from panel (c) with the cross-classification from panel (b). One way to do this would be to treat newspapers as being nested in member states and years. This would result in a three-level model that could be used inter alia to assess how newspaper influence affects respondent’s EU support and how this varies across space and time.

Table 36.1 shows common choices for level-one units in international relations, political science, and public administration.

**Table 36.1** Common choices of levels

<i>Lowest level</i>	<i>Higher levels</i>
Individuals	Individuals
Measures	Institutions
Time points	Geographic units
	Networks
	Temporal units

At the lowest level, the units are frequently individuals, as in the EU example. This does not have to be the case, however. We could also treat a series of related outcome measures as the lowest level, thinking of these as nested in an individual. Or, we could take a single outcome measured at different occasions for the same person as the lowest level, as we would in panel data. In this case as well, the individual is the higher-level unit. Other common higher-level units are institutions (e.g., bureaucratic agencies), geographic units (e.g., countries), networks (e.g., alliances), or temporal units (e.g., years).

## STATISTICAL PROPERTIES OF MULTILEVEL DATA

A full grasp of the rich potential of multilevel data requires that we understand their statistical properties. The most crucial property is **clustering**, which we also know from *survey research*. Consider the hierarchical data structure from Figure 36.1 and call the EU member states clusters. Clustering is the phenomena that the observations within a particular cluster (i.e., member state) are not independent because they share something in common. The common experience may be as simple as a shared language or as complex as shared norms and institutions. We may be able to capture the common experience through a set of variables. In the context of EU support, for example, we might look at a country's net contributions to the EU in order to explain why the respondents in a particular cluster hold similar views of the EU. Regardless, clustering is a fact of life when it comes to multilevel-data structures.

We capture the degree of clustering through the **intra-class correlation (ICC)**, which ranges between zero and one. When the ICC is zero, then units within the cluster have nothing in common and a blanket independence assumption is reasonable. When the ICC reaches unity, then the units within

a cluster are all alike with respect to some variable.

Clustering may be viewed from two perspectives. On one hand, it could be viewed as a statistical nuisance: it causes a number of issues that affect statistical inferences. Specifically, clustering is associated with a design effect that needs to be considered when computing (deff) standard errors (Kish, 1965). Standard errors computed under the assumption of independence are too small when the ICC exceeds zero. One can also say that we are too optimistic about the amount of data that are available. The effective sample size is  $N/\text{deff}$ , where  $N$  is the total number of observations. This could be as low as the number of clusters when the ICC is unity. In that case, it would literally suffice to study only one unit per cluster; all other units are merely duplicates. If clustering is viewed merely as a nuisance, then it is often not necessary to use multilevel statistical models. One could use fixed effects or use cluster-corrected standard errors, although the feasibility of these strategies depends on the nature of the outcome variable as well as the number of clusters (e.g., Cameron and Miller, 2015; Huang, 2016).

There is another way to approach clustering, namely as something that is of inherent theoretic interest. Clustering speaks to **heterogeneity** – how different are clusters from each other. Data analysis frequently focuses on central tendency in the extreme. However, variation is not only the proverbial spice of life but also frequently of considerable scientific interest. If we can study central tendency and variation in tandem, then we can learn about trends and deviations from those trends. Multilevel analysis is an ideal tool for developing this dual understanding of our data and political phenomena.

## THE HIERARCHICAL LINEAR MODEL

Assume we have a continuous outcome variable  $Y$ , for example, net wealth. We assume

that the variable follows a normal distribution or has been transformed to approximate normality. We observe the variable in clusters  $j = 1, \dots, J$ , for example, countries. In each cluster, we have collected data on units  $i = 1, \dots, n_j$ . Here,  $n_j$  is the cluster size. We refer to the clusters as level-two units and to the units inside, such as individuals, as level-one units. The hierarchical linear model (HLM) is suitable for analyzing these data.

## Model

### Precursors of the HLM

The HLM has several precursors. By far the simplest of these is the **random effects analysis of variance** (ANOVA) model, which has found application in *experimental design* (Searle et al., 1992). Normal ANOVA treats the level-two units as fixed, meaning that these units are the only (relevant) clusters. This results in a fixed-effects approach to the analysis (see Troeger, Chapter 33, this *Handbook*). In the baseline cell specification, this amounts to including  $J - 1$  cluster dummy variables (Jobson, 1999). An F-test on the effects of these variables tests the null hypothesis, which states no mean differences exist across the clusters. The random-effects ANOVA model operates differently: it assumes that the clusters in our data have been sampled from a population, just like the level-one units constitute a sample (Snijders, 2005). The cluster means, then, can be treated as stochastic variables: had we sampled different clusters, we would have obtained different means. Parenthetically, there is some debate in the literature whether the clusters actually constitute a random sample (Searle et al., 1992) or *in principle* are a random sample from some larger population (read ‘super-population’ in Snijders, 2005). In social-scientific practice, both ideas prevail.

We formalize this idea through a set of three model equations. The level-one model contains the outcome variable on the left-hand side:<sup>1</sup>

$$y_{ij} = \beta_{0j} + \varepsilon_{ij} \quad (1)$$

Here,  $\varepsilon_{ij} \sim NID(0, \sigma^2)$  is experimental error and *NID* stands for normally and independently distributed. Equation (1) indicates that the response of level-one unit  $i$  nested in level-two unit  $j$  is made up of a cluster mean,  $\beta_{0j}$ , and stochastic deviations from that mean, captured by the level-one error  $\varepsilon_{ij}$ . Except for its parameterization, this does not deviate from the base cell ANOVA model. The difference arises when we consider the next equation, which is stated in terms of the parameters  $\beta_j$  and is called the level-two model:

$$\beta_{0j} = \gamma_{00} + \delta_{0j}, \quad (2)$$

where  $\delta_{0j} \sim NID(0, \tau_{00})$ . This equation states that the cluster means consist of a grand mean,  $\gamma_{00}$ , and stochastic deviations  $\delta_{0j}$  – the level-two errors – from that mean. We may also write this as  $\beta_{0j} \sim NID(\gamma_{00}, \tau_{00})$ , and the fact that we consider the cluster means to be stochastic is what sets the random-effects ANOVA apart from its traditional cousin. The final model equation combines the level-one and -two models and, as such, gives the mixed model:

$$y_{ij} = \gamma_{00} + \delta_{0j} + \varepsilon_{ij} \quad (3)$$

The *NID* assumption captures the idea of **exchangeability**, which we know from *Bayesian statistics*. The assumption is important as it means that any cluster in the data could have been replaced by any other cluster in the population (Snijders, 2005). This is a key assumption of random-effects models.

We make one additional assumption in the random-effects ANOVA model, to wit  $\mathbb{E}[\delta_{0j}\varepsilon_{ij}] = 0$ . Using this and the *NID* assumptions for the level-one and level-two error terms, we obtain the following expectation and variance functions:

$$\mathbb{E}[y_{ij}] = \gamma_{00} \quad (4)$$

$$\text{Var}[y_{ij}] = \tau_{00} + \sigma^2 \quad (5)$$

It can also be shown that  $\text{Cov}[y_{ij}, y_{mj}] = \tau_{00}$ ; this is the covariance between the outcomes for level-one units belonging to the same level-two unit. The covariance for level-one units belonging to different level-two units is zero. It then follows that

$$ICC = \frac{\tau_{00}}{\tau_{00} + \sigma^2} \tag{6}$$

The particular variance–covariance structure of the random-effects ANOVA model is known as compound symmetry.

The *ICC* captures a great deal of interesting information about the outcome variable. It shows what portion of the variance is due to inter-cluster variation and what portion, namely  $1 - ICC$ , is due to intra-cluster variation. In doing so, it shows how homogeneous the level-two units are. With  $ICC = 1$ , all of the variance is between clusters and none of it is within. By contrast,  $ICC = 0$  means that all of the variance is within clusters: the level-two means do not vary. Cluster homogeneity is one important aspect of multilevel theories (Klein et al., 1999) and the random-effects ANOVA model can be used to shed empirical light on it.

An obvious limitation of the random-effects ANOVA is that it merely shows variation and does not explain it. Enter random-coefficient models (RCMs), which have a long history in econometrics (Longford, 1993; Swamy, 1970; Swamy and Tavlas, 1995). RCMs add level-one covariates to the level-one model. Thus,

$$y_{ij} = \beta_{0j} + \sum_{k=1}^K \beta_{kj} x_{ijk} + \varepsilon_{ij} \tag{7}$$

Here,  $x_{ij1}, \dots, x_{ijK}$  are values on covariates that vary across both levels. The coefficients  $\beta_{0j}, \dots, \beta_{Kj}$  are **random coefficients**. Their behavior is described by the following level-two model equations:

$$\begin{aligned} \beta_{0j} &= \gamma_{00} + \delta_{0j} \\ \beta_{1j} &= \gamma_{10} + \delta_{1j}, \\ &\vdots \\ \beta_{Kj} &= \gamma_{K0} + \delta_{Kj} \end{aligned} \tag{8}$$

where the  $\gamma$ s are known as **fixed effects**. The mixed model is given by

$$y_{ij} = \gamma_{00} + \sum_{k=1}^K \gamma_{k0} x_{ijk} + \delta_{0j} + \sum_{k=1}^K \delta_{kj} x_{ijk} + \varepsilon_{ij} \tag{9}$$

As in the random-effects ANOVA model, we assume  $\varepsilon_{ij} \sim NID(0, \sigma^2)$ . In its most general form, the level-two error structure is given by

$$\delta \sim NID(0, \mathbf{T}) \tag{10}$$

Here,  $\delta$  is a vector containing all of the level-two errors,  $\mathbf{0}$  is the vector of error means, which are all zero, and  $\mathbf{T}$  is the variance–covariance matrix. This has diagonal elements  $\tau_{pp}$  ( $p = 0, \dots, K$ ), which are **variance components**, and off-diagonal elements  $\tau_{pq}$ , which are covariance components.

The level-two model captures heterogeneity writ large. It shows how the intercepts and slopes vary across level-two units. In this sense, it reflects what Western (1998) calls ‘causal’ heterogeneity. Here, I use the quotation marks deliberately because multilevel models are not inherently causal models. We can learn a great deal from studying the heterogeneity, i.e., the matrix  $\mathbf{T}$  and the coefficients  $\beta_{kj}$ . Specifically, we can ascertain how regression regimes vary across level-two units. Do the regression slopes just vary in intensity, always pointing in the same direction? Or do we have slopes that can be positive, negative, and null?

We can place restrictions on the model. Not all of the coefficients need to be random so that we can remove some of the  $\delta$  terms. This is tantamount to restricting the variances of those terms to zero in the matrix  $\mathbf{T}$ ; all of the covariances involving the error terms are then also zero. Another common strategy is to restrict all of the off-diagonal elements in  $\mathbf{T}$  to zero. As a general rule, however, one should try to avoid this strategy because it is often detrimental to the empirical fit.

Figure 36.2 illustrates a number of different random-coefficient models with a single

**Figure 36.2 Three types of random-coefficient models**

covariate. Panel (a) shows a random intercept model, which is quite common in international relations, political science, and public administration. In this model,  $\beta_{1j} = \gamma_{10}$ , and thus only the intercept is allowed to vary. This results in a series of parallel regression lines. Panel (b) shows a much less common model – the random slope model. Here  $\beta_{0j} = \gamma_{00}$ , but the slopes are allowed to vary across level-two units. Thus, we observe regression lines that fan out from a common intercept. Panel (c) shows a random intercept and slope model, meaning that both the intercepts and slopes vary across level-two units.

In addition to the assumptions of the random-effects ANOVA model, the RCM adds assumptions about the level-one predictors, specifically  $\mathbb{E}[x_{ijk}\epsilon_{ij}] = \mathbb{E}[x_{ijk}\delta_{kj}] = 0$ . This means that weak exogeneity is assumed. Note that this assumption is identical to that of random-effect models in Troeger (Chapter 33, this *Handbook*).

We conclude the discussion of RCMs by considering their implied moment structure. It can be demonstrated that

$$\mathbb{E}[y_{ij} | x_{ij1}, \dots, x_{ijK}] = \gamma_{00} + \sum_{k=1}^K \gamma_{k0} x_{ijk} \quad (11)$$

$$\begin{aligned} \text{Var}[y_{ij} | x_{ij1}, \dots, x_{ijK}] &= \tau_{00} + \sum_{k=1}^K x_{kij}^2 \tau_{kk} \\ &+ 2 \sum_{k=1}^K \tau_{01} x_{ijk} + 2 \sum_{k=1}^K \sum_{l>k}^K \tau_{kl} x_{ijk} x_{ijl} + \sigma^2 \end{aligned} \quad (12)$$

We see that the conditional variance function is now a complex function of the covariates and the (co)variance components. This reflects the heterogeneity inherent in multilevel data. The covariances between outcomes measured in different clusters is zero. When the outcomes pertain to the same level-two unit, the covariance is given by

$$\begin{aligned} \text{Cov}[y_{ij}, y_{mj} | x_{ij1}, \dots, x_{ijk}, x_{mj1}, \dots, x_{mjK}] \\ &= \tau_{00} + \sum_{k=1}^K \tau_{0k} (x_{ijk} + x_{mjk}) \\ &+ \sum_{k=1}^K \tau_{kk} x_{ijk} x_{mjk} + \\ &\sum_{k=1}^K \sum_{l=1}^K \tau_{kl} (x_{ijk} x_{mjl} + x_{ijl} x_{mjk}) \end{aligned} \quad (13)$$

This means that the ICC for  $Y$  is no longer constant, as it was in the random-effects ANOVA, but depends on the values of the covariates: the degree of clustering varies.

**The HLM**

The HLM moves beyond the RCM by allowing the addition of level-two covariates to account for heterogeneity. The RCM allows us to ascertain whether some covariate exerts an effect that varies across level-two units. The HLM allows us to explain this variation by bringing in properties of the level-two units.

Level-two properties come in two different guises (Lazarsfeld and Menzel, 1980). Derived properties are aggregates of level-one variables, whereas integral properties are inherently contextual variables that cannot be reduced to level-one attributes. An example of a derived property is the average skill level in an EU member state. An example of an integral property is the net EU contributions of a member state.

The level-one model of the HLM is identical to that of the RCM (see Equation (7)). The difference arises in the level-two model:

$$\begin{aligned}
 \beta_{0j} &= \gamma_{00} + \sum_{q=1}^Q \gamma_{0q} z_{jq} + \delta_{0j} \\
 \beta_{1j} &= \gamma_{10} + \sum_{q=1}^Q \gamma_{1q} z_{jq} + \delta_{1j} \\
 &\vdots \\
 \beta_{Kj} &= \beta_{K0} + \sum_{q=1}^Q \gamma_{Kq} + \delta_{Kj}
 \end{aligned}
 \tag{14}$$

The level-two error structure is that shown in Equation (10), although the errors should be understood as residual variation in the coefficients that has not been explained by the  $Q$  level-two predictors  $Z_{jq}$ . The mixed model is obtained by substituting Equation (14) into Equation (7):

$$\begin{aligned}
 y_{ij} &= \gamma_{00} + \sum_{q=1}^Q \gamma_{0q} z_{jq} + \sum_{k=1}^K \gamma_{k0} x_{ijk} \\
 &+ \sum_{k=1}^K \sum_{q=1}^Q \gamma_{kq} x_{ijk} \cdot z_{jq} + \\
 &\delta_{0j} + \sum_{k=1}^K \delta_{kj} x_{ijk} + \varepsilon_{ij}
 \end{aligned}
 \tag{15}$$

The variables  $x_{ijk} \cdot z_{jq}$  play an important role in the HLM. They are the **cross-level** interactions and show how the effect of a level-one covariate depends on level-two attributes. As such, they build a model of the heterogeneity

in slopes. The main effects of the predictors  $Z_{jq}$ , by contrast, model the heterogeneity in intercepts.

The matrix  $T$  also plays an important role. The change in this matrix relative to the RCM gives us an impression of how well the level-two predictors account for the variation in intercepts and slopes. If  $T = \mathbf{0}$ , then we would know that the level-two predictors account perfectly for the variation in intercepts and slopes.

This also shows an important contrast with another precursor of the HLM, to wit **contextual analysis** (Boyd and Iversen, 1979). Here, the assumption is that  $T = \mathbf{0}$ , i.e., there are no level-two errors. The HLM turns this claim into a testable proposition but does not a priori impose it as a restriction on the error structure.

Equation (15) is relatively complex. In the literature, it is often re-written in terms of matrices: let  $y$  be the vector of responses across all level-one and level-two units; let  $X$  be a matrix of level-one covariates, including a constant; let  $Z$  be a matrix of level-two covariates, also including a constant; let  $\varepsilon$  be the vector of level-one errors. Then the HLM is given by

$$\begin{aligned}
 y &= XZ\gamma + X\delta + \varepsilon \\
 &= M\gamma + X\delta + \varepsilon
 \end{aligned}
 \tag{16}$$

The model has the following expectation and variance functions:

$$\begin{aligned}
 \mu &= \mathbb{E}[y | X, Z] = XZ\gamma = M\gamma \\
 \Sigma &= \text{Var}[y] = X(I_J \otimes T)X^\top + \sigma^2 I_N
 \end{aligned}
 \tag{17}$$

where  $N$  is the total number of observations.

Ordinarily, restrictions are placed on the elements of  $\gamma$  so that not every random coefficient is accounted for by every level-two predictor. Indeed, theory should guide which predictors are used in a particular level-two equation. As in the RCM, restrictions usually are also placed on  $T$ , reducing the number

of (co)variance components. In terms of the variance–covariance matrix of the level-one errors, the restriction that this should be a diagonal matrix with identical variances can be relaxed. For example, one could allow for heteroskedasticity or serial correlation. I discuss the latter aspect in the section on longitudinal data.

### *Extending the Levels of the Model*

Returning to the EU-support example, we can actually extend the levels beyond respondents and countries. Often, we also have information about the sub-national region (or state or province) in which a respondent resides, and this may be highly relevant for his or her opinions about the EU. For example, the region may depend heavily on agricultural subsidies and this could increase EU support.

Consider level-three units  $k = 1, \dots, K$  (e.g., EU member states). Nested inside those units are level-two units  $j = 1, \dots, J_k$  (e.g., regions). Finally, we have level-one units  $i = 1, \dots, n_{jk}$  (e.g., respondents). A random-effects ANOVA now requires level-one, -two, and -three models. Specifically, the level-one model is

$$y_{ijk} = \alpha_{0jk} + \varepsilon_{ijk} \quad (18)$$

subject to  $\varepsilon_{ijk} \sim \text{NID}(0, \sigma^2)$ . The equation states that the responses consist of a level-two mean  $\alpha_{0jk}$  and a level-one deviation from that mean of  $\varepsilon_{ijk}$ . The level-two model is given by

$$\alpha_{0jk} = \beta_{00k} + \delta_{0jk} \quad (19)$$

subject to  $\delta_{0jk} \sim \text{NID}(0, \tau_\alpha)$ . This equation states that the level-two mean is made up of a level-three mean  $\beta_{00k}$  and a deviation  $\delta_{0jk}$  from that mean. Finally, the level-three model shows how the level-two means relate to the grand mean:

$$\beta_{00k} = \gamma_{000} + \omega_{00k} \quad (20)$$

where  $\omega_{00k} \sim \text{NID}(0, \tau_\beta)$ . The mixed model is

$$y_{ijk} = \gamma_{000} + \omega_{00k} + \delta_{0jk} + \varepsilon_{ijk} \quad (21)$$

We can now define two ICCs:

- 1  $(\tau_\alpha + \tau_\beta)/(\tau_\beta + \tau_\alpha + \sigma^2)$  is the share of the variance among level-two units, for example, inter-regional variation.
- 2  $\tau_\beta/(\tau_\beta + \tau_\alpha + \sigma^2)$  is the share of the variance among level-three units, for example, countries.

It is straightforward to extend the random-effects ANOVA model to an RCM. With a single level-one covariate, for example, we obtain the following random intercept and slope model:

$$y_{ijk} = \alpha_{0jk} + \alpha_{1jk}x_{ijk} + \varepsilon_{ijk} \quad (22)$$

$$\alpha_{0jk} = \beta_{00k} + \delta_{0jk} \quad (23)$$

$$\alpha_{1jk} = \beta_{10k} + \delta_{1jk} \quad (24)$$

$$\beta_{00k} = \gamma_{000} + \omega_{00k} \quad (25)$$

$$\beta_{10k} = \gamma_{100} + \omega_{10k} \quad (26)$$

We can add level-two and -three covariates to obtain a fully fledged HLM. For instance, using the same level-two predictor  $Z_{jk}$  in the equations for  $\alpha$  and the same level-three predictor  $W_k$  in the equations for  $\beta$ , we obtain the following mixed model:

$$\begin{aligned} y_{ijk} = & \gamma_{000} + \gamma_{001}w_k + \gamma_{010}z_{jk} + \gamma_{100}x_{ijk} \\ & + \gamma_{011}z_{jk}w_k + \gamma_{101}x_{ijk}w_k + \gamma_{110}x_{ijk}z_{jk} \\ & + \gamma_{111}x_{ijk}z_{jk}w_k + \omega_{00k} \\ & + z_{jk}\omega_{01k} + x_{ijk}\omega_{10k} \\ & + x_{ijk}z_{jk}\omega_{11k} + \delta_{0jk} + x_{ijk}\delta_{1jk} + \varepsilon_{ijk} \end{aligned} \quad (27)$$

The model contains three two-way cross-level interactions ( $x_{ijk}$  with  $z_{jk}$ ,  $x_{ijk}$  with  $w_k$ , and  $x_{ijk}$  with  $w_k$ ) and a three-way cross-level interaction. The last line of the equation shows the composite error term.

Extensions to more than three levels proceed in an analogous fashion. Whether it is necessary to do so obviously depends on the complexity of the data and the theory. One should not make this decision too lightly, because statistical power may be in short supply when interactions entail ever more levels. In addition, effectively communicating complex interactions can be a challenge.

**Longitudinal Data**

Time can enter the HLM in a number of different places. We could think of it as higher-level unit, as we did in panel (b) of Figure 36.1. We could also think of it as a level-one unit nested in individuals, geographic units, or institutions. This is appropriate when the data constitute a panel.

Imagine we are interested in military spending in countries across time (years). We have countries  $j = 1, \dots, J$  and time points  $i = 1, \dots, n_j$ . Note that  $n_j$  varies; there is no requirement of balanced data. A very simple model for this data is  $y_{ij} = \gamma_{00} + \delta_{0j} + \varepsilon_{ij}$  with  $\delta_{0j} \sim \text{NID}(0, \tau_{00})$  and  $\varepsilon_{ij} \sim \text{NID}(0, \sigma^2)$ . We say that spending across time and countries is expected to be  $\gamma_{00}$ . A particular country deviates from this by  $\delta_{0j}$  and in a particular year the deviation is  $\varepsilon_{ij}$ .

The problem with this basic setup is that we assume the level-one errors to be independent; this is reflected in the last term of Equation (17), which is a diagonal matrix. For time-series data, such an assumption is unrealistic. We would like to specify an alternative level-one error structure, and some of the available options are shown in Table 36.2 (cf. Kincaid, 2005). A simple structure is the (exponential) AR(1) (autoregressive-1) structure, which stipulates

$$\text{Var} \begin{bmatrix} \varepsilon_{1j} \\ \varepsilon_{2j} \\ \vdots \\ \varepsilon_{n_jj} \end{bmatrix} = \begin{bmatrix} \sigma^2 & \rho\sigma^2 & \dots & \rho^{n_j-1}\sigma^2 \\ \rho\sigma^2 & \sigma^2 & \dots & \rho^{n_j-2}\sigma^2 \\ \vdots & \vdots & \ddots & \vdots \\ \rho^{n_j-1}\sigma^2 & \rho^{n_j-2}\sigma^2 & \dots & \sigma^2 \end{bmatrix} \tag{28}$$

Only two parameters need to be estimated:  $\sigma^2$  and  $\rho$ . The Toeplitz structure requires  $n_j$  parameters and takes the form of

$$\text{Var} \begin{bmatrix} \varepsilon_{1j} \\ \varepsilon_{2j} \\ \vdots \\ \varepsilon_{n_jj} \end{bmatrix} = \begin{bmatrix} \sigma_1 & \sigma_2 & \dots & \sigma_{n_j} \\ \sigma_2 & \sigma_1 & \dots & \sigma_{n_j-1} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{n_j} & \sigma_{n_j-1} & \dots & \sigma_1 \end{bmatrix} \tag{29}$$

where  $\sigma_1$  is the level-one error variance. We can render the AR(1) and Toeplitz structures more complex by allowing for heteroskedasticity. The most complex structure arises when we allow all of the elements of the variance-covariance matrix to be freely estimated:

$$\text{Var} \begin{bmatrix} \varepsilon_{1j} \\ \varepsilon_{2j} \\ \vdots \\ \varepsilon_{n_jj} \end{bmatrix} = \begin{bmatrix} \sigma_1^2 & \sigma_{1,2} & \dots & \sigma_{1,n_j} \\ \sigma_{1,2} & \sigma_2^2 & \dots & \sigma_{2,n_j} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{1,n_j} & \sigma_{2,n_j} & \dots & \sigma_{n_j}^2 \end{bmatrix} \tag{30}$$

This requires estimating  $.5n_j(n_j + 1)$  parameters and is usually unpractical.

The random-effects ANOVA model for panel data, that we have considered so far does not model any time trends. We can accommodate such trends by formulating the HLM as a **growth curve model**. The general growth curve model is given by

$$y_{ij} = \beta_{0j} + \sum_{k=1}^K \beta_{kj} t^k + \varepsilon_{ij} \tag{31}$$

$$\beta_{kj} = \gamma_{k0} + \delta_{kj} \tag{32}$$

Here,  $t$  is a time indicator such as years passed since some starting point, and  $K$  determines the order of the time polynomial. Level-two predictors can be added to explain differences in time trends.

**Table 36.2 Level-one error structures for longitudinal data**

Type	No. of parameters	$i, j$ th element
AR(1)	2	$\sigma_{ij} = \sigma^2 \rho^{ i-j }$
Toeplitz	$n_j$	$\sigma_{ij} = \sigma_{ i-j +1}$
Heterogeneous AR(1)	$n_j + 1$	$\sigma_{ij} = \sigma_j \sigma_j \rho^{ i-j }$
Heterogeneous Toeplitz	$2n_j - 1$	$\sigma_{ij} = \sigma_j \sigma_j \rho_{ i-j }$
Unstructured	$.5n_j (n_j + 1)$	$\sigma_{ij} = \sigma_{ij}$

## INFERENCE

### Identification and Sample Size

Identification of the HLM (and other multi-level models) requires that we avoid perfect multicollinearity and micronumerosity, i.e., sample sizes that fall short of the number of parameters to be estimated. This is also true in linear-regression analysis, but the difference is that the identification requirements vary with the level. For the fixed effects associated with level-one covariates, the relevant sample size is  $N$ , i.e., the total number of observations in the data. For the fixed effects associated with the level-two predictors, the relevant sample size is  $J$ , i.e., the number of clusters. The same is true for the matrix  $T$ .

The fact that  $J$  limits the number of variance and covariance components means that one typically cannot leave it to the data to show which slopes are random and which ones are not. In political science, international relations, and public administration,  $J$  is typically small. With  $K$  level-one covariates, the unrestricted  $T$  has  $.5K(K + 1)$  elements. This can be a sizable number, one that easily exceeds  $J$ . Prior restrictions on  $T$  are almost always necessary, requiring the researcher to make theoretical choices upfront.

Even if  $.5K(K + 1) \leq J$  and formal identification is assured, identification issues can still arise in practice. The off-diagonal elements of  $T$  frequently pose difficulties for the estimation. The problem tends to be more severe, the greater the dimensionality of  $T$  is.

Due to identification concerns, researchers sometimes restrict the covariance components to zero, thus turning  $T$  into a diagonal matrix. While this frees up degrees of freedom and may avoid estimation difficulties, the approach is questionable. As an empirical matter, slopes and intercepts tend to correlate. If one rules such correlation out, the model fit suffers. The HLM may also produce far different variance component estimates than those obtained from models allowing covariance components.

If one wants identification to be less of a concern, it pays off to invest in expanding  $J$ . Indeed, the payoff from expanding  $J$  is usually far greater than that of expanding  $n_j$  (Stoker and Bowers, 2002). One should take this into consideration when designing a multilevel study.

Indeed, the topic of how large of a  $J$  is required is hotly debated in the literature. An older literature argued that as many as 100 clusters would be required to draw valid inferences about random effects and (co)variance components. In the meantime, statisticians have become more relaxed on the requirement. Stegmueller (2013) argues that  $J$  can be reduced if one switches to a Bayesian framework. Browne and Draper (2000) claim that valid classical inference is possible with as few as 6–12 groups, provided that one uses restricted maximum likelihood (see below). Maas and Hox (2005) suggest  $J = 30$  with REML and advise against  $J \leq 10$ . Baldwin and Fellingham (2013) show that Bayesian inference is no panacea: when  $J$  is too small, the specification of the prior becomes ever more important, as should be expected. These

results are important because students of international relations, political science, and public administration often have relatively few clusters at their disposal. Especially in cross-national research,  $J$  is often limited and there is usually no way to expand it (we cannot generate new countries for the purposes of our research).

**Estimation**

For estimation, it makes a difference what is actually being estimated: fixed effects, variance-covariance components, or random effects. Fixed effects can be estimated using Bayesian methods, least squares, and maximum likelihood. Variance components are estimated using Bayesian inference of maximum likelihood. Random effects are typically estimated using (empirical) Bayes methods.

**Least Squares**

One of the oldest ideas in multilevel analysis is to estimate fixed effects using least squares. A two-step estimator requires that one first regresses the outcome on the level-one covariates in each cluster using OLS. Next, one stacks the OLS estimates and regresses them onto level-two predictors (Jusko and Shively, 2005; van den Eeden, 1988). The resulting fixed-effects estimator is unbiased but inefficient (de Leeuw and Kreft, 1986). The inefficiencies can be removed using generalized least squares or making adjustments to the standard errors (de Leeuw and Kreft, 1986; Lewis and Linzer, 2005).

**Maximum Likelihood**

While least squares estimation works well for fixed effects, the general consensus is that it performs less than ideally for random effects and variance components. It is because of this problem that researchers propose using maximum-likelihood estimation, which comes in two flavors: full information maximum likelihood (FIML) and restricted maximum likelihood (REML),

which is also known as residual maximum likelihood.

**FIML** takes advantage of the normality assumption we have made throughout the discussion of the HLM. Using Equation (17), we can show that  $y \sim MVN(\mathbf{M}\boldsymbol{\gamma}, \boldsymbol{\Sigma})$ , where *MVN* denotes the multivariate normal distribution. Accordingly, the log-likelihood may be written as

$$\ell_{FIML} = -.5N \ln(2\pi) - .5 \ln \det(\boldsymbol{\Sigma}) - .5(\mathbf{y} - \mathbf{M}\boldsymbol{\gamma})^\top \boldsymbol{\Sigma}^{-1}(\mathbf{y} - \mathbf{M}\boldsymbol{\gamma}) \tag{33}$$

Writing  $\mathbf{v} = \mathbf{y} - \mathbf{M}\boldsymbol{\gamma}$ , the first-order conditions are

$$\frac{\partial \ell_{FIML}}{\partial \boldsymbol{\gamma}} = \mathbf{M}^\top \boldsymbol{\Sigma}^{-1} \mathbf{v} = 0 \tag{34}$$

$$\frac{\partial \ell_{FIML}}{\partial \boldsymbol{\theta}} = -.5 \left\{ \frac{\partial \ln \det \boldsymbol{\Sigma}}{\partial \boldsymbol{\theta}} - \mathbf{v}^\top \boldsymbol{\Sigma}^{-1} \frac{\partial \boldsymbol{\Sigma}}{\partial \boldsymbol{\theta}} \boldsymbol{\Sigma}^{-1} \mathbf{v} \right\} = 0 \tag{35}$$

Here,  $\boldsymbol{\theta}$  is some parameter, i.e., (co)variance component, of  $\boldsymbol{\Sigma}$ .

Various algorithms have been proposed to optimize the likelihood. Goldstein (1986) proposed iterative generalized least squares, whereby the algorithm iterates between estimating the fixed effects and the (co)variance components. Longford (1987) proposed Fisher scoring to accomplish the same task. Under normality, both approaches essentially produce the same results. Other algorithms include BFGS and (penalized) Newton-Raphson.

A significant problem with FIML is that the (co)variance components tend to be underestimated when the number of clusters is small. This is caused by the need to estimate the fixed effects first. That operation consumes degrees of freedom, which the estimation of the matrix  $\mathbf{T}$  and the scalar  $\sigma^2$  does not account for. In very simple terms, a (co)variance estimator divides a sum of

squared deviations or cross-products by a particular denominator and, in FIML, that number is set too high. The result is a downward bias. The problem is more pronounced for  $T$  than for  $\sigma^2$ ; the denominator in the latter case is a function of  $N$ , whereas it is a function of  $J$  for  $T$  and generally  $J \ll N$ .

REML overcomes the problem (Harville, 1974; Patterson and Thompson, 1971). The idea here is to use error contrasts  $A^T y$ . An error contrast has the property that  $A^T M = 0$  and ensures that  $A^T y$  is free from  $\gamma$ . That makes it possible to remove the bias from the (co)variance component estimates. The kernel of the REML log-likelihood function for the (co)variance components is (cf. Longford, 1993)

$$\begin{aligned} \ell_{REML} = & -.5 \ln \det(\Sigma) \\ & -.5 \ln \det(M^T \Sigma^{-1} M) \\ & -.5 (y - M\hat{\gamma})^T \Sigma^{-1} (y - M\hat{\gamma}) \end{aligned} \quad (36)$$

Computational details can be found in de Leeuw and Meijer (2008) and Longford (1993).

### Bayesian Inference

Multilevel models have a strong affinity to Bayesian approaches to statistical inference, since we can think of the higher-level models as priors of sorts. It is no surprise then that Bayesian approaches have made their way into statistical inference about HLMs. Draper (2008) provides a detailed discussion of Bayesian methods. The essence is that we derive the posterior distributions over  $\gamma$  and  $\Sigma$  by introducing priors over both sets of parameters. Different priors have been proposed. Jackman (2011) proposes using a multivariate normal prior over  $\gamma$ , an inverse Gamma prior over  $\sigma^2$ , and an inverse Wishart distribution over  $T$ . Chung et al. (2015) propose uniform priors, with the exception of  $T$ , which receives a weakly informative Wishart prior.

Estimation proceeds using MCMC, either using the Gibbs sampler Draper (2008) or the No U-Turn Sampler (Hoffman and

Gelman, 2014). One should perform the usual diagnostics to ascertain proper convergence (see *Bayesian inference*). While the Bayesian approach is already very useful in the case of hierarchical linear models, it is particularly relevant for generalized linear models, as we shall see below.

### Empirical Bayes Estimation

Inferences about random effects  $\beta_{kj}$  are either part of Bayesian inference or are computed using empirical Bayes' (EB) estimation (Carlin and Louis, 1998). Reconsidering the random-effects ANOVA model (Equations 1–2), one could estimate  $\beta_{0j}$  in two ways. First, one could fit constant-only regression models in each of the clusters. The resulting OLS estimators are  $\hat{\beta}_{0j} = \bar{y}_{.j}$  and have a variance of  $\sigma^2/n_j$ . Alternatively, one could estimate the fixed effect  $\gamma_{00}$ , the rationale being that  $\mathbb{E}[\beta_{0j}] = \gamma_{00}$ . Here, we obtain the estimator  $\hat{\gamma}_{00} = \bar{y}_{..}$  with a variance of  $\tau_{00}$ . The idea behind EB estimation is that we compute a weighted average of the two estimators, shrinking toward the most precise of the two estimators. Let

$$\lambda_j = \frac{\tau_{00}}{\tau_{00} + \frac{\sigma^2}{n_j}} \quad (37)$$

be the reliability. Then, the EB or shrinkage estimator of the cluster means is

$$\tilde{\beta}_{0j} = \lambda_j \bar{y}_{.j} + (1 - \lambda_j) \bar{y}_{..} \quad (38)$$

If  $\sigma^2 = 0$ , i.e., there is no within variance, then  $\lambda_j = 1$  and all of the weight is placed on  $\bar{y}_{.j}$ . By contrast, if  $\tau_{00} = 0$ , i.e., there is no between variance, then  $\lambda_j = 0$  and all the weight is placed on  $\bar{y}_{..}$ .

The idea can be generalized quite easily. Given the level-one regression model  $y_j = X_j \beta_j + \varepsilon_j$  and the level-two regression model  $\beta_j = Z_j \gamma + \delta_j$ , we again can derive two estimators. The within-regression estimators are given by  $\hat{\beta}_j = (X_j^T X_j)^{-1} X_j^T y_j$  and have a variance-covariance matrix of

$\sigma^2(\mathbf{X}_j^\top \mathbf{X}_j)^{-1}$ . The between-regression estimator is  $\hat{\boldsymbol{\gamma}}$  and has a variance of  $\mathbf{T}$ . Define  $\boldsymbol{\Lambda}_j = \mathbf{T}[\mathbf{T} + \sigma^2(\mathbf{X}_j^\top \mathbf{X}_j)^{-1}]^{-1}$ . Then

$$\tilde{\boldsymbol{\beta}}_j = \boldsymbol{\Lambda}_j \hat{\boldsymbol{\beta}}_j + (\mathbf{I} - \boldsymbol{\Lambda}_j) \hat{\boldsymbol{\gamma}} \tag{39}$$

Equation (39) is important because it reveals an extremely useful property of hierarchical linear models, namely the ability to **borrow strength**. Should the within estimator be very imprecise, for example because  $n_j$  is small, then we can compensate for this – i.e., borrow strength – by considering the between estimator,  $\hat{\boldsymbol{\gamma}}$ . One important application of this idea is *multilevel regression with post-stratification*.

**Hypothesis Testing**

Hypothesis tests about the fixed effects are straightforward extensions of what we know from *linear-regression analysis*. Given the null hypothesis  $H_0: \gamma_{pq} = k$ , the test statistic is given by

$$T = \frac{\hat{\gamma}_{pq} - k}{\widehat{SE}[\hat{\gamma}_{pq}]} \stackrel{asy}{\sim} \mathcal{N}(0,1) \tag{40}$$

The reliance on an asymptotic (*asy*) result is often problematic. A safer approach is to rely on the student’s t-distribution with adjusted denominator degrees of freedom (Kenward and Roger, 1997; Satterthwaite, 1941).

Hypothesis testing about the variance components is typically done via a likelihood-ratio test. The typical setup tests  $H_0: \tau_{pp} = 0$ . Such a hypothesis is relevant, for example, if we want to determine whether any variance in the intercepts or slopes remains after we have included level-two covariates. We test the hypothesis by comparing the fit of a model containing the variance component and a model that restricts it to zero. Let  $D = -2\ell$  be the deviance. Then

$$LR = D_r - D_u \stackrel{asy}{\sim} \chi_q^2 \tag{41}$$

Here,  $D_r$  and  $D_u$  are the deviances of the restricted and unrestricted models, respectively, and  $q$  equals the number of restrictions. LaHuis and Ferguson (2009) propose using a one-tailed test, as it provides the best balance between statistical power and Type-I errors.

**Fit**

When we speak of model fit, we speak of the relative performance of successive models. A typical modeling sequence starts by fitting a random-effects ANOVA, which serves the purpose of showing the variance decomposition of the outcome. Next, level-one covariates are added, which might reduce the level-one variance component. In a third step, one or more random effects are specified. A final step is to introduce level-two covariates, which might reduce the level-two variance components (cf. Hox et al., 2017).

Each step adds complexity to the model. At each step, one could compute the AIC or BIC to ascertain whether the added complexity brings a sufficient improvement in the fit. Alternatively, one can compute  $R^2$  values (Hox et al., 2017). For example, when going from the random-effects ANOVA ( $M_1$ ) to a fixed-effects model with level-one covariates ( $M_2$ ), one can compute

$$R_1^2 = \frac{\hat{\sigma}_{M1}^2 - \hat{\sigma}_{M2}^2}{\hat{\sigma}_{M1}^2} \tag{42}$$

as the variance in  $Y$  that is explained by the covariates. In going from a random intercept model ( $M3$ ) to a model that introduces level-two covariates ( $M4$ ), one can compute

$$R_2^2 = \frac{\hat{\tau}_{00}^{M3} - \hat{\tau}_{00}^{M4}}{\hat{\tau}_{00}^{M3}} \tag{43}$$

**Software**

Hierarchical linear models are now so common that all major statistical computing packages, including R, SAS, SPSS, and Stata, cover them. In addition, several stand-alone

packages for multilevel modeling remain popular, including HLM and MLwiN.

**INTERPRETATION**

**Population-Averaged Interpretation**

Most social scientists rely on a population-averaged interpretation of HLMs. Here, we take the expectation over all units, which has the effect of removing all error terms. The result is shown in Equation (17).

A common approach to interpretation is to compute the marginal effect. Specifically, in a level-two model,

$$\frac{\partial \mu}{\partial x_r} = \gamma_{r0} + \sum_{q=1}^Q \gamma_{rq} z_{jq} \tag{44}$$

$$\frac{\partial \mu}{\partial z_s} = \gamma_{0s} z_{js} + \sum_{k=1}^K \gamma_{ks} x_{ijk}$$

Obviously, these equations have to be adjusted in higher-level models. Bauer and Curran (2005) show a general approach to assessing the statistical significance of these marginal effects.

Less common is the use of a discrete-change interpretation, although it is the best approach to addressing the effects of discrete predictors. Let  $X_r$  change from  $x_r$  to  $x_r + \Delta$ . Then

$$\Delta \mu = \gamma_{r0} \Delta + \sum_{q=1}^Q \gamma_{rq} z_{jq} \Delta \tag{45}$$

A similar expression can be derived for the effects due to level-two predictors.

**Subject-Specific Interpretation**

Imagine we have measured EU support in various member states. Rather than interpreting the effect of (say) left–right for the average citizen in the average member state, we would like to see what the effect

is in a specific member state. Now we are in the domain of subject-specific effects. We take the expectation over level-one units – we are still looking at the average citizen – but fixate on a particular level-two unit. Thus, the level-one errors disappear but not the level-two errors.

If we consider the marginal effect of the  $r$ th level-one predictor, we obtain

$$\frac{\partial \mu}{\partial x_{ijr}} = \gamma_{r0} + \sum_{q=1}^Q \gamma_{rq} z_{jq} + \delta_{rj} \tag{46}$$

For estimation purposes, then, we need to add the EB residual,  $\tilde{\delta}_{rj}$ , to the population-averaged marginal effect. Nothing changes for the marginal effect due to a level-two covariate.

Moving to the discrete change, the subject-specific analogue to Equation (45) is

$$\Delta \mu = \gamma_{r0} \Delta + \sum_{q=1}^Q \gamma_{rq} z_{jq} \Delta + \delta_{rj} \Delta \tag{47}$$

Again, this is useful when the level-one covariate is a factor.

**CROSS-CLASSIFICATIONS AND MMMCS**

Imagine we consult Eurobarometer data from several years. As shown in Figure 36.1, this can be considered a cross-classified data structures with respondents  $i$  nested in country–year units  $j_1 j_2$ . An example of the structure is shown in Table 36.3, which is based on the 1970–2002 trend file. A random-effects ANOVA for this structure is given by

$$y_{i(j_1 j_2)} = \gamma_{0(00)} + \delta_{0j_1} + \delta_{j_2} + \epsilon_{i(j_1 j_2)} \tag{48}$$

with  $\mathbb{E}[y_{i(j_1 j_2)}] = \gamma_{0(00)}$  and  $\text{Var}[y_{i(j_1 j_2)}] = \tau_{00_1} + \tau_{00_2} + \sigma^2$ . Units from different rows and columns in the cross-classification are independent. Units within the same row have a covariance of  $\tau_{00_1}$ . In our example, this

**Table 36.3 A cross-classified structure**

Year	Country			
	AT	BE	...	UK
1970	⋮	$Y_{(1,2)} \cdots Y_{1296(1,2)}$	...	⋮
1971	⋮	$Y_{(2,2)} \cdots Y_{1459(2,2)}$	...	⋮
⋮	⋮	⋮	...	⋮
2002	$Y_{1(32,1)} \cdots Y_{4078(32,1)}$	$Y_{1(32,2)} \cdots Y_{4153(32,2)}$	...	$Y_{1(32,18)} \cdots Y_{5255(32,18)}$

covariance is due to the same time point of measurement. Units within the same column have a covariance of  $\tau_{00_2}$ , which in our example is due to the shared country. Units within the same cell have a covariance of  $\tau_{00_1} + \tau_{00_2}$ .

One can expand the model by adding attributes of the respondents in a random intercept and slope specification. In general,

$$\begin{aligned}
 y_{i(j_1j_2)} &= \gamma_{0(00)} \\
 &+ \sum_{k=1}^K \gamma_{k(00)} x_{i(j_1j_2)k} + \delta_{0j_1} \\
 &+ \delta_{0j_2} + \sum_{k=1}^K \delta_{kj_1} x_{i(j_1j_2)k} \\
 &+ \sum_{k=1}^K \delta_{kj_2} x_{i(j_1j_2)k} + \varepsilon_{i(j_1j_2)} \quad (49)
 \end{aligned}$$

This equation can be modified further by adding level-two covariates. In our example, those might be (1) net budgetary intakes, (2) the year that a country joined the EU, and (3) a dummy for the growth of the Dow-Jones in a particular year. The first variable varies across both countries and years, the second across countries, and the last across years.

The MMMC accommodates the possibility that a level-one unit belongs to multiple level-two units. Imagine a newspaper reader who, two-thirds into the year, switched from reading the Times to reading the Guardian. If we want to consider the effect of newspaper slant on the reader’s evaluations of Brexit, for example, then we might want to give

different weights to the two newspapers, say two-thirds to the Times and one-third to the Guardian.

In general, consider a set of weights  $w_{ij}$  such that  $\sum_j w_{ij} = 1$ . The random-effects ANOVA model now takes the form of

$$y_{ij} = \gamma_{00} + \sum_{j \in C(i)} w_{ij} \delta_{0j} + \varepsilon_{ij} \quad (50)$$

where  $C(i) \subset \{1, \dots, J\}$ . The intra-class correlation is  $\tau_{00} \sum_{j \in C(i)} w_{ij}^2 / (\tau_{00} \sum_{j \in C(i)} w_{ij}^2 + \sigma^2)$ . As always, this model can be expanded by adding level-one covariates with or without random slopes. One can also add level-two covariates, but these again will have to be weighted. For example, a measure of the slant of the Times should carry twice as much weight for our hypothetical respondent as that of the Guardian.

## GENERALIZED LINEAR MODELS

### Binary Outcomes

Many outcomes in international relations, political science, and public administration are binary. Think about the absence or presence of (civil) war, voting yay or nay in a legislature, or voting vs abstaining in an election. Such outcomes are ordinarily dealt with using logit, probit, and related models, which can easily be extended to multilevel-data structures.

Consider the decision to vote for or against Brexit in 2016. We know that the outcome of the vote varied across constituencies.

This fact can be captured most simply via an analogue of the random-effects ANOVA:

$$\begin{aligned}
 y_{ij}^* &= \beta_{0j} + \varepsilon_{ij} \\
 \beta_{0j} &= \gamma_{00} + \delta_{0j} \\
 y_{ij} &= \mathbf{1}(y_{ij}^* \geq 0)
 \end{aligned}
 \tag{51}$$

Here,  $y_{ij}^*$  is the latent disposition of voting for Brexit,  $\beta_{0j}$  is the baseline tendency in the  $j$ th constituency,  $\varepsilon_{ij}$  is voter  $i$ 's deviation from this tendency,  $\gamma_{00}$  is the baseline tendency across the UK, and  $\delta_{0j}$  is the constituency's deviation from the overall trend. We assume that a voter in this referendum voted for Brexit if her latent disposition is at least zero. As in the HLM, we assume  $\delta_{0j} \sim \text{NID}(0, \tau_{00})$ . For  $\varepsilon_{ij}$ , we typically choose the standard normal or logistic distributions, although other choices are available. The key is that the error distribution is centered about zero and has a fixed variance to identify the scale of  $y_{ij}^*$ .

The probability of the outcome being one (e.g., a vote for Brexit) is  $\pi_{ij}$ . Assuming a symmetric level-one error distribution, as in the logit and probit variants, it follows that

$$\pi_{ij} = F(\gamma_{00} + \delta_{0j})
 \tag{52}$$

Here,  $F(\cdot)$  is the cumulative distribution function. Equation (52) is the primary quantity of interest, which can be used for purposes of interpretation.

A fully fledged hierarchical model requires the addition of level-one and -two covariates. For symmetric level-one error distributions, it takes on the following form:

$$\begin{aligned}
 \pi_{ij} &= F(\eta_{ij}) \\
 \eta_{ij} &= \gamma_{00} + \sum_{q=1}^Q \gamma_{0q} z_{jq} + \sum_{k=1}^K \gamma_{k0} x_{ijk} \\
 &+ \sum_{k=1}^K \sum_{q=1}^Q \gamma_{kq} x_{ijk} \cdot z_{jq} + \\
 &\delta_{0j} + \sum_{k=1}^K \delta_{kj} x_{ijk}
 \end{aligned}
 \tag{53}$$

Here,  $\eta_{ij}$  is the so-called **linear predictor**. The model is easily adjusted to accommodate cross-classified and MMMC structures. Note that the model has some affinities with heteroskedastic logit and probit models, since the variance of  $y_{ij}^*$  is not constant.

Estimation of HLMs for binary outcomes is complicated by the presence of the level-two stochastic components. Had we full knowledge of those components, then it would suffice to maximize the likelihood  $\mathcal{L}(y, \gamma | \delta_j) = \prod_{i,j} \pi_{i,j}^{y_{ij}} (1 - \pi_{i,j})^{1-y_{ij}}$  with respect to the fixed effects. In actuality, we do not know the level-two errors and therefore will need to optimize

$$\mathcal{L}(y | \gamma, \delta_j) = \int_{-\infty}^{\infty} \phi_{K+1}(\delta_j) \mathcal{L}(y, \gamma | \delta_j) d\delta_j
 \tag{54}$$

Here,  $\phi_{K+1} = \mathcal{N}(\mathbf{0}, T)$  is the  $K + 1$ -variate normal distribution.

The presence of the multivariate integral in the likelihood function makes this a difficult estimation problem, except for the special case of the random intercept model. In practice, two approaches are used. One can approximate the integrals using a Laplace approximation (Shun and McCullagh, 1995) or (adaptive) Gaussian quadrature (Skrondal and Rabe-Hesketh, 2004). One can also bypass the integration altogether and opt for inference via MCMC (Draper, 2008).

Interpretation is another area where complexities arise. Consider a random intercept model with a single level-one covariate. Here,  $\eta_{ij} = \gamma_{00} + \gamma_{10} x_{ij} + \delta_{0j}$ . For the population-averaged predicted probabilities, one might be tempted to set  $\delta_{0j} = 0$  and then take the inverse of the logit or probit link function over  $\gamma_{00} + \gamma_{10} x_{ij}$ , but this is not correct. Instead, we need to integrate out the level-two error term:  $\Pr(y_{ij} = 1 | x_{ij}) = \int \Pr(y_{ij} = 1 | x_{ij}, \delta_{0j}) \phi(\delta_{0j}) d\delta_{0j}$ . The term  $\Pr(y_{ij} = 1 | x_{ij}, \delta_{0j})$  is the subject-specific predicted probability. The integral can be evaluated numerically and some packages will do this automatically.

**Figure 36.3** Conceptualizing ordinal outcomes

One way to bypass the integral in logit models is to perform the interpretation in terms of odds ratios. The expected logit is  $\gamma_{00} + \gamma_{10}x_{ij}$ . A change of  $\Delta$  units in the level-one covariate generates a change in the logit of  $\gamma_{10}\Delta$ . This translates into a change in the odds ratio of  $\exp(\gamma_{10}\Delta)$ . A point estimate can be obtained by substituting  $\hat{\gamma}_{10}$ . For an interval estimate, one should apply endpoint transformation or the delta method to  $\hat{\gamma}_{10}$ .

**Ordinal Outcomes**

Imagine we have asked a question about whether a person feels (1) exclusively national, (2) both national and European, or (3) exclusively European. We treat this as an ordinal measure of the extent to which a person possesses a European identity ( $y_{ij}^*$ , where  $j$  is a European country and  $i$  is a respondent). The relationship between this latent variable and the observed responses is shown in Figure 36.3. If  $y_{ij}^* > \kappa_{1j}$ , then the respondent indicates a mixed identity, and if  $y_{ij}^* > \kappa_{2j}$ , she indicates an exclusive European identity. Note that we let the thresholds,  $\kappa$ , vary across level-2 units.

Define  $\pi_{ij(m)} = \Pr(Y_{ij} > m)$ , where  $m$  is a response category, as the cumulative response probability. For instance,  $\pi_{ij(1)}$  is the probability of indicating a mixed or European identity. If we do not include any predictors,  $\pi_{ij(m)} = \Pr(y_{ij}^* > \kappa_{mj}) = \Pr(\epsilon_{ij} > \kappa_{mj})$ . For a symmetric level-one error distribution, this becomes  $F(-\kappa_{mj})$ .

We can also parameterize this differently. Let  $\beta_{0j} = -\kappa_{1j}$  and let  $\theta_{mj} = \kappa_m - \beta_{0j}$  for  $m > 1$ . Thus, we introduce a random intercept and define the thresholds at fixed distances from it. Now,

$$\pi_{ij(m)} = F(\beta_{0j} - \theta_m) \tag{55}$$

This is the ordinal equivalent of the random-effects ANOVA, where  $\beta_{0j} \sim \mathcal{N}(\gamma_{00}, \tau_{00})$ . The effect of this specification is that the distance between the thresholds remains the same while their location depends on  $\beta_{0j}$ .

Table 36.4 shows how different values of  $\delta_{0j}$  affect the cumulative response probabilities for a scenario in which we have set  $\gamma_{00} = 0$  and  $\theta_2 = 1$ . We observe that probability of scoring one decreases as  $\delta_{0j}$  increases. Conversely, the probability of scoring three increases.

We can add level-one and level-two covariates to the model. Specifically,

$$\begin{aligned} \pi_{ij(m)} &= F(\eta_{ij} - \theta_m) \\ \eta_{ij} &= \gamma_{00} + \sum_{q=1}^Q \gamma_{0q} z_{qj} + \sum_{k=1}^K \gamma_{k0} x_{ijk} \\ &+ \sum_{k=1}^K \sum_{q=1}^Q \gamma_{kq} x_{ijk} \cdot z_{qj} + \\ &\delta_{0j} + \sum_{k=1}^K \delta_{kj} x_{ijk} \end{aligned} \tag{56}$$

After substitution, we obtain  $\delta_{0j} + \sum_{k=1}^K \delta_{kj} x_{ijk} - \theta_m$ , which may be viewed as context- and covariate-adjusted thresholds.

The estimation of Equation (56) proceeds analogous to the binary model. From a statistical viewpoint, the easiest interpretation is when the focus is on cumulative odds ratios. For example, in the model  $\pi_{ij(m)} = F(\gamma_{00} + \gamma_{10}x_{ij} + \delta_{0j} + \delta_{1j}x_{ij} - \theta_m)$ , the population-averaged odds ratio is  $\exp(\gamma_{10}\Delta)$  for an increase in  $X$  of  $\Delta$  units.

**Table 36.4 Cumulative response probabilities with  $\gamma_{00} = 0$  and  $\theta_2 = 1$**

	$\pi_{ij(1)}$	$\pi_{ij(2)}$	$\pi_{ij(3)}$
$\delta_{0j} = -1$	0.731	0.881	1.000
$\delta_{0j} = 0$	0.500	0.731	1.000
$\delta_{0j} = 1$	0.269	0.500	1.000

**Choice Models**

Choice variables occur in every context in which decisions are being made. Consider, for instance, voting in the UK: voters *i* decide which party, if any, receives their vote. At the same time, such decisions may be shaped by the particulars of the constituency.

In statistics, choice is often analyzed using random utility models. Let  $U_{ijm}$  be the utility that voter *i* in constituency *j* adheres to party *m*. We assume that utility consists of a systematic (*V*) and stochastic ( $\epsilon$ ) component:

$$U_{ijm} = V_{ijm} + \epsilon_{ijm} \tag{57}$$

Under utility maximization, the voter is expected to vote for party *p* if  $U_{ijp} > U_{ijr}$  for all  $r \neq p$ .

The probability of voting for party *p* is given by  $\pi_{ijp}$ . The functional form for this probability depends crucially on the assumptions about the joint distribution over the stochastic components. A simple assumption – and the only one we shall consider here – is to assume the errors to be independent draws from identical, generalized, extreme value distributions. In this case,

$$\pi_{ijp} = \sum_{m=1}^M \exp(V_{ijm}) \tag{58}$$

Here, *M* is the number of parties, which may depend on the constituency, in which case we write  $M_j$ . The model in Equation (58) is known as the Luce model.

The specifics of the model depend on how we formalize  $V_{ijm}$ . In a multinomial logit (MNL) model, we make  $V_{ijm}$  a function of

attributes of the decision maker. In the most general form, a hierarchical version of MNL takes the following form:

$$V_{ijm} = \gamma_{00m} + \sum_{q=1}^Q \gamma_{0qm} z_{qj} + \sum_{k=1}^K \gamma_{k0m} x_{ijk} + \sum_{k=1}^K \sum_{q=1}^Q \gamma_{kqm} x_{ijk} \cdot z_{qj} + \delta_{0jm} + \sum_{k=1}^K \delta_{kjm} x_{ijk} \tag{59}$$

For identification purposes, the fixed effects and level-two errors are fixed to zero for one of the alternatives. The specification in Equation (59) shows the utility for a party as a function of voter attributes, features of the constituency, the interaction between those, and stochastic elements.

If  $V_{ijm}$  depends on attributes of the alternatives, then we obtain the conditional logit model. Here, the attributes *X* and *Z* vary across the alternatives, but the coefficients do not. For identification purposes, the intercept is set to zero so that

$$V_{ijm} = \sum_{q=1}^Q \gamma_{0q} z_{qjm} + \sum_{k=1}^K \gamma_{k0} x_{ijkm} + \sum_{k=1}^K \sum_{q=1}^Q \gamma_{kq} x_{ijkm} \cdot z_{qjm} + \sum_{k=1}^K \delta_{kj} x_{ijkm} \tag{60}$$

This model can be extended by adding attributes of the voters and/or allowing for varying effects for attributes of the alternatives.

We can think of the models presented here as three-level models. Party alternatives are nested in voters, which in turn are nested in constituencies. When viewed from this perspective, it is conceptually straightforward to impose different level-one error structures to accommodate correlated errors between parties. In practice, this can create considerable estimation difficulties, so care has to be taken.

**Count Models**

A final example of a GLM is a count model. For the sake of simplicity, we restrict ourselves to the Poisson regression model. Count models are useful, for example, to study social protest activities such as strikes and demonstrations. The intensity of those activities is frequently recorded as an integer from zero onwards.

The Poisson distribution lends itself to modeling counts. Let  $Y_{ij}$  denote the number of demonstrations against the government city  $j$  during month  $i$ . The Poisson distribution gives

$$\Pr(Y_{ij} = y_{ij}) = \frac{\mu_{ij}^{y_{ij}} \exp(-\mu_{ij})}{y_{ij}!} \quad (61)$$

where  $\mu_{ij} > 0$  is the parameter. A simple model stipulates

$$\mu_{ij} = \exp(\beta_{0j}) \quad (62)$$

with  $\beta_{0j} \sim \mathcal{N}(\gamma_{00}, \tau_{00})$ . By exponentiating, we ensure that the inequality constraint on the parameter holds. The model states that the expected count,  $\mu_{ij}$ , depends on a common tendency for protest,  $\gamma_{00}$ , and a city deviation,  $\delta_{0j}$ .

A simple random intercept Poisson regression model is given by

$$\mu_{ij} = \exp(\gamma_{00} + \gamma_{10}x_{ij} + \delta_{0j}) \quad (63)$$

This is an interesting model because it has built-in overdispersion:

$$\text{Var}[y_{ij}] = \mu_{ij} + \mu_{ij}^2 (\exp(\tau_{00}) - 1) \geq \mu_{ij} \quad (64)$$

In an ordinary Poisson regression model,  $\text{Var}[y_{ij}] = \mu_{ij}$ . This is often an unrealistic constraint, especially when data are collected from different contexts.

**CONCLUSION**

Multilevel models have come a long way since they first arrived on the scene. Considerable progress has been made in the areas of inference and interpretation. Moreover, the range of outcomes that can be modeled continues to grow. In this respect, the current review has only managed to scratch the surface. We have had nothing to say, for example, about event duration, structural equations, and latent-variable models.

As strong as the potential of multilevel analysis is, we should also note that current practice in international relations, political science, and public administration realizes only a fraction of what is possible. Most of the research focuses on hierarchical data structures, uses random intercepts only, and limits itself to population-averaged interpretation. We hope that our review has shown that much more is possible and will inspire scholars to explore the many possibilities that we have sketched here.

**Note**

- 1 My notation relies heavily on Bryk and Raudenbush (1992) but deviates by following the standard econometric practice of representing error terms by a Greek symbol.

# Selection Bias in Political Science and International Relations Applications

Tobias Böhmelt and Gabriele Spilker

## INTRODUCTION

Empirical scholars in international relations and, more generally, political science regularly face challenges stemming from selection bias, which arise when researchers are confronted with non-random samples. The study of the effectiveness of international institutions, for example, sees countries mainly joining those organizations whose obligations they find rather unproblematic to adhere to. This non-random self-selection, in turn, has probably severe consequences for how international institutions perform. Likewise, the decision to go to war often-times hinges on the same factors that afterwards determine their duration or outcome. Similar problems occur in almost any sub-field of political science from the study of electoral behavior to the examination of protests, public opinion, political economy or environmental politics. After a short introduction of what selection issues are in more detail, this chapter provides an overview of

some of the most commonly used estimation methods to deal with selection problems. It also illustrates several of those methods using examples of recent scholarship in the field.

A selection problem arises if measured or unmeasured factors affect both the selection into the sample, which is used to analyze a specific phenomenon, as well as the outcome variable of interest (Sartori, 2003). Imagine we would like to estimate whether countries that are part of preferential trade agreements (PTAs) including hard, i.e., enforceable, human-rights clauses actually protect human rights in their territory better than those states that are not bound by such strict clauses in their treaties (Hafner-Burton, 2005). To this end, we may consider estimating a simple linear regression model:

$$y_i = x_i \beta + \varepsilon_i$$

where  $y_i$  is some measure of human-rights protection and  $x_i$  the number of hard human-rights clauses a respective country  $i$  is bound

by in its PTAs. However, such an approach would face the problem that the countries that select themselves into PTAs with enforceable human-rights clauses might differ from those that decide to ratify PTAs with only 'soft', i.e., non-enforceable, or no human-rights clauses at all. Hence, in this case, a classic confounding problem,<sup>1</sup> there exist *unmeasured* factors that influence both the decision to ratify a PTA with hard human-rights standards and actual human-rights protection levels. One such factor, for example, is how likely the specific country is to protect human rights even in the absence of international commitments, i.e., the domestic costs of human-rights protection. This implies that one could think of a so-called selection equation that might consist of

$$P_i = w_i \gamma + u_i$$

where  $P_i$  is the probability of country  $i$  to enter into a PTA with hard human-rights clauses and  $w_i$  is some measure of how costly it is for country  $i$  to protect human rights in its territory.

The selection problem now arises due to two reasons (Achen, 1986; Sartori, 2003). First, countries finding it unproblematic due to whatever reason to protect human rights themselves, i.e., those countries having low values of  $w_i$  – the cost of human rights protection – should be more likely to enter into PTAs with hard and enforceable human rights clauses. This is simply driven by the fact that they should encounter few costs in ratifying such agreements, but mostly benefit in terms of, for example, pleasing specific domestic audiences. States with gross human-rights violations, however, i.e., those with high levels of  $w_i$ , should find it more costly to ratify such agreements to begin with and, thus, should be more likely to abstain from doing so. The second source of the selection effect comes exactly from the latter countries if they ratify PTAs with strict human-rights clauses. If these countries do so, this is likely driven by their large error terms  $u_i$ . As a consequence, our sample of analysis consists of

countries that find it easy to protect human rights and have a 'more well-behaved' range of errors, and of states that find it difficult to protect human rights and, hence, have large error terms. In turn, though, the two variables, hard human-rights clauses in PTAs and the cost of protecting human rights, will be correlated leading to biased estimation.

As a consequence of this discussion, one can posit in short that a selection problem occurs if the error term of the selection equation and the error term of the outcome equation are correlated. This leads to inconsistent estimates because the error term in the outcome equation does not have mean 0 and is correlated with the explanatory variables (Heckman, 1979). The literature proposes several ways to address selection bias in quantitative analysis. In the following, we outline five such methods. In the third section of this chapter, we discuss the application of these methods in the context of two empirical examples, the PTA and human rights example and an example of EU enlargement. We also provide R and Stata code for the straightforward replication of these examples.

## EMPIRICAL METHODS TO ADDRESS SELECTION BIAS IN QUANTITATIVE APPLICATIONS

### *The Heckman (1976) Model*

We start our discussion with the 'classical' Heckman (1976) Selection Model, in which the estimated mean function in the outcome stage is conditioned on the first stage selection process and, thereby, provides a consistent estimate for the truncated distribution of the second stage sample (Heckman 1979). It consists of a selection equation

$$s_i^* = w_i \gamma + u_i$$

$$\text{where } s^* = \begin{cases} 1 & \text{if } s^* > 0 \\ 0 & \text{if } s^* \leq 0 \end{cases}$$

and an outcome equation:

$$y_i = \begin{cases} x_i\beta + \varepsilon_i & \text{if } s^* > 0 \\ - & \text{if } s^* \leq 0 \end{cases}$$

If a researcher estimated a simple OLS regression on the outcome equation, the following quantity would be estimated given observation  $i$  is in the sample:

$$E(y_i) = x_i\beta + \theta \left[ \frac{\phi(\gamma'w)}{\Phi(\gamma'w)} \right]$$

where  $\phi$  is the standard normal distribution and  $\Phi$  is the cumulative standard normal distribution. This second part of the equation is thus the omitted variable bias due to selection therefore rendering estimation of  $\beta$  in the outcome equation inconsistent.

However, given the following additional assumptions,

$$u_i \sim N(0,1)$$

$$\varepsilon_i \sim N(0,\delta^2)$$

$$\text{corr}(u_i, \varepsilon_i) \sim \rho$$

researchers can estimate the selection and outcome variable simultaneously. The correlation of the error terms in the two stages,  $\rho$ , and its significance can then be interpreted in line of how important selection in the particular context really is. Its estimation, however, is sensitive to model specifications.

In practice, the Heckman Selection Model is commonly implemented as a two-step model, in which step one consists of estimating a probit model for the selection equation and to obtain the estimated  $\gamma$  to calculate  $\left[ \frac{\phi(\gamma'w)}{\Phi(\gamma'w)} \right]$ , which is the inverse Mills ratio, or sometimes called the 'non-selection hazard', for each observation. More precisely, the inverse Mills ratio indicates the probability for each observation to enter our sample. In the example mentioned in the introduction, it would be a function of the

probability of a specific country to enter into a PTA with hard human rights clauses. Step two implies estimating a corrected version of the outcome equation using OLS. This corrected version of the outcome equation includes as an additional regressor the inverse Mills ratio estimated from the first stage. The coefficient of the inverse Mills ratio indicates the direction of the bias that would have occurred without estimating a selection model. In particular, a positive estimate of the coefficient implies that our actual coefficient of interest, for example, PTAs with hard human-rights clauses, would have been biased upward while a negative coefficient would imply a downward bias. Important for the identification of the Heckman model is that at least one variable influences only the selection into the sample but not the outcome of interest. If this is not the case, the outcome equation will result in imprecise estimates (Sartori, 2003). This implies that researchers need to find an extra exogenous variable for selection, which must have the same properties as an instrument in instrumental-variables estimation and needs to be defended with similar care. In practice, however, such a variable is often not available and violations of the exclusion restriction are just as biasing as they are in instrumental-variables estimation (Achen, 1986).

### **Bivariate Probit Model**

The Heckman model is appropriate in situations where the selection equation is binary, but the outcome variable is continuous. In cases in which the outcome variable is also dichotomous, the Bivariate Probit Model is applicable (Greene, 2003). The Bivariate Probit Model is similar to the Heckman Selection Model:

$$y_{1i}^* = x_{1i} \beta_1 + \varepsilon_{1i}$$

$$y_{2i}^* = x_{2i} \beta_2 + \varepsilon_{2i}$$

$y_1^*$  and  $y_2^*$  are two latent variables where

$$y_{ji} = \begin{cases} 1 & \text{if } y_{ji}^* > 0 \\ 0 & \text{if } y_{ji}^* \leq 0 \end{cases}$$

for  $j=1, 2$ .

In the case of a selection problem, the errors of the two probit models will be

$$\begin{aligned} \varepsilon_{1i} &= v_i + u_{1i} \\ \varepsilon_{2i} &= v_i + u_{2i} \end{aligned}$$

This implies that each error term consists of a unique part,  $u_{1i}$  and  $u_{2i}$ , and of a component that is common to both equations,  $v_i$ . Hence, the two error terms are no longer independent. To estimate the joint probability for non-independent events, the Bivariate Probit Model assumes that the joint distribution of the two dichotomous dependent variables, one in the selection and one in the outcome equation, is a bivariate normal distribution. This implies that the Bivariate Probit Model assumes the errors of the selection and the outcome equation are independent and identically distributed as a standard bivariate normal with correlation  $\rho$ . Their joint pdf will therefore look like this:

$$\begin{aligned} \phi_2 &= \phi_{(\varepsilon_1, \varepsilon_2)} \\ &= \frac{1}{2\pi\sigma_{\varepsilon_1}\sigma_{\varepsilon_2}\sqrt{1-\rho^2}} \\ &\quad \exp\left[-\frac{1}{2}\left(\frac{\varepsilon_1^2 + \varepsilon_2^2 - 2\rho\varepsilon_1\varepsilon_2}{1-\rho^2}\right)\right] \end{aligned}$$

As in the case of the Heckman Selection Model,  $\rho$  stands for the correlation coefficient between the two error terms. However, in case of the Bivariate Probit Model, identification does not hinge upon the inclusion of an additional extra variable to the selection equation, but on a distributional assumption concerning the error terms.

**Sartori (2003) Selection Model**

Sartori (2003) starts the derivation of her selection estimator by pointing out

the difficulty of finding a truly exogenous variable needed for identification in the selection equation in Heckman-type models. She proposes a maximum likelihood estimator for binary outcomes *without* exclusion restriction. The additional assumption she introduces to identify the model is that for any observation in the sample, the error terms in the two equations are the same. She argues that while this assumption might not be true in all settings, it is a reasonable assumption if both the selection into the sample and the outcome of interest follow a similar goal or involve a similar decision, selection and outcome have the same causes, and the two aspects either cluster in time or in space (Sartori, 2003). To illustrate when these conditions are potentially met, Sartori (2003) suggests the analysis of rivalry and war as the same conditions should matter for states' decision to go to war with each other, which have resulted in them being rivals in the first place. In particular, the model looks like this:

$$\begin{aligned} U_{1i} &= x_i \beta_1 + u_i \\ U_{2i} &= x_i \beta_2 + u_i \end{aligned}$$

As in the case of the bivariate probit,  $U$  stands for a latent continuous variable for which

$$Z_{ji} = \begin{cases} 1 & \text{if } U_{ji} > 0 \\ 0 & \text{if } U_{ji} \leq 0 \end{cases}$$

for  $j = 1, 2$ .

Given the assumption that the error terms,  $u_i$ , are identical for both equations the following likelihood function is derived

$$L^* \equiv \ln L \propto \sum_{i=1}^n \sum_{j=0}^2 Y_{ij} \ln P_{ij}$$

where

$$P_{ij} \equiv \text{prob}(Y_{ij} = 1)$$

and

$$Y_{i0} = \begin{cases} 1 & \text{if } Z_1 = 0 \\ 0 & \text{otherwise} \end{cases}$$

$$Y_{i1} = \begin{cases} 1 & \text{if } Z_1 = 1 \text{ and } Z_2 = 0 \\ 0 & \text{otherwise} \end{cases}$$

$$Y_{i2} = \begin{cases} 1 & \text{if } Z_1 = 1 \text{ and } Z_2 = 1 \\ 0 & \text{otherwise} \end{cases}$$

This model can be estimated via maximum likelihood with the following estimator

$$\hat{\beta}_1, \hat{\beta}_2 := \max_{\beta_1, \beta_2 \in \Theta} L^*$$

where  $\theta$  is the vector consisting of all parameters and  $\Theta$  the parameter space.

Using Monte-Carlo simulations, Sartori (2003) shows that this estimator outperforms the Heckman Selection Model in cases in which no exogenous variable for identification exists and the assumption of identical errors for the two equations is plausible, as discussed above.

### Two-Part Model (Vance and Ritter, 2014)

While Heckman-type models can be effective in addressing selection bias, they do rest on certain assumptions, which researchers must be aware of and should be clearly spelled out. If these assumptions are not met, alternative estimators are likely more appropriate. First, Heckman-based models treat censored observations as missing data. This can be appropriate, but it may be equally plausible to treat them as 0s. As Vance and Ritter (2014: 529) state,

[w]ith respect to the modeling of foreign aid, for example, a missing value would indicate that there is some latent level of foreign aid that is unobservable to the analyst, while a zero value would indicate that the level of foreign aid is just that, zero. This distinction has far-reaching implications for both the type of model applied to the data and the conclusions drawn from it.

Second, Heckman-type models focus on *potential* rather than *actual* outcomes: the coefficient estimates capture the effect of an

explanatory variable on the outcome variable, but this is done irrespective of whether values of the dependent variable are expended.

With respect to arms exports, for example, the question arises as to whether interest really centers on modeling the latent expected value of arms exports that might have occurred under different circumstances for countries that export no arms, or on the actual observed level of exports for countries that do export arms. (Vance and Ritter, 2014: 531)

Vance and Ritter (2014), following Cragg (1971), advocate instead the use of a two-part model (2-PM). The general setup of the 2-PM is similar to that of Heckman-type estimators consisting of a selection equation

$$S_i = \begin{cases} 1 & \text{if } S_i^* = x_{1i} \beta_1 + \varepsilon_i \\ 0 & \text{if } S_i^* \leq 0 \end{cases}$$

where  $S_i^*$  is, again, a latent variable and where  $S_i = 0$  is equivalent to observing a zero on the dependent variable of the outcome equation,  $y_i$ , and  $S_i = 1$  implies that  $y_i > 0$ . The 2-PM model estimates this first selection equation using a probit specification. In a second step, 2-PM estimates an OLS regression conditional on  $S_i = 1$ :

$$E[y_i | S_i = 1, x_{2i}] = E[y_i | y_i > 0, x_{2i}] = x_{2i} \beta_2 E[\varepsilon_{2i} | y_i > 0, x_{2i}]$$

In this set-up, the prediction of the outcome variable in the second stage consists of two parts. It includes the outcome of the first stage,  $P(y_i > 0) = \Phi(x_{1i} \beta_1)$ , and it consists of the conditional expectation of  $y_i$ , namely  $E[y_i | y_i > 0]$ . The 2-PM model differs in two important ways from the Heckman Selection Model. On one hand, the inverse Mills ratio is not included in the outcome equation. On the other hand, the 2-PM produces results for actual outcomes, ‘with the coefficients measuring the effect of an

explanatory variable on the actual amount of the outcome variable expended (Vance and Ritter, 2014: 529). The 2-PM has three main advantages over the standard Heckman procedures. First, it is usually the actual outcome researchers and practitioners are interested in, not the potential one. Second, Monte Carlo simulations suggest that the 2-PM is superior. And, finally, the 2-PM is not tied to the Heckman-based identification requirement: the exclusion restriction.

Note, however, that the 2-PM is also based on another (strong) assumption (Vance and Ritter, 2014: 529): it

assumes that both parts of the model are independent conditional on the observed characteristics  $[x]$ . When this assumption is invalid, that is, when unobserved factors that affect the binary outcome are correlated with factors that affect the continuous outcome, then the Heckman Selection model may be more appropriate for corner-solution data.

### **Matching (Selection on Observables)**

Finally, we describe Matching as a technique to deal with selection problems but refer the reader to the more extensive chapter on matching by Richard Nielsen in this volume. In their study on peace-keeping operations, Gilligan and Sergenti (2008) demonstrate that purely parametric strategies, such as the Heckman Selection Model or the Bivariate Probit, can be inaccurate in addressing non-random assignment, since they rely on unverifiable modeling assumptions and are generally unable to deal with the influence of other existent covariates. The authors propose matching as a more effective solution to these problems as it corrects for the non-random assignment while controlling for the existence of confounding factors.

Matching pre-processes the data to form quasi-experimental contrasts by sampling a subset of comparable cases from the overall pool of observations. The observations contained in this subset resemble each other

as closely as possible, i.e., the differences due to confounding factors are reduced to a minimum. The only – and actually crucial – exception is that these ‘most-similar’ cases differ in whether they received the treatment, what would correspond to the outcome of the selection equation in the examples above, or not. After the matching, researchers can then estimate the effect of the treatment by analyzing the matched sample using parametric methods in order to control for any remaining imbalances (Ho et al., 2007; Morgan and Winship, 2007). In practical terms, the goal of matching is to pre-process the data such that

$$\tilde{p}(X | T = 1) = \tilde{p}(X | T = 0)$$

where  $T$  is a dichotomous variable indicating whether a unit has received the treatment ( $=1$ ) or not ( $=0$ ),  $X$  is a vector of independent variables and  $\tilde{p}(\cdot)$  ‘refers to the observed empirical density of the data, rather than a population density’ (Ho et al., 2007: 212). To obtain the matched data, several matching methods exist. First, one could employ one-to-one or exact matching in that each treated unit would be matched to a non-treated unit possessing the exact same characteristics on the other independent variable. In practice, however, this method is rarely used as it requires that exact matches need to be found, which can be difficult in practice. Furthermore, if no exact match can be found for some of the treated units, this can imply extrapolation bias or change the quantity of interest since these observations cannot be used in the later analysis.

However, matching does not require the exact pairing of the observations but only that the distributions of the treated and the non-treated units should be as similar as possible. Two other methods are therefore often used to perform the matching: propensity score and genetic matching. Propensity score matching summarizes all relevant independent variables, which here are represented as  $X$ , in a common propensity score (Rosenbaum and

Rubin, 1983) often estimated via a logistic regression:

$$\pi(X_i) \equiv \Pr(T_i = 1 | X_i) = E(T_i | X_i),$$

given the true propensity score treatment assignment and the observed covariates are conditionally independent

$$X \perp T \mid \pi(X)$$

Yet, since researchers do not know the true propensity score model, misspecification of the model can result in bias. Genetic Matching could address parts of this problem by incorporating an algorithm that iteratively checks and improves the covariate balance (Diamond and Sekhon, 2013). In particular, Genetic Matching minimizes a generalized version of the Mahalanobis distance (GMD)

$$\begin{aligned} GMD(X_i, X_j, W) \\ = \sqrt{(X_i - X_j)^T (S^{-1/2})^T W S^{-1/2} (X_i - X_j)} \end{aligned}$$

where  $W$  is a  $k \times k$  positive definite weight matrix, for which all elements except those on the diagonal are 0, and  $S^{-1/2}$  is the Cholesky decomposition of  $S$ , i.e.,  $S = S^{-1/2} (S^{-1/2})^T$ . It is possible to incorporate, in addition to the independent variables in  $X$ , also the propensity score  $\pi(X)$ .

## EMPIRICAL ILLUSTRATIONS

In light of the theoretical overview of selection problems and ways of addressing them in political science and international relations, we now turn to a series of illustrations. We ultimately opted for three such examples that, in combination, likely cover the majority of selection problems that analysts face in their own research: selection on observables, selection on unobservables and selection issues in light of overly limiting exclusion

restrictions. The first illustration is based on Spilker and Böhmelt (2013) who propose using matching methods to overcome challenges stemming from sample selection. The illustration for the second selection problem follows Plümper et al. (2006) and demonstrates the use of the ‘classical’ Heckman (1976) selection model to address selection on unobservables. Finally, we discuss the work of Vance and Ritter (2014) who have introduced a two-part model (2-PM), which is straightforward in the estimation and requires less difficult identification criteria than the more ‘traditional’ approaches to deal with sample selection.

For each illustration, we first outline the key argument and demonstrate where and how problems stemming from sample selection emerge. Second, we then summarize the results of one ‘naïve’ estimation that does not take sample selection into account. Third, we show the studies’ ways of addressing selection bias, which includes presenting the replication code of the methods used, and discuss the ‘corrected’ results, i.e., model estimates when taking selection bias seriously.

### *Illustration 1: Treaty Design and States’ Self-Selection into International Agreements*

Scholars have long assumed that PTAs can induce domestic policy changes and, most importantly for the discussion in the following, reduce human rights violations. The mechanism of this states that if these treaties, which aim at liberalizing trade between their member countries, comprise ‘hard’, i.e., legally binding and precise human rights standards, trade benefits can be made conditional on treaty members’ compliance with international human rights. In essence, by linking gains from trade to the compliance with human rights, PTAs offer a way to withhold economic benefits or impose economic sanctions in the case of abuse, torture or

repression (Hafner-Burton, 2005). Hence, PTAs comprising a ‘hard-human rights standard’ should lead to an increase in their member countries’ respect for human rights.

Spilker and Böhmelt (2013) question this presumption. They argue that previous work on PTAs and members’ human rights compliance neglects a selection process underlying the formation of these treaties: states take into account what may happen at the succeeding enforcement stage already when they establish a particular regime (von Stein, 2005; Hill, 2010). Put differently, countries are likely to be aware of the ‘shadow of the future’ and, hence, should already consider what may happen at the succeeding enforcement stage when establishing a particular PTA. This implies that countries that agree to include ‘hard’, i.e., binding and precise, human rights standards in their PTAs should differ in important and predictable ways from those countries that do not want to include these standards in their PTAs. Specifically, states should agree on ‘hard’ human rights standards in PTAs only if they have a general propensity to abide by human rights in the first place. If this selection process holds, scholars need to acknowledge countries’ preferences for the establishment of international institutions, including PTAs, when studying their effects in order to avoid biased inferences. It is therefore crucial for studies examining the effectiveness of PTAs in promoting human rights that both theory and empirics acknowledge the factors that motivate countries to include hard human rights standards and those that do not require the inclusion of any human rights clauses. Otherwise, it may well be that the findings we obtain are spurious or biased.

To examine the effect of hard human rights standards in PTAs on countries’ compliance with human rights, Spilker and Böhmelt (2013) have compiled a monadic country-year data set on human rights compliance and PTAs between 1976 and 2009. Ultimately, their time-series cross-section data comprise 4,117 country-years for 174 countries with

249 PTAs. The outcome variable in this study, *Political Repression*, is operationalized by the level of political terror, i.e., data on ‘murder, torture or other cruel, inhuman or degrading treatment or punishment; prolonged detention without charges; disappearance or clandestine detention; and other flagrant violations of the right to life, liberty, and the security of the person’ (Hafner-Burton, 2005: 615–619). The final item follows Gibney et al.’s (2011) 5-point ordinal scale operationalization of the Political Terror Scale with higher values pertaining to more governmental repression. The core explanatory variable in this study, and also the treatment item that helps identifying sample selection, is *PTA Hard Law*, which measures state membership with PTAs supplying hard standards: an observation takes on a value of 1 in a specific year if a state belongs to any PTA with hard law human rights standards.

With these specifications in mind, Spilker and Böhmelt (2013) first estimate a naïve model that ignores the likely selection effect. This model is a replication of Hafner-Burton’s (2005) ordinal logistic regression. Several control variables are included in this model, but we omit them from the presentation in the following. Instead, we focus on the impact of *PTA Hard Law*. As demonstrated in Table 37.1a, this variable exerts a substantial and significantly negative impact on governmental repression (significant at the 0.1 level). However, this finding might be misleading and actually driven by a selection process, since tough human rights standards

**Table 37.1a Naïve estimation**

should be systematically included in PTAs due to certain kinds of country interests or domestic characteristics.

Spilker and Böhmelt (2013) employ matching to address this problem. Matching corrects for the non-random assignment while controlling for the existence of confounding factors. Matching pre-processes the data to form quasi-experimental contrasts by sampling a subset of comparable cases from the overall pool of observations. The observations contained in this subset resemble each other as closely as possible, i.e., the differences due to confounding factors are reduced to a minimum. The only – and actually crucial – exception is that these ‘most-similar’ cases differ in whether they received the treatment (*PTA Hard Law*) or not. After the matching, one can estimate the effect of the treatment by analyzing the matched sample using parametric methods in order to control for any remaining imbalances. Specifically, Spilker and Böhmelt (2013) use genetic one-to-one matching with replacement (Sekhon, 2007; Diamond and Sekhon, 2013), refraining from matching on all explanatory variables due to two reasons. First, this would not avoid matched datasets with still significant imbalances. Second, and in the words of Ho et al. (2007: 216f):

the theoretical literature emphasizes that including variables only weakly related to treatment assignments usually reduces bias more than it will increase variance, and so most believe that all available control variables should always be included. However, the theoretical literature has focused primarily on the case where the pool of potential control units is considerably larger than the set of treated units. Some researchers seem to have incorrectly generalized this advice to all datasets. If, as is often the case, the pool of potential control units is not much larger than the pool of treated units, then always including all available control variables is bad advice.

The approach in Spilker and Böhmelt (2013), thus, corresponds to the general genetic algorithm used by Sekhon (2007: 12ff), which maximizes the smallest  $p$ -value for  $t$ -tests in

each iteration of the matching procedure. The **R** code for the matching used by Spilker and Böhmelt (2013) is:

```
library("foreign")
library("Matching")
mydata<-read.dta("01_RIO shapefile.
dta")
attach(mydata)

Des<-cbind(ccode, year)

X<-cbind(trade_lag_log, polity2_lag,
hras_lag)
BalanceMatrix<- cbind(trade_lag_log,
gdp_lag, polity2_lag, durable_lag,
density_lag, hras_lag)

gen1<-GenMatch(Tr=hard_lag, X=X,
BalanceMatrix=BalanceMatrix, pop.
size=1000)

mgen1<- Match(Y=repression_final,
Tr=hard_lag, X=X, Weight.matrix=gen1)
balancetest<-MatchBalance(hard_
lag~trade_lag_log+gdp_lag+polity2_
lag+durable_lag+density_lag +hras_
lag, match.out=mgen1, nboots= 1000)
attach(mgen1)

U<-cbind(mgen1$mdata$Y, mgen1$mdata$Tr,
mgen1$mdata$X, mgen1$index.treated,
mgen1$index.control)

V<-d(BalanceMatrix[index.treated,],
BalanceMatrix[index.control,])
X<-rbind(Des[index.treated,], Des
[index.control,])
GenMatch1data<-cbind(U, V, X)
GenMatch1dataset<-data.frame
(GenMatch1data)
summary(mgen1, full=TRUE)
write.dta(GenMatch1dataset, file="02_
Matched data hard PTA")
```

Ho et al. (2007: 211f) suggest using the same parametric estimator for the matched data one would have employed in the first place, i.e., before the matching. Table 37.1b summarizes the main results (control variables omitted) that are based on the matched data. Indeed, unlike in Table 37.1a above or Hafner-Burton (2005), *PTA Hard Law* is insignificant. In other words, the effect of hard human rights standards vanishes once

**Table 37.1b Corrected estimation**

	<i>Model 2</i>
PTA Hard Law	0.191 (0.195)
Observations	2,754
Log Pseudolikelihood	-3,058.422
Wald $\chi^2$	468.19

selection is taken seriously: countries agree on including hard law human rights standards in PTAs only if they intend to comply with these standards anyway, i.e., if there is a general tendency to abide by human rights in the first place. Under those circumstances and considering the nature of selection, however, it is unlikely that PTAs can exert a causal impact on states' human rights compliance.

### ***Illustration 2: A Two-Stage Selection Process of EU Enlargement***

Our second illustration focuses on the enlargement process of the European Union (EU). States seeking to join the EU have to adjust legislation prior to accession: laws, regulatory frameworks and administrative practices all have to be brought in line with the *acquis communautaire* (Hillion, 2002; Böhmelt and Freyburg, 2013). Scholars generally agree that the conditional incentive of EU membership was the main force driving the incorporation of the *acquis* by candidate countries (Schimmelfennig and Sedelmeier, 2004). Accession conditionality aims to induce formal and practical compliance with the EU accession criteria as an instrumentally and strategically calculated reaction by the target countries in response to the incentive of EU membership. In other words, governments comply with EU law if the calculated benefits of membership exceed the expected political costs of compliance that

are associated with the accession criteria. Thus, EU conditionality is a (limited) bargaining strategy of 'reinforcement by reward' (Schimmelfennig and Sedelmeier, 2004: 662) used by the EU to make the target countries comply with its conditions.

This perspective treats the EU and applicant countries as two different actors that pursue their own interests in a bargaining environment, but are also closely linked to each other with actions on one side influencing the other. However, the dominant view has been for a long time to study EU enlargement as 'EU-centric', which was driven by the assumption that it is the EU setting the rules and procedures. Plümper et al. (2006) were among the first to move beyond this overly simplistic approach. On one hand, they explicitly sought to model the interaction of the two independent players, i.e., the EU and a potential member state. On the other hand, Plümper et al. (2006) suggested seeing EU accession as a two-stage process: a first stage that pertains to an individual country's decision to apply for membership, and a second stage focusing on the EU as an actor making a decision on whether or not to accept these applicants as new members.

It is precisely this two-stage process that comprises a self-selection process: as Plümper et al. (2006: 17–18) state, 'the EU's repeated declaration to accept only stable democracies with a market-oriented economic system and the clearly stated regulatory conditionality resulted in a self-selection process among transition countries'. This mechanism induced two related, albeit different, outcomes. First, the set of states seeking membership in the EU is not random. Overly autocratic countries, for example, with few possibilities (or incentives) to democratize were excluded ex-ante and, thus, would probably not even submit an application in the first place. Second, the set of countries that eventually applied for EU membership were somewhat similar in their characteristics, for example, some satisfactory degree of democracy to begin with. Applicants thus varied

little in key features that may have motivated them to apply for EU membership in the first stage but would be of little use to the EU in the second stage when deciding to grant membership. As a result, ‘while the factors identified in the enlargement literature may explain the self-selection among the transition countries, they do not contribute much to the EU’s selection amongst applicant countries’ (Plümper et al., 2006: 18).

In sum, EU accession is a strategic, two-stage selection process in which potential members decide whether to apply or not, before, secondly, the EU decides to grant membership to some (or all) of those that submitted an accession application. Both stages are intertwined and ignoring the prior selection stage when evaluating the EU’s actions in the second phase may induce biased estimates. Plümper et al. (2006: 23) eventually argue that despite the strong association between the two levels, there are different factors shaping their outcomes in that the level of

democracy matters only in the first stage, where political leaders in transition countries decide whether to apply or not. In the second stage, the EU primarily uses information on the revealed preferences of political parties. We expect that the strength of parties hostile to the EU and the capability of these countries to implement *acquis communautaire* reforms have the greatest influence on EU’s accession decision.

However, ‘simply excluding non-applicant countries would cause a severe estimation bias that might lead to wrong inferences’ (Plümper et al., 2006: 26).

Plümper et al. (2006) have compiled a monadic, country-year time-series cross-section data set comprising all European transition countries between 1990 and 2001. As above, we start empirically by estimating a naïve model, which does not take into account the outlined selection problem. For that model, we concentrate on Plümper et al.’s (2006) second stage. The dependent variable here is binary, receiving a value of 1 if a country has been selected by the EU

Commission for early accession according to the Copenhagen decision, or 0 otherwise. The explanatory variables pertain to the number of closed chapters and the existence of euroskeptic parties in government. First, applicants have to negotiate and close each of the 30 chapters of the *acquis communautaire* before accession is granted, and the chapter variable comprises scores from 0 to 30 as a result. Second, there is a dichotomous variable on whether a euroskeptic party is part of an executive coalition. It is expected that the chapter variable should be positive correlated with the outcome, while the euroskeptic dummy exerts a negative influence. Table 37.2a is our ‘naïve’ estimation based on a probit model.

When not taking the presumed selection effect into account, *Chapter* is positively signed and statistically significant – as expected. However, the second variable on euroskeptic parties in government is also positively signed and significant at the 10% level, suggesting that euroskeptic parties in government have actually increased the likelihood of the EU granting early accession. Clearly, this finding appears less plausible and, in fact, points to the possibility that we have not taken selection seriously into account. In order to do so, we need to modify the naïve estimation along the lines proposed in Plümper et al. (2006): we must specify variables for the first stage and, in addition, change the estimator. On one hand,

**Table 37.2a Naïve estimation**

	<i>Model 1</i>
Chapter	0.269 (0.048)
Gov. Participation of Euroskeptic Parties	0.809 (0.463)

Observations	120
Log Likelihood	-21.457
Wald $\chi^2$	77.18

Table entries are coefficients. Standard errors in parentheses.

we add a first stage considering the argument of a two-stage process in Plümper et al. (2006), which then captures states' decision whether to apply for EU membership or not. The outcome variable here indicates whether (1) or not (0) a state applies for membership in the EU. Plümper et al. (2006) focus on two explanatory variables for this first stage: a measure from the European Bank for Reconstruction and Development on regulatory quality and a modified version of the *polity2* scale of the Polity IV database. Both variables are expected to positively influence the likelihood of a country applying for EU membership.

On the other hand, we now use a probit version of the classical Heckman (1976) selection model. This 'probit model with sample selection' was originally developed by Van de Ven and Van Praag (1981) and it endogenizes, in this context, the decision to apply for EU membership in the first stage, with the estimated probability of non-application then being used as a regressor in the second stage on early accession (Plümper et al., 2006: 26). In this model,

the estimated mean function in the second stage is conditioned on the selection process of the first stage. [...] It reflects well the self-selection process in the first stage and also assumes that the probability of a country's non-application bears an influence on the likelihood of accession in the second stage. (Plümper et al., 2006: 26)

In the first stage, all possible applicant countries for EU membership are included in 1990–2001, while the second stage only considers the self-selected sample. The code for implementing this in Stata is as follows:

```
heckprob accneg lag_chapter lag_
  oppcoal, select (euapp = lag_regqual
  lag_democ) first nocon
```

The command `heckprob` calls the probit selection model, while `accneg` is the outcome variable in the second stage. The selection equation or first stage is specified in the second part of the code above, with `euapp`

**Table 37.2b Corrected estimation**

being the dependent variable here. The option `first` specifies that the first-stage probit estimates are shown, while `nocon` suppresses the constant term as it is not required (Plümper et al., 2006: 37). Table 37.2b summarizes the findings from the Heckman model. In the first stage, both explanatory variables exert a positive influence, which is expected according to the theory. Countries that were more democratic and had higher regulatory quality were more likely to apply for accession. Coming to the second stage, the number of concluded chapters is, as it was the case in the naïve estimation above, positively correlated with the chances of accession. Strikingly, though, *Gov. Participation of Euroskeptical Parties* is now negatively signed and, hence, has the opposite sign of the coefficient in the naïve model. The corrected model thus suggests that more euroskeptical parties in the government do in fact lower the chances of accession. Finally, the significant estimate of the  $\rho$  parameter indicates that the Heckman model fits the data better than independent estimates of the selection and outcome equations.  $\rho$  is an estimate of the correlation of the error terms in the two stages. The estimate of  $\rho$  is

expected to be negative if unobserved features that increase the likelihood of selection decrease the probability accession, which is given in this case.

### ***Illustration 3: The Self-Selection into Peace and Conflict – A Two-Part Model Application***

The selection problem underlying our third illustration is similar to the ones discussed above, i.e., the analysis of non-random data that induces bias as the error term is correlated with the explanatory items. However, we discuss an estimator that allows researchers to circumvent some of the problems associated with the ‘classical’ Heckman selection models. Recall that Heckman-type models jointly estimate two stages: a selection equation that is usually based on a probit model, which captures the determinants of censoring; and an outcome equation, usually based on OLS, which focuses on the non-censored observations. The key component of such models is that the latter stage comprises the inverse Mills ratio, i.e., the ratio of the density function of the standard normal distribution to its cumulative density function, estimated from the first stage as an additional regressor (Vance and Ritter, 2014: 529).

While Heckman-type models can be effective in addressing selection bias, they do rest on certain assumptions, which might be problematic in practice as discussed in Section 2 of the chapter above. In the following, we there for illustrate the usefulness of the 2-PM as proposed by Vance and Ritter (2014). We present a basic analysis based on Vance and Ritter (2014) who employ Sweeney’s (2003) data on militarized interstate dispute intensity. The selection process is based on incidence and severity of interstate disputes: the outcome variable is censored at 0 for cases in which severity is low or a conflict has not occurred. In what follows, we focus on *Contiguity*, which is a binary item capturing

whether two states in a dyad are contiguous or not. But there are also controls for power (*Capability Ratio*), regime type, trade, alliance, IGO links and countries’ major power status. As before, we present a naïve estimation, which is a simple OLS model using intensity as the outcome variable, and a corrected model, which is based on the 2-PM.

Note the statistical insignificance of *Contiguity* in the naïve model. The item becomes statistically significant, however, when using a specification based on the 2-PM. The replication code used for Table 37.3b is depicted below:

```
probit disputex ln_capratio smlpmat
smldep smigoabi allies contigkb log-
dstab majpower
estimates store v
regress brl2 contigkb if disputex==1
estimates store z
suest v z, robust
```

In a first step, a probit model on dispute incidence (1 = incidence; 0 = no incidence) is estimated, while the estimates are stored in a

**Table 37.3a Naïve estimation**

Table entries are coefficients. Standard errors in parentheses.

second step (*estimates*). Third, we run an OLS model using dispute intensity as the outcome, employing contiguity as an explanatory variable and calculating this conditional on a dispute having occurred. The estimates are stored again, while the final step in the 2-PM is the estimation of a seemingly unrelated regression using the *suest* command in *Stata*. When running these commands, *Contiguity* now becomes statistically significant in Table 37.3b

While the 2-PM can outperform the Heckman-based estimation procedures, there are no ‘hard and fast rules that point to the superiority of one model over the other in any given situation’ (Vance and Ritter, 2014: 536). Instead, theoretical, practical,

and statistical considerations should drive the choice. However, given the right assumptions and if researchers want to focus on actual rather than potential outcome values while circumventing the sometimes overly restrictive identification requirement of any Heckman procedure, the 2-PM can be a powerful estimation tool.

## CONCLUSION

Sample selection and selection bias can pose serious challenges to inferences drawn from systematic data analysis. If neglected, as we have sought to demonstrate theoretically and via three different illustrations, it can bias results quite severely, rendering any conclusions for practitioners and policymakers useless. Fortunately, methods in the social sciences and data analysis have advanced, and there now exist various methodological approaches – albeit with sometimes very strong assumptions that are untestable – for effectively addressing problems stemming from sample-selection bias.

The main motivation of this chapter was to define what selection bias is, what consequences it can have and from an application-based point of view to show where and how this is given in actual empirical work. We have sought to focus on the most important challenges and solutions in this context, but space limitations clearly prevent us from reviewing the broad range of all possible solutions to selection bias that social science methodology has identified. Leemann’s (2014) Strategic Selection Estimator is one of the approaches we could not fully discuss in this chapter, although such strategic estimators are likely to gain importance in the future.

## Note

- 1 Heckman (1976, 1979) introduces his estimator not in the context of a confounding problem, such as our PTA and human-rights example, but

for a situation in which the dependent variable is only observable for specific observations. While in our case it is not random which country enters into which PTA, in the classic Heckman example of women's hourly wages, we cannot observe the dependent variable, i.e., wages, for those women who decided not to go to work, which makes it problematic to estimate, for example, the effect of having children on wages.

# Dyadic Data Analysis

Eric Neumayer and Thomas Plümpert

## INTRODUCTION

Humans are social beings because it is in their interest and their nature to interact with each other. Scholars have studied social relations since at least the work of Georg Simmel and Emile Durkheim, who both argued that social relations should be the very focus of social scientists. Yet, though the social sciences carry the label ‘social’ for good reason, arguably we devote by far the largest share of our attention and resources to the analysis of *individual* preferences, strategies, behaviours and outcomes (Krasikova and LeBreton, 2012). The analysis of the causes and consequences of social interactions, while important, remains a rather neglected field of research.

One important, though by no means the only, way of studying social interactions is by employing dyadic data, defined as data in which the unit of analysis is the relation between two actors, as opposed to monadic data, in which the unit of analysis is an individual actor. Dyadic data require a

link, an interaction, a relation or a contract between two actors. Dyadic data analyses are employed in political science, international relations, international economics, psychology and sociology, among others. Poast (2016: 369) calls it ‘the standard research design in quantitative international relations’. Nevertheless, given that the analysis of social relations, interactions and so on ought to be hardwired into the DNA of the social sciences, why is it that dyadic analyses of social relations are relatively few and far between across the social sciences?<sup>1</sup>

We believe that the widespread neglect of dyadic analyses results from the added difficulty of analysing dyadic data, which shares many of the specification problems and inferential challenges that exist with monadic analyses<sup>2</sup> – with many more on top. Dyadic data can be directed or undirected (see the second section of this chapter), they exacerbate the problem of rare events (third section), allow for regressors from multiple levels of analyses (fourth section) and

introduce an additional form of potentially unobserved heterogeneity (fifth section), and the specification and analysis of spatial interdependence among dyads is much more complex than in monadic data (sixth section). We briefly discuss extensions and alternatives to dyadic designs in the seventh section but conclude in the final section that dyadic analyses are here to stay – and for good reason.

We employ two running examples, namely international trade and international war. Both phenomena cry out for, and have extensively been studied with, dyadic data. They differ, however, in the kinds of specification challenges and inferential problems posed: bilateral trade is continuously measured and not rare, whereas international war is often dichotomously measured (war vs no war or, increasingly, war onset vs no war onset) and is a phenomenon that is rare both in absolute and relative terms. This allows us to discuss problems and solutions separately for continuous and also binary categorical data whenever a problem or solution depends on the measurement scale of the dependent variable.

## DIRECTED VS UNDIRECTED DYADS

Dyads can be undirected or directed (Handcock and Gile, 2010; Neumayer and Plümper, 2010a). While in undirected dyads the two actors  $i$  and  $j$  (we also call them ‘nods’) are functionally identical to each other, such that  $y_{ij}$  is indistinguishable from  $y_{ji}$ , these actors are functionally different in directed dyads, such that  $y_{ij} \neq y_{ji}$ . Directed dyads distinguish between source and target, sender and receiver, proposer and acceptor, attacker and defender, exporter and importer and so on. For simplicity and terminological neutrality, for the most part we will say that directed dyad relations occur between source  $i$  and target  $j$ .

Directed dyads, in turn, fall into two categories: symmetric directed dyads, where each potential source is also a potential target, and

asymmetric directed dyads, where sources and targets are entirely separable so that each nod is exclusively either a source or a target. Examples of asymmetric directed dyads include employment relations between employers and employees, shop–customer relations and asymmetric relations between nations in the form of, for example, international aid from donors to recipients (Elkins et al., 2006; Neumayer and Plümper, 2010a). In asymmetric directed dyadic interactions,  $i$  can do something to  $j$  that  $j$  cannot or does not do to  $i$ .

Whether an analysis employs monadic or dyadic data and, if the latter, employs directed or undirected data often follows more from research tradition, data availability and convenience than from the underlying data generating process. For our two examples, it is possible to analyse why some countries trade more in total than others, analyse war at the monadic level and ask why country  $i$  is involved in a war. It is also possible, however, to analyse these phenomena with undirected dyadic data and ask why there is more total trade between some countries than other country pairs and why country  $i$  is at war with country  $j$  but not others. Finally, employing directed dyadic data allows one – in fact, forces one – to distinguish between exporter and importer and between attacker and defender.

The kind of data employed exerts a strong influence on the research question and on the inferences one can derive from the analysis. Yet, it should be the research question and the intended inferences one wishes to make that determine whether one employs monadic data, undirected dyadic data or directed dyadic data, and not vice versa. Crucially, the analysis of dyadic data supports the inclusion of regressors that vary at the ‘nod’ level (properties of the units that form the dyad), thus allowing inferences that at least resemble inferences from the analysis of monadic data. In contrast, the analysis of monadic data does not allow researchers to make inferences about the dyadic level.

Data generating processes that call for directed dyadic data are fairly common. For

example, in many country dyads, trade is somewhat unbalanced in that the volume of exports from  $i$  to  $j$  differs from the volume of exports from  $j$  to  $i$ . International wars are typically started by one side, though whether this means the side that formally started the conflict can be (entirely) blamed for the war is a different matter, as the debate around the German 'Alleinschuld' (sole guilt) for the First World War testifies.

As an example to illustrate how the choice of unit of analysis impacts upon findings and inferences, consider the so-called 'democratic peace' literature in particular (De Mesquita et al., 1999; Maoz and Russett, 1993). Though war and peace are both social interactions, for a surprisingly long period of time researchers studied conflict parties in isolation. The question why some countries are more likely than others to be involved in a war is important; but is it not even more important to know why country  $i$  is at war with country  $j$ , or why country  $i$  attacked country  $j$  (Gleditsch and Hegre, 1997; Rousseau et al., 1996)? Crucially, results and inferences based on different units of analysis also differ. At the monadic level, the democratic peace research asked whether democracies are more pacific than autocratic regimes and it generated rather mixed results (Benoit, 1996; Weede, 1984): some scholars found that democracies are more pacific; others did not find a statistically significant difference between democracies and autocracies. This variety of results disappears in dyadic data analysis. Democracies may not be less likely to fight wars, but they are significantly less likely to go to war with each other (Maoz and Abdolali, 1989; Maoz and Russett, 1992; Raknerud and Hegre, 1997). As another example, Buhaug et al. (2008) find that in a dyadic 'political centre-periphery' analysis, the discrimination of large ethnic groups increases the likelihood of civil war – a finding absent from the most highly cited monadic study of civil war, by Fearon and Laitin (2003).

## THE PROBLEM OF RARE EVENTS

Moving from monadic to undirected dyadic data and from undirected to directed dyadic data dramatically increases the number of observations but not the number of events or the aggregate of the analysed phenomena. With categorical outcomes at least, the analysis of dyadic data often, though not always, generates two related and at times confused problems: relatively and absolutely rare events. Events are relatively rare when potential outcomes – say, war and peace – are not equally likely: peace years are much more frequent than war years. Events are absolutely rare when the number of one potential outcome is low in absolute terms: for example, there simply are very few war years. Of course, the combination of relatively and absolutely rare events is also possible: international wars are both absolutely and relatively rare in one year and their onset is even rarer than their incidence, since many wars last more than one year. In an ideal world, outcomes would be neither rare in absolute nor relative terms. The worst outcome for quantitative analysts is the combination of an extremely low number of outcomes of a particular type with an extreme imbalance between outcomes, i.e., the combination of relative and absolute rarity.

With respect to our two examples, the problem of rare events is not so much an issue for international trade but it is for international war. If we extend the number of years, war years remain rare relative to peace years, but the absolute number of wars increases. This can help with conventional logit or probit analysis of dichotomous dependent variables, as Paul Allison (2012) explained in a blog entry:

[M]any researchers worry about whether they can legitimately use conventional logistic regression for data in which events are rare. [...] The problem is not specifically the rarity of events, but rather the possibility of a small number of cases on the rarer of the two outcomes. If you have a sample size of 1000 but only 20 events, you have a problem. If

you have a sample size of 10,000 with 200 events, you may be OK. If your sample has 100,000 cases with 2000 events, you're golden. There's nothing wrong with the logistic model in such cases. The problem is that maximum-likelihood estimation of the logistic model is well-known to suffer from small-sample bias.

Yet, there will be events that remain so rare that even after more years are added, conventional maximum-likelihood estimation like logit or probit are unlikely to be useful, since they will sharply underestimate the likelihood of these absolutely rare events to occur. To see how moving to the undirected dyadic or, worse still, to the directed dyadic level exacerbates the problem of rare events, let us take a closer look at international war. For 2003, Uppsala and PRIO's Armed Conflict Data coded two international war onsets with six involved countries. At the same time, roughly 200 independent countries existed. At the monadic level, international war was a rare event in the year 2003 with approximately 3% of units of analysis at war (6/200). Coding undirected dyads of war gives four bilateral war events, namely between Pakistan and India, Iraq and Australia, Iraq and the UK, and Iraq and the United States. Not only has the number of observations with war events actually decreased from six to four but the problem of rare events is massively exacerbated by the fact that 200 independent countries result in 19,900 undirected and 39,800 directed country dyads, thus generating approximately 0.02% of units of analysis at war in undirected dyads (4/19,900) and 0.01% of units at war in directed dyads (4/39,800). Granted, other years may see a slightly larger number of international war onsets, and increasing the number of years included in the sample will reduce the absolute rarity of the war-onset event but not its relative rarity.

In order to reduce relative rarity or even perfectly balance the outcomes, one can match peace-year observations to annual war-year observations based on observables. Alternatively, one can randomly draw a specified number of peace-year observations to at

least equal the number of war-year observations. This is indeed the ingenious method called rare-events logit, which King and Zeng (2001) have suggested for dealing with the problem of relatively rare events. In a nutshell, the procedure includes all rare events in the analysis and repeatedly draws at least an equal number and at most up to five times more observations with the frequent outcome – here, dyads not at war – to the sample and then corrects the estimated coefficients and standard errors to account for the sampling.<sup>3</sup> By drastically reducing the number of observations, rare-events logit has the additional advantage of researchers being able to focus their efforts on collecting more and better data for a much smaller sample. For events that are absolutely rare, Firth (1993) has proposed a technique called penalized maximum likelihood, which reduces small sample bias in logistic models.

## MULTILEVEL ANALYSIS

The analysis of dyadic data increases the 'levels' of analysis and therefore the kinds of regressors that can be included in the analysis. Even in relatively simple model specifications, three different types of factors may influence the relation between actors *i* and *j* that form the dyad *ij*, which is the unit of analysis:

- properties of *i*:  $x_i$
- properties of *j*:  $x_j$
- properties of *ij*:  $x_{ij}$

The standard workhorse assumption of simple additivity between these factors is not necessarily plausible in the analysis of dyadic data. Dyadic data are multilevel data with the two nodes and the dyad constituting separate levels. Potentially complex multiplicative causal relations between explanatory variables have been suggested by theorists.

Consider the example of the gravity model of international trade, which strongly relies on inverse distance and the gross domestic

product (GDP) of *i* and *j* to explain trade relations (Mátyás, 1997). The distance variable is often motivated and theoretically justified by Tobler's (1970) law, which states that 'everything is related to everything else, but near things are more related than distant things'.<sup>4</sup> Tobler's law is consistent with any monotonically increasing function. Alternatively, gravity models can also be motivated by Newton's law of gravity, which states that 'every particle attracts every other particle in the universe with a force which is directly proportional to the product of their masses and inversely proportional to the square of the distance between their centers'.<sup>5</sup> Of course, countries are not bodies, but the logic could apply if we accept the countries' GDP as the equivalent of 'mass'. This is indeed how the gravity model of international trade is typically specified (hence the name), following Tinbergen (1962), namely as:

$$y_{ij} = GDP_i \cdot GDP_j \cdot 1 / distance_{ij} \cdot \varepsilon_{ij}$$

Operationally, the gravity model is either estimated linearly after log-linearizing the above equation, which creates the issue of what to do about observations of zero bilateral trade, or with a Poisson pseudo maximum-likelihood estimator, following Silva and Tenreyro (2006), which has become standard practice now.

Similar multiplicative effects could also exist between the factors accounting for the properties of the dyad *ij* – distance in a gravity model of international trade – and properties of actors *i* and *j*, such that these factors condition each other. For example, the effect of distance on trade volumes depends on the production structure of *i* and *j*. The assumption that distance between two countries reduces trade is of course plausible and can be derived from virtually any model of international trade that allows for the existence of transaction and transportation costs. However, the effect of distance on trade is probably strongest for countries that produce goods that are both heavy and perishable and weakest for

countries that produce modern skill-intensive services that can be exported with the click of a button. Accordingly, the production structure of *i* and *j* enters the model explaining trade between *i* and *j* not just additively but also as a multiplicative term that conditions the effect of distance of trade.

In other contexts, the multiplicative effect may not be the appropriate specification and instead properties of *i* and *j* can have an additive effect so that  $y_{ij} = f(x_i + x_j)$ , a weakest link effect so that  $y_{ij} = f[\min(x_i, x_j)]$ , a strongest link effect so that  $y_{ij} = f[\max(x_i, x_j)]$  or combinations of these options. In international-conflict research, Oneal and Ray (1997) have argued for the existence of a 'weakest link' in the effect of democracy. They suggest that the lowest level of democracy in a dyad of countries is the decisive factor for the probability of international conflict. This hypothesis gives one nod in a dyad a strong influence and the other nod no influence on outcomes. Consistent with this hypothesis, they find that only the lower democracy score in a country dyad has a statistically significant effect, whereas the higher democracy score has an effect that is both small in size and statistically insignificant.

## UNOBSERVED DYADIC HETEROGENEITY

Regression models assume conditional homogeneity. After controlling for all factors included in the model, all remaining variation should be random. Of course, this assumption can hardly ever be satisfied in empirical research, regardless of whether the dependent variable is monadic or dyadic. Empirical models need to simplify the true data generating process, and simplification always leads to a violation of the conditional homogeneity assumption.

Yet, because dyadic data bring multiple levels into the analysis, the relevance of potentially unobserved heterogeneity increases: on

top of potentially unobserved factors at nodes *i* and *j* comes potentially unobserved dyad heterogeneity. For the example of international war, such unobserved dyad heterogeneity may result from numerous factors, including unmeasured animosities between countries in a dyad. As King (2001: 499) explains:

[S]uppose a degree of antipathy exists between pairs of countries, based on cultural, historical, or personal animosities, that has not been measured. (For example, completely accounting for problems between India and Pakistan by the usual list of annual dyadic variables we have measured seems unlikely.) The ‘historical animosity’ variable is (1) unmeasured, probably (2) causally prior to and (3) correlated with democracy, and (4) affects the probability of conflict—precisely the conditions for large omitted variable biases.

The combination of potentially unobserved heterogeneity at the level of either node *i* or node *j* or at the *ij* dyad level has naturally prompted many to call for the inclusion of fixed effects at the unit *i*, unit *j* and/or dyadic *ij* level.<sup>6</sup> For example, according to Wilson et al. (2005: 849), ‘a correct specification of the gravity model is parsimonious in specific economic variables’ and ‘rich in fixed effects’. In fact, because of the multilevel nature of dyadic analysis, the following most stringent fixed-effects specification is possible for a variable of interest that varies at the dyadic level over time, namely unit *i*-specific year fixed effects ( $\eta_{it}$ ), unit *j*-specific year fixed effects ( $\lambda_{jt}$ ), and dyad fixed effects ( $u_{ij}$ ), as in the following specification:

$$y_{ijt} = \alpha + \beta x_{ijt} + \eta_{it} + \lambda_{jt} + u_{ij} + \varepsilon_{ijt}$$

This specification obliterates the need to control for anything that is constant over time within dyads or that varies in any shape or form over time at the level of unit *i* or unit *j*.

However, what works well for a continuously measured variable such as international trade, which has great variation over time and is neither relatively nor absolutely rare (see, for example, Czaika and Neumayer, 2017), can represent the equivalent of ‘throwing

out the baby with the bath water’ (Beck and Katz, 2001) for dyadic data such as international war, which is dichotomous and both relatively and absolutely rare.

And yet, this is exactly what Green et al. (2001: 442) called for in a paper that attracted much attention at the time, based on the contention ‘that analyses of pooled cross-section data that make no allowance for fixed unobserved differences between dyads often produce biased results’. We agree with King’s (2001) assessment that Green et al. (2001) rightly draw attention to an important problem but that the proposed solution does not work for rare dyadic categorical data. Beck and Katz (2001: 490) offer Weibull duration models with gamma heterogeneity and the frailty Cox proportional hazards model that allows for random effects (frailty) as alternatives to the fixed-effects model, exploiting the fact that many dyadic data with binary outcomes resemble event history data. Collecting further data that can control for some dyadic heterogeneity is another option promoted by King (2001) – an option considerably aided if the relevant sample for the analysis of rare events can be drastically pruned by randomly drawing observations of the frequent event to all observations of the rare event (see the earlier section on ‘The Problem of Rare Events’). Last but not least, in Neumayer and Plümper (2017b), we propose a number of robustness tests that can be employed to test the extent to which potentially omitted variables, be they time-invariant or not, change the substantive findings.

A more radical approach to dealing with heterogeneity across dyads is to make dyads more homogeneous via the selection of relevant dyads or, equivalently, by dropping irrelevant dyads. The idea that sampling on the dependent variable – which is widely regarded as a sampling strategy that generates the most biased estimates – can be a solution to the problem of unobserved heterogeneity that ultimately results from the notion that fixed-effects models do not work well with a binary dependent variable and rare events

(Beck and Katz, 2001; King, 2001). The dyad fixed-effects model simply drops all dyads that never fought a war. The selection-of-relevant-dyads approach, on the other hand, distinguishes between those dyads that have never been at war that are relevant for the study of international war and those dyads who have never been at war that are irrelevant or ‘nearly irrelevant’ (Maoz and Russett, 1993: 627). Relevant dyads are those which have been never at war but could, whereas irrelevant dyads have an assumed a priori zero probability of going to war against each other.

Maoz and Russett (1993) have employed a very simple rule-based approach and assumed that country dyads are relevant for the study of international war only where the two countries are geographically contiguous or where at least one of the two countries is a major power. Lemke (1995) finds this rule to be neither necessary nor sufficient and accordingly redefines dyads relevant for the study of international war based on a complex relation between military strength, distance and terrain. In other words, a dyad is irrelevant if the two countries cannot overcome the obstacles of fighting a war due to limited military resources, a large distance between them and terrain that is not conducive to war. For example, two small and poor, landlocked countries on two different continents will not be able to go to war with each other. And indeed, Nepal and Chad never fought a war with each other. However, on the other hand, being landlocked has not always prevented countries from having a navy, which would give them at least some potential for a sea battle (Xiang, 2010).

Proponents of the selection-of-relevant-dyads approach argue that the inclusion of irrelevant dyads biases results and the exclusion of irrelevant dyads therefore improves the reliability of inferences. But does it in reality? Firstly, tens of thousands of ‘irrelevant’ dyads do not provide no information. At the very least, the very low to zero probability of war in these ‘irrelevant’ dyads demonstrates the importance of distance, terrain,

military capability and so on for the study of international war. Secondly, any rule-based selection will create measurement error and selection bias, as Lemke and Reed (2001) recognize. They suggest that even a selection rule as simple as contiguity and major power status produces only negligible bias due to these misspecification errors. Yet, we concur with Clark and Regan (2003) that it is better to explicitly model the opportunity to fight, which gives rise to a separate decision on willingness to fight, conditional on opportunity being present. Ultimately, the opportunity to fight is not fixed, and *probabilistic* modelling of the selection into the relevant sample of country dyads that can then be willing or unwilling to go to war trumps a *deterministic* rule-based selection. Only probabilistic modelling correctly accounts for the fact that there are no strict necessary or sufficient conditions for dyads to become relevant.

## SPATIAL DEPENDENCE OF DYADS

At least implicitly, the vast majority of analyses of dyadic data assume that observations are independent of each other. This is a problematic assumption even in analyses of monadic data, where actors learn from each other, where one actor coerces another or where the action of one actor triggers externalities for other actors, thereby influencing the behaviour of others (Franzese and Hays, 2008; Neumayer and Plümper, 2012). Yet, while independence of units is perhaps unlikely but certainly possible in monadic data, observations in dyadic data – almost by definition – cannot be independent of each other unless each node occurs only in one dyad. Thus, analyses of dyadic data dramatically increase the need to take seriously the dependence structures among observations.

The fact that dyadic data ‘have complex dependence structures’ (King, 2001: 498) has triggered three approaches for dealing with this. Firstly, some have explored how standard

errors can be adjusted to account for the dyadic and necessarily interdependent data structure that generates correlation across dyads in the error term (Aronow et al., 2015; Cameron et al., 2011; Cameron and Miller, 2014; Fafchamps and Gubert, 2007). This approach has yet to penetrate the mainstream and make its way into standard statistical software such as Stata. Secondly, some reject the dyadic approach altogether, arguing it is inconsistent with spatial dependence among dyads and suggesting network analysis instead. We deal with this fundamental objection to the use of dyadic data in the next section. Here we focus on the third approach, which is to model the spatial dependence in the dependent variable, in the explanatory variables or error term or combinations thereof.

At the very least, two dyads have to be partly dependent on each other if one actor is included in more than one dyad. In the language we use here, dyad  $ij$  cannot be entirely independent from dyads  $im$  and  $kj$ . To give an example, trade between the United States and the EU influences trade between the United States and China in multiple ways. In a static perspective, it is obvious that a product a US exporter sells to the EU cannot be sold to China at the same time. In a dynamic perspective, at least in sectors with economies of scale, the exports of a US company to European customers reduce the production cost per item for the US company and thus potentially increase competitiveness of US companies on the Chinese market. Whatever the perspective is, trade between the United States and China is unlikely to be independent from trade between the United States and the EU. In directed dyads, there also could be dependence between dyads  $ij$  and  $ji$ . For example, exports from the United States to China should not be entirely independent of exports from China to the United States. Clearly, as these countries enter into a 'trade war', trade in both directions will be affected.

Directed dyadic data offer a particularly rich set of modelling spatial dependence due to the distinction between sources and

targets (see Neumayer and Plümper, 2010a). As explained above, the most obvious source of spatial dependence in dyads results from the lack of independence between dyads that have one actor or nod, either source  $i$  or target  $j$ , in common. Directed dyad  $ij$  can therefore be influenced by what other sources  $k$  do with respect to the *specific* target  $j$  only, which results in what we have dubbed specific-source contagion:

$$y_{ij} = \rho \sum_{k \neq i} w_{pq} y_{kj} + \varepsilon_{ij}$$

or by what other targets  $m$  do with respect to the *specific* source  $i$  only (specific target contagion):

$$y_{ij} = \rho \sum_{m \neq j} w_{pq} y_{im} + \varepsilon_{ij}$$

Alternatively, directed dyad  $ij$  can be influenced by what other sources  $k$  do with respect to *any* other target  $m$ , not just  $j$ , which results in what we have dubbed aggregate-source contagion:

$$y_{ij} = \rho \sum_{k \neq i} \sum_m w_{pq} y_{km} + \varepsilon_{ij}$$

or by what other targets  $m$  do with respect to *any* source  $k$  and not just  $i$ , which results in aggregate-target contagion:

$$y_{ij} = \rho \sum_k \sum_{m \neq j} w_{pq} y_{km} + \varepsilon_{ij}$$

Finally, dyad  $ij$  can be influenced by what other dyads  $km$  do, which we have dubbed directed dyad contagion:

$$y_{ij} = \rho \sum_{\substack{k,m, \\ ij \neq km}} \omega y_{km} + \varepsilon_{ij}$$

Undirected dyadic data, by contrast, only allow the dyad  $ij$  ( $=ji$ ) to be influenced by other dyads  $km$ , which may either include nod  $i$  or nod  $j$  in them (i.e., including  $im$  and  $kj$ ) or exclude them ( $k,m \neq i,j$ ), resulting in inclusive or exclusive undirected dyad contagion, respectively.

Add to this richness in specification of contagion channels the fact that the link function  $w_{pq}$  that links dyad  $ij$  to other dyads can be modelled as any link between  $i, j, k$  and  $m$  and any combination of these links, it becomes clear that spatial dependence in dyadic data offers incredible modelling flexibility, which can be daunting to those who come with little theory to an empirical research question. Analysing spatial dependence in dyadic data therefore requires more prior theorizing than the equivalent analysis in monadic data.

There is of course no reason why only one of these dependencies should be relevant for any given data generating process. All these dependencies can be simultaneously relevant. However, if researchers want to estimate the spatial effects of different types of dyadic spatial dependence simultaneously, they are likely to run into the problem that the spatial-effect variables are highly correlated with each other. If so, we recommend including only the one or ones that the theory predicts to be the most relevant. In many applications, the spatial effect of dyads that include either  $i$  or  $j$  will be more relevant than the spatial effect of dyads that do not include one of the nodes.

If, as we have argued above, the analysis of dyadic data should typically include an analysis of spatial dependence – or at least make allowance for it – why then is it that such analyses are even rarer at the dyadic than at the monadic level? One reason is that many of the ‘canned’ estimators will not work with dyadic data, not least because it is typically computationally impossible with standard computers to create the 4-adic dataset required for the weighting matrix to link dyads with dyads, for data with a large number of dyads. We have made Stata ado-files available that allow researchers to generate spatial-effect variables for dyadic data, by parsing through each row of a virtual 4-adic dataset (Neumayer and Plümper, 2010b). From the standpoint of an econometrician purist, the disadvantage of our approach is that it does not allow for spatial maximum-likelihood estimation to account for the endogeneity that comes from spatial

feedback loops among dyads. However, it does allow for spatial-2SLS to account for this specific kind of endogeneity, a technique that is only marginally less efficient than spatial maximum likelihood. For example, for a spatial autoregressive model with specific-source contagion, one would use the following variables as instruments for  $\sum_{k \neq i} w_{pq} y_{kj}$ , the spatially lagged variable:  $\sum_{k \neq i} w_{pq} X_{kj}$  as well as, in so far as not already included in the estimation model,  $X_k$  and  $X_j$ . Naturally, the identifying assumptions are that the spatial dependence is not additionally of the spatial- $x$  type (implying spatial dependence in  $X_{kj}$ ), since otherwise  $\sum_{k \neq i} w_{pq} X_{kj}$  cannot serve as an instrument, and that  $X_k$  and  $X_j$  are not themselves endogenous for any reason and only affect the outcome variable through  $\sum_{k \neq i} w_{pq} y_{kj}$ , which is why they were not already included in the estimation model itself. Note, however, that if these identifying assumptions do not hold, then the autoregressive spatial estimation model is misspecified and estimating this model with spatial maximum likelihood will also result in biased estimates. In other words, as always, model misspecification results in biased estimates and spatial maximum likelihood does not provide a miraculous cure against it. The computationally much easier spatial-2SLS therefore dominates spatial maximum likelihood for models containing dyadic spatial dependence unless the number of dyads  $ij$  and the number of time periods  $T$  are small.

## EXTENSIONS AND ALTERNATIVES

As mentioned in the previous section, dyadic data analysis has its discontents. Cranmer and Desmarais (2016: 361) are probably those most explicit in their rejection of dyadic research designs: ‘We believe (...) that dyadic design is almost never appropriate for IR theory and data’. They base this conclusion principally on the claim that ‘a fundamental assumption of dyadic analysis

is that dyads exist in isolation from anything else going on in the world' (2016: 357). We hope to have shown in the previous section that this claim is simply untenable, since it is very much possible to model dyadic interaction without losing the spatial dependencies between dyads out of sight.

That is not to say, however, that dyadic designs are always superior to other modelling options. One challenge to such designs stems from events that are truly multilateral rather than bilateral in nature, i.e., when multiple actors jointly act simultaneously, such as in entering the world wars or when multilateral treaties are created. In principle, this can still be modelled in a dyadic design with spatial interdependence. However, Poast (2016: 371) is right to say that, in principle, a multilateral event represents a distinct phenomenon from interdependence among dyads, and so a *k*-adic design, where *k* stands for the number of actors that act jointly, can prove better in certain circumstances (see Fordham and Poast, 2016; Poast, 2010). Yet, *k*-adic designs – a *k*-dimensional extension to dyadic designs – have their own problems, creating a gigantic number of observations unless the sample can be heavily pruned by employing a strict rule for cutting out 'irrelevant' *k*-ads and/or random sampling of non-event observations to the rare event observations. Moreover, spatial dependence among *k*-ads is even more difficult to model than among dyads.

Cranmer and Desmarais (2011) prefer exponential random graph models and other models from inferential network analysis as alternatives to dyadic designs. Again, we acknowledge that network analysis can offer an interesting modelling choice (see Ward et al., 2011 for a general overview). And yet, we are not convinced of the superiority of these alternative research designs. Even if dyads are not the closest approximation to the data generating process, they can nevertheless represent the most useful research design, which should be the dominant decision-making criterion (Diehl and Wright, 2016). After all, what Cranmer and Desmarais (2016: 356) seem to regard as a

weakness, namely that 'the dyad constitutes the simplest level of measurement at which we can record a relationship', can actually be regarded as its main strength, since social-science analysis depends on simplification in order to make sense of a causally complex world (Clarke and Primo, 2012; Neumayer and Plümper, 2017b). We agree with Diehl and Wright (2016: 367), who come to the conclusion that dyads 'are often *appropriate* and *useful* units of analysis, contingent upon the questions that researchers ask and the outcomes they wish to explain'.

It is also possible to bring the dyadic model with spatial dependence closer to traditional network analysis.<sup>7</sup> This can be done by including two additional factors in the analysis: systemic nod and systemic dyad information. While systemic nod information describes the position of both *i* and *j* in the sample of nodes – their network centrality or the total number of their interactions to mention just two examples – systemic dyad information measures the systemic position of a dyad in a population of dyads. For example, the dyad United States–Russia traditionally obtains a central network position in international relations. The relevance of the relations between the United States and Russia to other dyads is not necessarily accounted for by systemic nod information available for these countries individually. Systemic nod and systemic dyad information can be measured and included in the dyadic analysis as an independent explanatory variable or, alternatively, such information can be used in the weighting matrix for the spatial-effect variables. Thus, one can, for example, test whether spatial dependence among dyads depends on the centrality of dyads – a plausible assumption consistent with many theories of social networks.

## CONCLUSION

Undoubtedly, dyadic data challenge analysts. Specifying models for dyadic data analysis

sufficiently well is vastly more complicated than doing so for models for monadic-data analysis. However, some of these complications – the choice between directed and undirected dyads, the interactions between different levels of analysis, the mutual dependencies between dyads – actually also present new opportunities that often allow researchers to gain novel insights. No doubt, getting the specification of a dyadic model sufficiently right such that inferences are reliable is difficult. However, there is much to learn from analysing dyadic data that cannot be learned from the analysis of monadic data.

The good news is that over the last two decades, the most severe specification problems have been solved or at least reduced. Today, social scientists know – at least in principle – how to deal with the lack of independence of dyads and they know how to address the problems associated with rare events and the multiple heterogeneity issues. The methodological frontier of dyadic data analysis has therefore shifted and moved on. The new debates focus on utilizing spatial analyses of dyadic data for network analysis and whether social scientists should progress to higher dimensions in the form of k-adic data analysis. But dyadic data analysis has been and, we predict, will remain the design of choice for the analysis of relationships between actors in political science, international relations and beyond.

## Notes

- 1 In political science, for each article with 'dyad' or 'dyadic' as a keyword in the Social Sciences Citation Index, roughly 250 articles which do not, at least not explicitly, state to be concerned with dyadic data are published. Aronow et al. (2015: 564) have counted 62 dyadic analyses over a five-year period published in the *American Political Science Review*, *American Journal of Political Science* and *International Organization*. That amounts to an average of merely four per journal per year.
- 2 Common model misspecifications that cause bias include selection, concept invalidity, measurement error, omitted variables, functional form misspecification, causal heterogeneity and context conditionality, structural change, dynamic

misspecification and lack of independence of observations (Neumayer and Plümpert, 2017b).

- 3 The procedure is also known as choice-based or case-control sampling.
- 4 Tobler's (1970) law does not only motivate the gravity model but also spatial models (Franzese and Hays, 2007; Neumayer and Plümpert, 2017a; Plümpert and Neumayer, 2010). Hence, it can be applied to monadic as well as dyadic phenomena.
- 5 [https://en.wikipedia.org/wiki/Newton%27s\\_law\\_of\\_universal\\_gravitation](https://en.wikipedia.org/wiki/Newton%27s_law_of_universal_gravitation).
- 6 Though we do not wish to underestimate the relevance of unobserved heterogeneity, we need to stress that the fixed-effects approach makes the very strong and largely unjustified assumption that all heterogeneity between dyads and thus all model misspecification is strictly time-invariant with constant effects. Once this assumption is removed, differences between the pooled-OLS estimates and fixed-effects estimates could just result from misspecified dynamics, omitted time-varying variables, unexplained trends in the data, misspecified lag structures or similar (Plümpert and Troeger, 2019). The test that Green and co-authors (2001) propose does not work any better than the Hausman test, which rests on the assumption that the fixed-effects model is unbiased: 'The Hausman test is not a reliable tool for identifying bias in typically sized samples; nor does it aid in evaluating the balance of bias and variance implied by the two modelling approaches' (Clark and Linzer, 2015).
- 7 See Hays et al. (2010) for a proposal on how network behaviour can be incorporated into a spatial model at the monadic level, which is straightforward to generalize to the dyadic level.

# Model Specification and Spatial Interdependence\*

Scott J. Cook, Jude C. Hays, and Robert Franzese

## INTRODUCTION

Researchers now regularly estimate spatial models in applied political science, both to enhance the validity of their direct (i.e., non-spatial) covariate-effect estimates and to test explicitly spatial theories. While this is a welcome advance over past practices, we worry that much of this first generation of applied spatial research overlooks certain aspects of spatial models. In particular, while different theories imply different spatial-model specifications, statistical tests frequently have power against incorrect alternatives. As a consequence, researchers who fail to discriminate explicitly between the different manifestations of spatial association in their outcomes are likely to erroneously find support for their theoretically preferred spatial process (e.g., contagion or endogenous global spillovers) even where an alternative process instead underlies the association (e.g., diffusion or exogenous local spillovers). To help researchers avoid

these pitfalls, we (1) elaborate the alternative theoretical processes that give rise to a taxonomy of spatial models, (2) indicate why and provide evidence that these alternative processes are frequently mistaken for one another during conventional hypothesis testing, and (3) suggest a set of strategies for effectively discriminating between the seven alternative spatial-lag models (with one, two, or all three of spatially lagged errors, spatially lagged independent variables, and/or spatially lagged dependent variable).

Cross-sectional, or spatial, interdependence is ubiquitous in the social sciences. Theories indicating that the actions of/outcomes in some units are a function of (i.e., depend upon) those of other units – as they are coerced by, compete with, learn from, and emulate one another – span across the sub-fields and substance of political science, for example.<sup>1</sup> The diffusion of political institutions and policy is well established in American and comparative politics, with units learning from and/or emulating the institutions and instruments

of other units. Similarly, political behavior, from voting to violence, is necessarily interdependent as expectations over outcomes are a function of beliefs about the actions of others. The very structure of the global economy indicates the importance of interdependence in the study of comparative and international political economy, evidenced both in deepening economic integration and more prevalent policy coordination or competition. The very field name International Relations, meanwhile, centrally implicates interdependence in that area of study. More generally still, spatial interdependence is present whenever units are affected by the actions, behaviors, and outcomes of other units.

Given the theoretic centrality of spatial interdependence in political science and international relations, early work sought to introduce and extend methods for analyzing this dependence directly (Beck et al., 2006; Franzese and Hays, 2007). Beyond the classic linear model, statistical methods have been developed for spatial analysis of binary outcomes (Franzese et al., 2016; Wilhelm and de Matos, 2013), count data (Hays and Franzese, 2017), durations (Hays and Kachi, 2009; Hays et al., 2015), and endogenous predictors (Betz et al., 2020). Moreover, researchers have built on the dictum that space is ‘more than geography’ and indicated how the specification of the connectivity matrix itself enables researchers to test a range of political theories (Neumayer and Plümper, 2016; Plümper and Neumayer, 2010). As a result, there has been a proliferation of empirical work in political science, which offers theories, estimates models, and conducts tests of spatial interdependence.<sup>2</sup>

While this is a welcome advance over past practices – treating spatial dependence as a nuisance or ignoring it altogether – we worry that much of this first generation of applied spatial research does not fully appreciate or is unfamiliar with certain aspects of spatial models. Importantly, distinct spatial-model specifications arise from different theoretical explanations of spatial clustering

in the outcomes: *i*) endogenous interaction effects (e.g., spillovers in the outcomes), *ii*) exogenous interaction effects (e.g., spillovers in the predictors), and/or *iii*) interactions or clustering in the residuals (Elhorst, 2010).<sup>3</sup> Problematically, these theoretically distinct statistical models are quite similar and so produce similar patterns in empirical data, which complicates specification testing (Anselin, 2001; Gibbons and Overman, 2012). Specifically, diagnostic tests have power against incorrect alternatives (testing rejects A in favor of B, when, in fact, C is present and causes the rejection, not B), making it difficult to statistically distinguish between these various models. To the extent that researchers attach theoretic importance to these different model specifications, which they should, and subsequently draw substantively meaningful inferences off these diagnostic tests, it is important to understand how and the extent to which these tests can distinguish between these alternatives. Thus, while we can now estimate a variety of spatial models in many different contexts, these ambiguities, left unaddressed, limit what we can learn from analyses utilizing spatial methods.

To begin to redress these limitations here, we first detail and describe the possible sources of spatial clustering and the econometric models that are implied when any combination of these sources is present. While a general model that allows for all three sources of spatial clustering is discussed, we show that this model is weakly identified based on structural assumptions and therefore can provide only a precarious guide to our specification search. This precludes a Hendry-like general-to-specific specification search, as has been advocated in time-series modeling (in political science by De Boef and Keele, 2008). Instead, researchers generally must constrain one of the possible sources of spatial clustering in order to discriminate effectively between the remaining alternatives. While research design or theory should be the preferred bases on which to justify this constraint, we offer guidance for

researchers in situations where these solutions are not available.

Our intention is not to discourage the use of spatial methods, as we feel spatial analysis is necessary and appropriate whenever one has cross-sectional or time-series-cross-sectional observational data.<sup>4</sup> Instead, we simply advocate that researchers exercise greater caution when estimating these models, especially when attempting to articulate and test specific theories of spatial interdependence. Taking ‘space’ seriously does not simply mean estimating a spatial model but rather estimating the *appropriate* spatial model. In the following section, we outline the variety of alternative spatial models, show how easy it is to mistake one of these models for another when drawing inferences, and suggest tests to aid researchers in identifying and specifying appropriate models for estimation. Subsequently, we evaluate the small-sample performance of these tests under a variety of simulated conditions.

## SPECIFYING SPATIAL MODELS

In prior work, we have highlighted the substantive/theoretical ubiquity of interdependence across political science. While the emergence of applied spatial research in political science suggests broad agreement on the importance of spatial theories, some research may have too quickly turned to articulating and testing specific mechanisms (e.g., emulation vs learning) and sources (e.g., distance vs trade) for spatial dependence across a range of issue areas without first devoting sufficient attention to the various broader ways in which spatial dependence can manifest in observational data. Before discriminating between competing theories of the bases of diffusion, researchers must first evidence that there is some form of diffusion. Researchers need to be aware of the various possible sources of spatial correlation in their outcomes and adopt models

that appropriately nest and test between these competing alternatives. Therefore, we open by discussing the potential sources of spatially correlated outcomes, before outlining the spatial-econometric models implied by each.<sup>5</sup>

According to Anselin (2010), spatial heterogeneity is the uneven distribution of a trait, event, or relationship across a region. Therefore, it is present whenever we observe spatial clustering in the outcomes across some set of sample units. By which we mean that when there is non-zero covariance among these units’ outcomes:

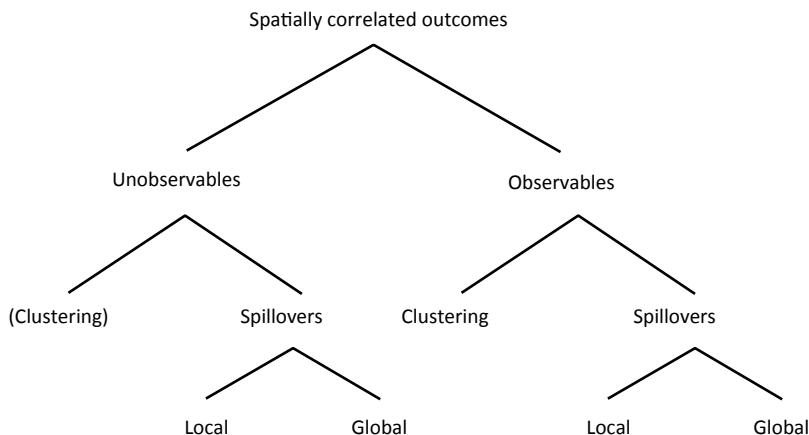

$$\begin{aligned} \text{cov}(y_i, y_j) &= E(y_i y_j) \\ &- E(y_i) \times E(y_j) \neq 0 \text{ for } i \neq j \end{aligned} \quad (1)$$

i.e., whenever variation in the outcome is not randomly distributed across units. This only becomes problematic for non-spatial analyses, however, when the (spatial) distribution of these outcomes is not entirely explained by the (spatial) distribution of predictors. In these instances, additional unmodeled factors give rise to the spatial correlation we observe in our outcomes, the failure to account for which potentially threatens the accuracy of our estimates and the validity of our inferences.

To elaborate the various manifestations of spatial association more fully, consider Figure 39.1. As we see, correlation in the outcomes arises from spatial (inter)dependence in the observable and/or unobservable inputs.<sup>6</sup> Broadly, there are two mechanisms that produce spatially correlated outcomes: *i*) spatial clustering and/or *ii*) spatial spillovers or interactions. As with the outcomes, spatial clustering in the observables (unobservables) occurs when the level, presence, or change of an observed (unobserved) determinant in one unit is correlated with but not a function of (not caused by) the value of that factor in other (spatially proximate) units:

$$y_i = f(x_i, \varepsilon_i) \text{ and } \text{cov}(x_i, x_j) \neq 0 \text{ for } i \neq j \quad (2a)$$

$$y_i = f(x_i, \varepsilon_i) \text{ and } \text{cov}(\varepsilon_i, \varepsilon_j) \neq 0 \text{ for } i \neq j \quad (2b)$$

**Figure 39.1 Manifestations of spatial association**

where  $y$  is the outcome,  $x$  is a predictor, and  $\varepsilon$  is the unobserved error, with subscripts  $i$  and  $j$  identifying cross-sectional units. Here, the predictors and/or errors are spatially clustered, which, in turn, produces spatial clustering in the outcomes.<sup>7</sup> This does not require or suggest interaction between the units, simply that proximate actors possess similar characteristics (e.g., natural endowments that span across units) that, when manipulated, cause these unit outcomes to vary concurrently. That is, a common factor in the observables or unobservables results in correlated group effects.<sup>8</sup> For example, policy or technological innovations that change in the costs of inputs or demand (holding supply fixed) impact the revenues of all producers of a good, even where there is no direct interaction between them.

Alternatively, spatially correlated outcomes can arise due to spatial spillovers, when the outcomes of one unit are a function of (are caused by) the outcomes, actions, and behaviors of *other* units:

$$y_i = f(x_i, x_j, \varepsilon_i) \quad (3a)$$

$$y_i = f(x_i, \varepsilon_i, \varepsilon_j) \quad (3b)$$

$$y_i = f(x_i, y_j, \varepsilon_i) = f(x_i, (x_j, \varepsilon_j), \varepsilon_i) \quad (3c)$$

These we label *interdependence*, which seems to be the spatial process most commonly assumed by contemporary applied researchers. In this case, there are spillovers and/or externalities that arise from the observables (Equation 3a), unobservables (Equation 3b), or outcomes (Equation 3c) of other units. Note that here we need not assume that the observables or unobservables are governed by a spatial process (are spatially correlated) – although they certainly may be – merely that there is cross-unit dependence, where the outcome in  $i$  is a function of the observables and/or unobservables in unit  $j$ . Theories of diffusion or contagion, or of strategic decision-making, for example, would generally imply such interdependent processes.

While many of our theories suppose interdependence in the outcomes, this necessarily implies that the relation of  $y_i$  and  $y_j$  operates through the combined spatial effects of the observables ( $x_j$ ) and unobservables ( $\varepsilon_j$ ) (Equation 3c). Anselin (2003) discusses that for specification, then, a more fundamental consideration is whether these externalities are global or local (the third dimension of Figure 39.1), i.e., whether actors only affect their immediate neighbors, peers, etc., as assumed by a local process, or, as in Tobler’s oft used expression ‘everything is related to everything’, suggesting a global process in

which actors affect proximate actors, who in turn affect their proximate actors, and so on. Perhaps more clearly, the distinction is between whether spillovers in the observables ( $\mathbf{X}$ ) and unobservables ( $\varepsilon$ ) in my neighbors affect me *directly*, or they affect me *indirectly* through my neighbors' outcomes ( $y_i$ ).<sup>9</sup>

Our theoretical propositions about which combination of these spatial effects produces spatial clustering in the outcomes imply different econometric specifications. Specifically, we have discussed three relevant dimensions which should inform spatial specification: *i*) whether spatial heterogeneity in the outcome is caused by observable or unobservable factors (or both), *ii*) whether these spatial effects arise from clustering or spillovers (or both), and *iii*) if spillovers, whether these spillovers are local or global.<sup>10</sup> Table 39.1 lists the spatial models most commonly discussed in the literature.<sup>11</sup>

Beginning with the most restrictive of these models, the non-spatial linear-regression model assumes that any spatial correlation in the outcomes is entirely a function of spatial correlation in the predictors:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \quad (4)$$

That is, to account for the spatial correlation in outcomes, we need simply to include appropriate predictors ( $\mathbf{X}$ ), as regularly done in non-spatial analysis. We emphasize this simple point as it seems to be misunderstood in some applied literature.<sup>12</sup> Moreover, it underscores the importance of model specification more

generally when undertaking spatial analysis, as misspecified models – those omitting relevant spatially clustered predictors – will exhibit spatial dependence in the residuals (and, in turn, give power to spatially lagged (in)dependent variables). As such, a better specified model is one obvious solution when confronting spatially clustered residuals.<sup>13</sup>

In estimating these models, researchers assume a spherical error variance–covariance matrix (and, by extension, that  $\rho = \lambda = 0$ ;  $\boldsymbol{\theta} = \mathbf{0}$ ), i.e., that the residuals are not spatially correlated. This can be easily tested through a variety of post-estimation diagnostic tests, including the familiar Moran's I and Lagrange Multiplier tests (Franzese and Hays, 2008). Should these tests reject the null, indicating spatial correlation in the residuals, further remedies are needed to avoid inefficiency and possible bias in our parameter estimates. Most applied spatial work in political science engages in this type of exploratory spatial analysis to justify the use of further spatial methods. However, these tests merely suggest *a* spatial process and generally are not very helpful for making specification choices from among the broad class of possible spatial models.

Of these models, the most widely discussed have been the spatial error model (**SEM**), the spatial lag model (**SAR**), and, more recently, the spatially lagged  $\mathbf{X}$  model (**SLX**). Each assumes that any spatial correlation in the outcomes arises from a single source, exogenous observables, unobservables, or

**Table 39.1 Common spatial econometric models**

Name	Structural model	Restrictions
General nesting model	$\mathbf{y} = \rho\mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} + \mathbf{W}\mathbf{X}\boldsymbol{\theta} + \mathbf{u}, \mathbf{u} = \lambda\mathbf{W}\mathbf{u} + \boldsymbol{\varepsilon}$	None
Spatial Durbin error model	$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{W}\mathbf{X}\boldsymbol{\theta} + \mathbf{u}, \mathbf{u} = \lambda\mathbf{W}\mathbf{u} + \boldsymbol{\varepsilon}$	$\rho = 0$
Spatial autocorrelation model	$\mathbf{y} = \rho\mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} + \mathbf{u}, \mathbf{u} = \lambda\mathbf{W}\mathbf{u} + \boldsymbol{\varepsilon}$	$\boldsymbol{\theta} = \mathbf{0}$
Spatial Durbin model	$\mathbf{y} = \rho\mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} + \mathbf{W}\mathbf{X}\boldsymbol{\theta} + \boldsymbol{\varepsilon}$	$\lambda = 0$
Spatial autoregressive	$\mathbf{y} = \rho\mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$	$\lambda = 0; \boldsymbol{\theta} = \mathbf{0}$
Spatially lagged Xs	$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{W}\mathbf{X}\boldsymbol{\theta} + \boldsymbol{\varepsilon}$	$\rho = \lambda = 0$
Spatial error model	$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{u}, \mathbf{u} = \lambda\mathbf{W}\mathbf{u} + \boldsymbol{\varepsilon}$	$\rho = 0; \boldsymbol{\theta} = \mathbf{0}$
(Spatial) Linear model	$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$	$\rho = \lambda = 0; \boldsymbol{\theta} = \mathbf{0}$

outcomes, restricting the other possibilities to zero. SEMs imply that the pattern of spatial dependence is attributable to unmeasured covariates that are orthogonal to the included regressors, resulting in a non-spherical error variance-covariance matrix.<sup>14</sup> Under these conditions, parameter estimates are unbiased but inefficient (and standard errors are incorrectly estimated). Efficient parameter estimates and correct standard errors can be obtained by accounting for the spatial structure of the residuals, as done in the SEM:

$$y = X\beta + u, \text{ where } u = \lambda W u + \varepsilon \quad (5)$$

where  $W$  is an  $N \times N$  connectivity matrix with elements  $w_{ij}$  indicating the (pre-specified, exogenous) relative connectivity (i.e., relationship) from unit  $j$  to unit  $i$  and  $\lambda$  indicating the strength of the spatial interdependence along this pre-specified pattern of connections.<sup>15</sup> In the terms of Table 39.1, this model assumes global spillovers in the unobservables, i.e., that the residuals are governed by a spatial autoregressive process.<sup>16</sup> This will also be the preferred specification when we believe there is clustering in the unobservables. Unlike with observable predictors, we have no means of introducing this heterogeneity into the systematic component of the model directly and must assume that these unobserved components are orthogonal to the observed ones (and so no bias issue), but accounting for the structure of the residuals should still provide some insurance against inefficiency resulting from this type of clustering and produce more accurate standard error estimates.<sup>17</sup>

If, instead, researchers believe that there are spillovers in the observables, one of the other single-source spatial models should be estimated to *i*) avoid bias in the estimated non-spatial effect-parameters and *ii*) obtain estimates of these spatial (spillover) effects. Where theory and substance suggest these spillovers/externalities are local, the SLX model should be preferred:

$$y = X\beta + WX\theta + \varepsilon \quad (6)$$

Alternatively, where theory indicates these spillovers/externalities are global and in the outcome, the widely used SAR model is called for:<sup>18</sup>

$$y = \rho Wy + X\beta + \varepsilon \quad (7)$$

This will likely be familiar to most readers, as it has quickly become the workhorse model of applied spatial work in political science (and elsewhere). While both SLX and SAR models allow for spillovers in observables, they differ over whether they model these as local or global processes, as discussed earlier, and whether there are spatial effects in the unobservables. More theoretically, they also differ over whether we believe there is cause to understand the spillovers of the observables as direct,  $x_j \Rightarrow y_i$ , as is more likely with social aggregates, like GDP for example, or indirect,  $(x_j, \varepsilon_j) \Rightarrow y_j \Rightarrow y_i$ , as is more likely with strategic interdependence among decision makers like as in public policies, for example.

We have noted that the similarity of these models creates challenges for diagnostic tests. While this may not be obvious from the structural forms given in Equations 5–7, we can re-express them to highlight the similarities. Taking the reduced form of  $u$  and substituting and rearranging terms, the SEM model becomes

$$y = \lambda Wy + X\beta - \lambda WX\beta + \varepsilon \quad (8)$$

The similarities between the SEM model and the SLX model (given in Equation 6) and the SAR model (given in Equation 7) are now readily apparent, as it is composed of a spatial lag of the outcomes ( $\lambda Wy$ ) and spatial lags of the predictors ( $\lambda WX\beta$ ). Similarly, taking the reduced form of the SAR model in Equation 7 and its expansion produces

$$y = (I - \rho W)^{-1}(X\beta + \varepsilon) \quad (9a)$$

$$y = X\beta + \rho WX\beta + \rho^2 W^2 X\beta \dots + \varepsilon + \rho W\varepsilon + \rho^2 W^2 \varepsilon \dots \quad (9b)$$

Again, the similarities between the **SAR** and **SLX** models are now apparent, with the only differences being the higher-order polynomials of the spatial lag of **X** and the spatial error process. As a consequence, unmodeled spatial spillovers/externalities in the observable predictors, in the unobservables, or in the outcomes will result in a rejection of the zero null for the spatial-effect parameter in *any* of these single-source models.

To ward against this possibility, spatial econometricians have increasingly recommended the two-source models:

$$\text{SDM: } \mathbf{y} = \rho \mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} + \mathbf{W}\mathbf{X}\boldsymbol{\theta} + \boldsymbol{\varepsilon} \tag{10}$$

$$\text{SAC: } \mathbf{y} = \rho \mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} + \mathbf{u}, \tag{11}$$

where  $\mathbf{u} = \lambda \mathbf{W}\mathbf{u} + \boldsymbol{\varepsilon}$

$$\text{SDEM: } \mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{W}\mathbf{X}\boldsymbol{\theta} + \mathbf{u}, \tag{12}$$

where  $\mathbf{u} = \lambda \mathbf{W}\mathbf{u} + \boldsymbol{\varepsilon}$

and a more general model still: the so-called General Nesting Spatial Model (**GNS**),

$$\text{GNS: } \mathbf{y} = \rho \mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} + \mathbf{W}\mathbf{X}\boldsymbol{\theta} + \mathbf{u}, \tag{13}$$

where  $\mathbf{u} = \lambda \mathbf{W}\mathbf{u} + \boldsymbol{\varepsilon}$

which imposes no constraints on the three spatial parameters ( $\rho$ ,  $\lambda$ ,  $\theta$ ).<sup>19</sup> Given that this model subsumes all the alternatives presented thus far, one might think to engage in a Hendry-like general-to-specific specification search (Hendry, 1995), thereby avoiding the pitfalls encountered when adopting a specific-to-general approach. While this strategy has much to recommend it and is commonplace in the time-series literature, there are two problems that prevent adopting the general-to-specific approach in the spatial context.

First, the **GNS** model is weakly identified. As discussed in Gibbons and Overman (2012), the **GNS** is the analog to Manski's

(1993) well known linear-in-means neighborhood-effects model:

$$y = \underbrace{\rho_1 E[y | a]}_{\text{Endog. Effects}} + x\boldsymbol{\beta} + \underbrace{E[x' | a]\boldsymbol{\gamma}}_{\text{Exog. Effects}} + v, \tag{14a}$$

where  $u = \underbrace{\rho_2 E[u | a]}_{\text{Corr. Errors}} + \boldsymbol{\varepsilon}$

$$y = x\boldsymbol{\beta} + E[x' | a] \frac{(\rho_1 \boldsymbol{\beta} + \boldsymbol{\gamma})}{1 - \rho_1} + \frac{\rho_1}{1 - \rho_1} E[v | a] + u \tag{14b}$$

This parallel should raise some red flags given the well known identification problems of the Manski model. As indicated in Equation 14b, it is impossible to separately identify the endogenous and exogenous spatial effects in this model.<sup>20</sup> With spatial econometric methods, however, one does not simply estimate one sum 'neighborhood' effect: each unit in a sample is known to be connected to others through **W**, and this matrix almost always provides more information than neighborhood membership. For example, within a given 'neighborhood', there are first-, second-, and higher-order neighbors.<sup>21</sup> As a result, spatial-econometric models are *usually* able to use the pre-specification of **W** to achieve identification in most cases.<sup>22</sup>

Focusing on an example with a single predictor, some algebraic manipulation of the **GNS** model in Equation 13 allows it to be re-written as

$$\mathbf{y} = (\rho + \lambda)\mathbf{W}\mathbf{y} - \rho\lambda\mathbf{W}^2\mathbf{y} + \mathbf{x}\boldsymbol{\beta} + (\theta - \lambda\boldsymbol{\beta})\mathbf{W}\mathbf{x} - \lambda\theta\mathbf{W}^2\mathbf{x} + \boldsymbol{\varepsilon} \tag{15a}$$

$$\mathbf{y} = q_1\mathbf{W}\mathbf{y} + q_2\mathbf{W}^2\mathbf{y} + \mathbf{x}q_3 + q_4\mathbf{W}\mathbf{x} + q_5\mathbf{W}^2\mathbf{x} + \boldsymbol{\varepsilon} \tag{15b}$$

where the spatial parameters are weakly identified by the second-order terms in the polynomial. The reduced form of the **GNS** provides five parameters from which we can recover the four structural parameters.

Substituting  $q_1$  into  $q_2$  and  $q_4$  into  $q_5$  gives a set of quadratic relationships for  $\lambda$ :

$$\lambda^2 = q_2 + \lambda q_1$$

$$\lambda^2 = \frac{-(q_5 + \lambda q_4)}{\beta}$$

These equations provide a unique solution for  $\lambda$  and, in turn, the other parameters:

$$\lambda = \frac{-(\beta q_2 + q_5)}{\beta q_1 + q_4}$$

$$\rho = q_1 + \frac{(\beta q_2 + q_5)}{\beta q_1 + q_4}$$

$$\theta = q_4 - \frac{\beta(\beta q_2 + q_5)}{\beta q_1 + q_4}.$$

The problem is that these parameters are identified solely by the structural assumptions of the functional form implied by autoregression and the pre-specified  $\mathbf{W}$ , and the performance of the **GNS** model deteriorates rapidly as these assumptions become more appreciably incorrect, as we show later in our Monte Carlo experiments.

How, then, should researchers who are interested in undertaking spatial analysis proceed? Broadly, there are two strategies one can pursue. The first is to constrain one of the spatial parameters to zero, thereby allowing firmer identification of the remaining free parameters and more robust estimation of the relevant two-source model.<sup>23</sup> The second is to add additional structure to the model in the form of unique weights matrices for the observables and unobservables. While possible, this second approach seems unappealing to us as a general strategy, given that we can think of no reason why we would generically expect to have strong prior information to indicate that unobserved effects are spatially governed in a manner distinct from observed predictors.<sup>24</sup> Accordingly, we focus on evaluating the efficacy of the first strategy, constraining one or more parameters, as a more generally applicable approach.

Implicitly, this is the approach currently advocated by most spatial econometricians, who have increasingly recommended one or another of the two-source models. However, to date, researchers have received conflicting advice over which model should be preferred as a general model, with some strongly advocating the **SDM** and others the **SAC**. Elhorst (2010: 10) offers a fun account that highlights this discord: ‘In his keynote speech at the first World Conference of the Spatial Econometrics Association in 2007, Harry Kelejian advocated [**SAC** models], while James LeSage, in his presidential address at the 54th North American Meeting of the Regional Science Association International in 2007, advocated [**SDM**] models’. Moreover, most of the work systematically exploring the small-sample performance of these models generally has done so with data-generating processes that satisfy the constraints assumed by the statistical model.

Instead of simply advocating one model over another, as is commonly done, we believe researchers should adopt a more systematic approach to motivating these constraints. First, one could use research design, such as natural experiments, to eliminate one (or more) of the three possible sources. This is the strategy suggested by Gibbons and Overman (2012), both to evade the issues that arise from the unidentified **GNS** and avoid models only identified off-structure (e.g., spatial econometric models, generally).<sup>25</sup> Focusing exclusively on those contexts where natural experiments are available, however, bounds the range of issues that can be studied. As such, we consider approaches where such strategies are not possible.<sup>26</sup>

A natural alternative in such instances is to use theory to guide these constraints. Where theory can eliminate one of the possible sources, we should be more confident in our selection of the appropriate two-source model. Even where we do not have strong theory to confidently eliminate one

of these sources, we suggest a third alternative: use the aim of the research to guide the model selection. That is, where researchers are principally interested in obtaining unbiased estimates of the non-spatial *parameters*,<sup>27</sup> the spatial Durbin model should be preferred. This should provide the most insurance against possible omitted variable bias by explicitly introducing both forms of observable spillovers into the systematic component of the model. However, where researchers are explicitly interested in evaluating spatial theories, we believe one of the other two-source models (**SAC** or **SDEM**) are best. Each frees one parameter to capture spillovers in observables (either  $\rho$  or  $\theta$ ) while accounting for spatial effects in the unobservables ( $\lambda$ ). To us, distinguishing between spatial spillovers in observables and spatial effects in unobservables is the most significant consideration. Importantly, this will help prevent researchers from drawing erroneous conclusions about diffusion and/or spillovers where none exist, i.e., where spatial clustering in the outcomes is determined in whole or part by spatial effects in unobservables. Where such spillovers still find support, we have only lost the ability to statistically and empirically distinguish whether they were truly global or local – a cost that, by comparison, seems less severe.

Using either theory or research focus to guide specification, however, also naturally risks a much more problematic cost: estimating the incorrect model (and so, generally, calculating incorrect effect estimates). This can occur in four ways with the estimation of two-source spatial models: (1) the truth is all three spatial effects; (2) the truth is two sources but our statistical model imposes the wrong constraint, yielding the wrong two-source model; (3) the truth is a single-source model; (4) the truth is a non-spatial model. In either of the first two, we risk bias in the estimates of the included spatial and non-spatial parameters, as is always the case with spatially misspecified models.

Thirdly, if the truth is a single source among our included two, the estimation should reveal that. If our two-source model does not include the true single source, the combination of estimated coefficients on the included should produce that omitted third, but we would incorrectly find support for *both* included spatial parameters being non-zero, even though the truth is that only the omitted third is non-zero (the fourth, non-spatial case should be unproblematic, as the estimation would return to zero for the spatial parameters.)

The possibility that an omitted single-source process would be reproduced through the combination of two-source parameter estimates has been well established for the **SEM** model, which can be re-expressed as a spatial Durbin model (noted above and re-expressed here):

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{u}, \text{ where } \mathbf{u} = \lambda\mathbf{W}\mathbf{u} + \boldsymbol{\varepsilon} \quad (17a)$$

$$\mathbf{y} = \lambda\mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} - \lambda\mathbf{W}\mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \quad (17b)$$

In this case, we can test the common-factor restriction of Burridge (1981),  $\boldsymbol{\theta} = -\lambda\boldsymbol{\beta}$ , after estimating an SDM to evaluate whether it can be constrained to the SEM. Similarly, we can see that the SAR model can be re-expressed as a higher-order variation of the SDEM:

$$\mathbf{y} = \rho\mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \quad (18a)$$

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \rho\mathbf{W}\mathbf{X}\boldsymbol{\beta} + \rho^2\mathbf{W}^2\mathbf{X}\boldsymbol{\beta} + \dots + (\mathbf{I} - \rho\mathbf{W})^{-1}\boldsymbol{\varepsilon} \quad (18b)$$

Thus, the only difference between the SDEM and the SAR model is the higher-order polynomials of  $\mathbf{W}\mathbf{X}$  in the latter.<sup>28</sup> Finally, while expressing the relationship between the SLX and the SAC model is not as straightforward, the basic intuition for why a true effect of  $\theta$  in the SLX model would cause significant findings for both  $\rho$  and  $\lambda$  in the SAC model

parallels the above discussions in that the estimates of each is a function of  $\mathbf{WX}$ :

$$\mathbf{y} = \rho \mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} + \mathbf{u},$$

where  $\mathbf{u} = \lambda \mathbf{W}\mathbf{u} + \boldsymbol{\varepsilon}$  (19a)

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \rho \mathbf{W}\mathbf{X}\boldsymbol{\beta} + \rho^2 \mathbf{W}^2 \mathbf{X}\boldsymbol{\beta} + \dots + (\mathbf{I} - \rho \mathbf{W})^{-1} (\mathbf{I} - \lambda \mathbf{W})^{-1} \boldsymbol{\varepsilon}$$
 (19b)

Both this and the SAR–SDEM relation do not allow for a simple common-factor restriction test (as in the SEM–SDM case). Therefore, rather than testing constraints on parameters, one could use tests that compare the performance of non-nested models. For example, the ‘closeness’ test in Vuong (1989) can evaluate whether the two models differ significantly in their ability to explain the data. In this context, a failure to reject the null hypothesis would indicate support for the more parsimonious single-source model. We do not explore this approach at length here, but it may warrant further consideration in subsequent work.

In the next section, we explore the consequences of imposing the wrong constraints when estimating spatial models.

**MONTE CARLO ANALYSIS**

In our simulations, we explore the possibility of detecting interdependence in outcomes and spillovers from covariates in cross-sections of data when there is spatial clustering in both observables and unobservables using the relevant models from Table 39.1. We define clustering as a common spatial or group fixed effect. Substantively, clustering differs from both interdependence and spillovers in that changes in covariates and disturbances inside one unit do not cause outcomes to change in other units. The simulation DGP is

$$\mathbf{y} = \rho \mathbf{W}\mathbf{y} + \boldsymbol{\beta}\mathbf{x} + \theta \mathbf{W}\mathbf{x} + \mathbf{u}$$

where  $\mathbf{y}$  is an  $N \times 1$  vector of outcomes,  $\mathbf{x}$  is an  $N \times 1$  covariate vector,  $\mathbf{u}$  is an  $N \times 1$  vector of disturbances,  $\mathbf{W}$  is an  $N \times N$  spatial weights matrix,  $\rho$  is the spatial interdependence parameter,  $\boldsymbol{\beta}$  is the ‘direct-effect’ parameter, and  $\theta$  is the spatial spillover parameter.

The individual elements of the vectors  $\mathbf{x}$  and  $\mathbf{u}$  are generated as

$$x_{ig} = \eta_g^x + \varepsilon_{ig}^x \text{ and } u_{ig} = \eta_g^u + \varepsilon_{ig}^u$$

where  $x_{ig}$  and  $u_{ig}$  refer to the covariate and disturbance for unit  $i$  in spatial group  $g$ ,  $\eta_g^x$  and  $\eta_g^u$  are the common spatial effects, distributed as standard normal variates (clustering), and  $\varepsilon_{ig}^x$  and  $\varepsilon_{ig}^u$  are the unit-specific components of the covariate and disturbance, which are also distributed as standard normal variates.

The spatial weights matrix identifies intra-group connectivity and takes the form

$$\mathbf{W} = \begin{bmatrix} \mathbf{W}_1 & 0 & \dots & 0 \\ 0 & \mathbf{W}_2 & \dots & 0 \\ \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & \mathbf{W}_G \end{bmatrix}$$

Thus, the complete weights matrix has a block diagonal structure for  $\mathbf{G}$  groups, when the units or individuals in the sample are stacked by groups. We set the number of groups ( $\mathbf{G}$ ) to 15, the number of members in each group ( $n_g$ ) to 20, and the degree of intragroup connectivity at 40%. We assume the connectivity weights are uniform and sum to one. That is, the weights are  $1/n_c$ , where  $n_c$  is the number of intragroup connections. This weights matrix is motivated by the fact that we usually do not know the relevant spatial groups. Should North Africa be grouped with Sub-Saharan Africa? Does Pennsylvania belong in the Northeast or Midwest? We do however observe intragroup relationships such as contiguity.

We evaluate the small-sample performance of the **SAR**, **SAC**, **SLX**, **SDEM**, **SDM**, and **GNS** models under four experimental conditions: (1) no spillovers and no interdependence ( $\theta = 0, \rho = 0$ ), (2) spillovers and no interdependence ( $\theta = 0.2, \rho = 0$ ), (3) no spillovers and interdependence ( $\theta = 0, \rho = 0.2$ ), and (4) both spillovers and interdependence ( $\theta = 0.2, \rho = 0.2$ ). We set  $\beta = 2$  in all of our experiments. Furthermore, clustering in the covariate and in the disturbances, as generated above, are present in all experiments.

Table 39.2 provides the ML estimates for the direct covariate effect ( $\hat{\beta}$ ). It is notable that all of the models perform reasonably well across the experiments, with

the exception of **SAR**. The direct effect is underestimated on average with this model. Clustering in the disturbances strengthens their correlation with the spatial lag, above and beyond the correlation that exists when the structural disturbances are independent and identically distributed (i.i.d.) This generates an inflating simultaneity bias in  $\hat{\rho}$ , which induces an attenuating bias in  $\hat{\beta}$ . Moreover, estimation using the SAR model performs relatively poor in root-mean-squared-error terms (largely a function of the bias), and the standard error estimates are overconfident (we should note, however, that SAR's underestimation of  $\beta$  tends to be in some partial way compensated by its overestimation of  $\rho$  in

**Table 39.2 ML estimates of covariate-coefficient estimate ( $\hat{\beta}, \beta = 2, N = 300, 1,000$  trials)**

terms of yielding an estimated total effect  $(\mathbf{I} - \hat{\rho}\mathbf{W})^{-1}\hat{\beta}$  closer to the true value, two.

The results for the spatial interdependence-parameter estimates ( $\hat{\rho}$ ) are presented in Table 39.3. Here, we see the inflation bias (in SAR and SDM, especially) driven by the unmodeled spatial clustering in the disturbances. The standard error estimates are highly overconfident as well. In SAR, across all four experiments, the standard deviation in the sampling distribution for  $\hat{\rho}$  is more than double the size of the average estimated standard error. The combination of an inflation bias and overconfident standard errors means the rejection rate is extremely high when the null hypothesis is true. In other words, estimation with SAR produces a high rate of false positive rejections when there

is unmodeled clustering (this is Galton's problem).

Estimation with SAC does better than with SAR or SDM in terms of bias, root-mean-squared-error performance, and standard error accuracy. The improvement stems from the fact that SAC accounts for the clustering in the disturbances (unmodeled/unobserved factors) by allowing them to follow a spatial AR process. This is not a perfect representation of the true DGP, but the AR specification is easy to implement when the spatial groups are not known, and there are substantial gains from doing so. The SAC provides protection against false positive rejections. The cost is a loss of power, which is large in column (3). However, the rate at which the SAC model correctly rejects the null hypothesis is

sensitive to experimental conditions. If we increase the strength of interdependence, for example, the power will improve. Both the **SDM** and **GNS** models perform poorly, producing biased estimates and overconfident standard errors.

Table 39.4 provides the ML estimates for the spillover parameter ( $\hat{\theta}$ ). Whenever there is no interdependence ( $\rho = 0$ ), estimates from the **SLX** model do well in terms of bias but not in terms of efficiency. The variance in the sampling distribution is relatively large. Also, the standard errors are highly overconfident. Across the experiments, the standard deviations for the empirical sampling distributions are about 2.5 times large than the average estimated standard error. Because of the overconfident standard errors, the **SLX**

model produces a high rate of false positive rejections, even when there is no interdependence. When there is interdependence, omitted variable bias causes the performance of **SLX** to deteriorate further. Similar to the **SAC** improvement over **SAR**, estimation with **SDEM** does better than with **SLX** in terms of bias, root-mean-squared-error performance, and standard error accuracy. **SDEM** provides some protection against false positive rejections; the cost for this protection is a loss of power. Again, both the **SDM** and **GNS** models perform poorly, producing biased estimates and overconfident standard errors.

To sum, clustering in unobservables – for example, unobserved or unmodeled clustered factors – complicates our ability to detect interdependence in outcomes and spillovers

**Table 39.4 ML estimates of spillover effect ( $\hat{\theta}$ ,  $\beta = 2$ ,  $N = 300, 1,000$  trials)**

from observable covariates in cross-sections of data. When one suspects both interdependence and exogenous spillovers, it would seem natural to estimate either the **SDM** or **GNS** models, but this is not advisable under these conditions. The **SDM** allows for both interdependence and spillovers, but it ignores the clustering in disturbances. This omission generates a bias in the estimates for the interdependence parameter ( $\rho$ ) and the spillover parameter ( $\theta$ ). Why not also allow for spatial correlation in the disturbances? This is what the **GNS** does. Unfortunately, this model is only identified from strong structural assumptions (functional form and **W**), and, in this case, the structural assumption about the disturbances is incorrect, so failure of these other strong assumptions has severe ramifications. Therefore, **GNS** tends not to perform any better than **SDM**. Both models frequently produce statistically significant estimates of interdependence and spillover parameters with the wrong sign!

When one suspects clustering on unobservables, it does not seem advisable to estimate either the **SDM** or **GNS** models. Instead, estimating either **SAC** or **SDEM** would seem to be a more prudent strategy (and preferable to **SAR** and **SLX** as well). While design should be leveraged to select between these models where possible, often this will not be an option and researchers will instead have to eliminate either interdependence or spillovers (plus spatial error dependence) on theoretical grounds.<sup>29</sup> This makes it difficult to offer a general prescription; however the nature of one's data will often be instructive. When the outcomes of interest are social aggregates – such as unemployment rates, crime rates, or the aggregate demand for cigarettes (these are common outcomes in the spatial-econometrics literature) – outcome contagion makes little sense. The unemployment rate in one locality does not literally cause the unemployment rate in another; rather, economic conditions cluster spatially and economic conditions in  $j$  cause unemployment in  $i$

(exogenous spillovers). On the other hand, when the outcomes are choices made by strategically interdependent actors – as is common in political science – interdependence is far more plausible: tax rates in  $i$  do likely respond to tax rates in  $j$ .

Ultimately, however, researchers are simply deciding whether theory indicates that changes to my neighbors' covariates affect me directly (as in **SDEM**) or indirectly through the changes they elicit in my neighbors' outcome (as in **SAC**). To us, this consideration seems less consequential (though not inconsequential because **Wy** implies multipliers whereas **WX** does not) than determining whether the spatial clustering we observe in the outcomes arises from spillovers of either exogenous (**WX**) or endogenous (**Wy**) type or merely through the presence of (spatially) common unobservables, which both **SDEM** and **SAC** better enable us to do.

## CONCLUSION

In general, there are two primary conclusions with which we hope to leave readers and practitioners. The first conclusion is the importance of undertaking appropriate diagnostics to explicitly test the restrictions implied by one's model, considering the different sources of spatial association, exogenous and endogenous, observed and unobserved. While this will seem obvious to readers more familiar with model specification in other literatures (e.g., time series), these issues have not been as well articulated in the spatial literature that guides political scientists to date. This is especially important in spatial-analytic contexts, where researchers are more likely to attach theoretic importance to these findings and, as such, should exercise greater care when specifying their models. The second is that no single model can or should serve universally as baseline specification that guards against misspecification. While some in the spatial-econometric literature have advocated

strongly for the **SAR**, **SLX**, or spatial Durbin models, we present a variety of theoretically plausible and empirically likely conditions where each of these models will cause researchers to draw faulty inferences. We have argued and presented support for the case that the heretofore relatively neglected **SAC** or **SDE** models will have broader utility as prudent defaults; but even those, we would acknowledge, can perform poorly under some plausible conditions.

For interested readers, we expand on the discussion presented here in Cook et al. (forthcoming, b) in several ways. First, we consider alternative specifications of the weights matrix, beyond the block-group structure examined here. Second, we increase the true effect size of the spatial lag of the predictor. Here, we have used a common coefficient size for each of the processes, however this implies a larger total effect size for the spatial lag of the outcome than the spatial lag of the predictor. Third, we consider not just coefficient estimates and hypothesis tests but substantive effects as well – i.e., the derivatives  $dy/dx$  (see Franzese, Chapter 31, this *Handbook*) – comparing the efficacy of the various models in capturing pre-spatial, post-spatial, and total effects. Fourth, we consider extensions to TSCS data, where temporal dynamics may also impair spatial-model specification. Finally, we illustrate our approach to model selection with an empirical example (democracy and income) to aid applied researchers.<sup>30</sup>

## ACKNOWLEDGEMENTS

We thank the participants at the 2015 Texas A&M Conference on Innovations in Comparative Political Methodology, the 2015 Summer Methods Meeting of the Society for Political Methodology, the 2016 Meeting of the American Political Science Association, and the 2018 Workshop Modeling Spatial and Network Interdependence in International Relations for their useful feedback on this project. Any remaining errors are ours alone.

## Notes

- 1 See Franzese and Hays (2008) for a fuller account of the substantive range of ‘spatial’ theories advanced in political science. In addition, Cook et al. (2019) discuss the application of spatial-econometric models to research in public administration and public management.
- 2 This trend is likely to continue growing as these methods become more familiar to researchers and packages facilitating their easy estimation become available in widely used statistical software languages, such as the ‘spdep’ package in *R* and the ‘sp’ suite in *Stata 15*.
- 3 Briefly noting the models that these would imply: spatial clustering can manifest due to unobserved factors common to proximate units, suggesting the spatial error model (**SEM**), or through exogenous perturbations to the predictors in my neighbor(s), which can influence me directly, motivating a spatially lagged X (**SLX**) model, or indirectly, by affecting my neighbors’ outcome and thereby my own outcome, as in a spatial autoregressive (**SAR**) model. Or it might be any combination thereof, suggesting one of several models that are more general.
- 4 We suspect this is often true in experimental data on human subjects as well.
- 5 For clarity, we confine our attention in this paper to the cross-sectional analysis of continuous data. While many of the themes and topics generalize to a broader set of circumstances, we save peculiarities confronted when dealing with qualitative outcomes and/or panel/time-series-cross-sectional for address in other work.
- 6 Although most of the literature uses the terms *observables* and *unobservables*, the actual issue is whether these factors are *observed* and included in the model’s systematic component or *unobserved* and left in the unmodeled residual component. We will continue to follow convention throughout, but the reader is encouraged to understand (*un*) *observed*s for all references to (*un*) *observables*.
- 7 Generally, this is discussed as the predictor and/or residual being governed by a spatial autoregressive process. However, it may also be that the predictor is a function of spatially correlated (but not autoregressive) factors. The consequences with respect to parameter estimates in the model of *y* are identical.
- 8 More formally, Andrews (2005) states common-factor residuals and predictors satisfy the following:

$$u_i = \mathbf{C}'_g \mathbf{u}_i^*$$

$$x_i = \mathbf{C}'_g \mathbf{x}_i^*$$

where  $\mathbf{C}_g$  is a random common (e.g., group) factor with random factor loadings  $\mathbf{u}_i^*$  &  $\mathbf{x}_i^*$ .

Therefore, if units  $i$  and  $j$  are each members of group  $g$ , they are jointly impacted by the respective loading.

- 9 The distinction also closely parallels that between moving-average (MA) and autoregressive (AR) processes in time-series contexts. Roughly, spatial-lag  $\mathbf{X}$  (and spatial-MA error) processes are local, MA-like, and spatial-lag  $y$  (and spatial-AR error) processes are global, AR-like (in the errors only, not the outcomes, as in the SAR-error case).
- 10 This is analogous to Anselin's (2003) two-dimensional taxonomy for externalities.
- 11 Note that this is a partial list. All of the models presented here assume parameter constancy, first-order spatial dependence (when present), and global (and not local) spatial autocorrelation in the unobservables (when present). As noted, these are the most common alternatives in the literature and importantly include those advocated by LeSage and Pace (2009) and Elhorst (2010).
- 12 For example, Buhaug and Gleditsch (2008) argue that conflicts cluster in space because the characteristics that produce conflict also cluster in space. If correct, this would be captured simply via the inclusion of the relevant country-characteristics. Instead, they estimate a model with spatially lagged independent variables (e.g., democracy in contiguous countries), these  $\mathbf{WX}$ s actually relate to a different argument as we discuss later.
- 13 As always, the distribution of our residuals – spatial or otherwise – is entirely dependent on the specification of the systematic component of our model.
- 14 In the remaining models, we will continue to assume that the residuals are orthogonal after the appropriate spatial specification is set. The possible endogeneity of the predictors present further complications as discussed in Betz et al. (2020).
- 15 Under spatial dependence in orthogonal residuals, standard errors can also be consistently estimated, leaving the parameter-inefficiency unaddressed, by using appropriately designed robust standard errors (Driscoll and Kraay, 1998).
- 16 The local (i.e., moving average) analog to this model would be given as

$$\mathbf{y} = \mathbf{X}\beta + \varepsilon + \gamma\mathbf{W}\varepsilon$$

where the residual is decomposed into a spatial and non-spatial component. However, unlike the more common **SEM**, there is not autoregression in the residuals and therefore there is no inverse required in the reduced form, as noted by Anselin (2003). This model is not widely used in practice, likely because researchers have little information

to justify this constraint, instead preferring the perhaps greater generality of the **SEM** model.

- 17 Note that this is not true of panel or time-series-cross-sectional data, where we can use spatial fixed effects to account for time-invariant heterogeneity in the unobservables directly. An example of this can be found in Cook et al. (2019).
- 18 In actuality, the **SAR** model suggests global spillovers in both the observables and unobservables as we can see from the reduced form given below.
- 19 We note again that each of these models assumes a global autocorrelation in  $\mathbf{y}$  and/or  $\varepsilon$  and that only first-order processes are considered.
- 20 Instead, all that is identified is the total spillover effect; this is *Manski's reflection problem*.
- 21 This should suggest the importance of  $\mathbf{W}$  given that the degree to which the weights matrix accurately reflects the true spatial relationships among the units is paramount. Both our ability to detect whether spatial dependence is present and to identify which source of spatial effects are present depend upon the accuracy of  $\mathbf{W}$ .
- 22 In this instance, the spatial analog is

$$\mathbf{y} = \mathbf{X}\beta + \mathbf{WX}(\beta\rho_1 + \gamma) + \rho_1\mathbf{WX}(\beta\rho_1 + \gamma) + \rho_1^2\mathbf{W}^2\mathbf{X}(\beta\rho_1 + \gamma) + \dots + \varepsilon$$

- 23 While we do not fully elaborate it here, the intuition – beyond simply being identified – as to why two parameter specification checks work well follows directly from Anselin et al.'s (1996) robust Lagrange Multiplier tests (here given for spatial error):

$$LM_{\lambda}^* = \frac{(\hat{\varepsilon}'\mathbf{W}\hat{\varepsilon} / \hat{\sigma}_{\varepsilon}^2 - \psi\hat{\varepsilon}'\mathbf{W}\mathbf{y} / \hat{\sigma}_{\varepsilon}^2)^2}{T[1 - \psi]}$$

which treats  $\rho$  – the spatial heterogeneity attributable to the spatial lag of the outcomes – as a nuisance parameter, adjusting for its effect on the likelihood. In effect, removing the portion of  $\text{cov}(\hat{\varepsilon}, \mathbf{W}\hat{\varepsilon})$  that can be attributable to  $\text{cov}(\hat{\varepsilon}, \mathbf{W}\mathbf{y})$ . Equivalently, we could construct additional pre-specification tests (or simply estimate models) that hold fixed the effect of one alternative while evaluating the second.

- 24 Even when these exist, the likely high degree of correlation between the weights matrices would likely leave a still weakly identified model.
- 25 See also Egami (2018) for a strategy attempting nonparametric causal-inference tests of spatial spillovers in observational data.
- 26 Egami's (2018) approach requires no temporally simultaneous interdependence and is designed to test for, but not estimate (see Franzese, Chapter 31, this *Handbook*), spatial effects. We are inter-

- ested in spatial-effect estimation in other contexts.
- 27 Unbiased estimation of isolated parameters is sufficient for testing purposes, for effect or response estimation; however, generally one needs more (see Franzese, Chapter 31, this *Handbook*).
  - 28 While this does not as easily permit a Burridge-type restriction, we could specify a higher-order SDEM model and then perform an F-test of zero coefficients on these higher-order polynomials. Rejection would indicate that the standard SDEM model is insufficient. To be clear, we would not be able to reject the possibility that the truth is some higher-order SDEM from this analysis. This problem is analogous to that discussed by Beck (1991) in the time-serial context, where the AR(1) model can be closely approximated by a higher-order MA model. While we have no information to discriminate between those two, researchers in these situations should typically prefer the more parsimonious SAR model.
  - 29 As an alternative, one could estimate both **SAC** and **SDEM**. If one rejects  $\lambda = 0$  in both models and  $\rho = 0$  and  $\theta = 0$  in the **SAC** and **SDEM** models, respectively, it is likely that all three sources of clustering in the outcome are present. Power concerns make it more difficult to interpret the other combinations of possible results.
  - 30 Interested readers can also find an empirical application in Cook et al. (2015), an earlier version of this paper.

# Instrumental Variables: From Structural Equation Models to Design-Based Causal Inference

Christopher L. Carter and Thad Dunning

## INTRODUCTION

Instrumental-variables (IV) analysis bridges structural equation modeling and design-based methods for causal inference. Early studies employed instrumental variables to overcome the endogeneity of price and quantity in a structural system of supply and demand curves; by finding a third variable that was correlated with the supply but not the demand of a good (or vice versa), scholars sought to map how supply and demand respond to changes in prices. More recently, researchers have used insights from IV analysis to estimate ‘complier average causal effects’ (CACEs) in randomized experiments—that is, effects for units that comply with their assignment to receive a given treatment. Thus, the use of IV spans observational and experimental research.

In both kinds of applications, IV analysis appeals to an assumption of random or as-if random assignment of units to causal conditions. In structural equation modeling,

randomization implies statistical independence of the causal variable(s) and the error term in a regression model – that is, exogeneity. In the observational world, such assignment occurs naturally or is otherwise out of the control of the researcher – often thereby raising concerns about whether treatment assignment is really as-good-as random. When plausible, however, this assumption allows researchers to obviate concerns about confounding variables that complicate drawing causal inferences from observational data. An IV approach thus promises to marry the realism and macro focus of observational research to the rigor of experimental methods.

Yet, in observational and experimental work alike, (as-if) random assignment alone does not guarantee valid causal inference under the IV framework. Other assumptions are also needed, and these often cannot be fully tested from the data. Furthermore, the assumptions invoked by structural equation models that are fit to observational data (e.g., supply and demand curves) carry different

weight and meaning, as compared to those required to estimate CACEs in experiments.

We draw attention to these points of overlap and divergence between different usages of instrumental variables in this chapter. We begin with a discussion of early IV work in the structural equation modeling (SEM) framework, highlighting the key assumptions and potential places where they may break down. We then discuss applications of instrumental variables to design-based (often experimental) research under a potential outcomes model. We detail similarities and differences in the assumptions that these two types of applications entail. A key distinction involves the stipulation of a linear response schedule with constant effects across units in the SEM framework. Relaxing this assumption under the potential outcomes framework allows for clear definition of heterogeneous unit-level causal effects, which proves particularly important in experiments with non-compliance. Moreover, the potential outcomes framework disaggregates and clarifies other key assumptions often left implicit in the SEM framework. Yet, both approaches face important challenges in generalizing effects beyond the variation induced by a particular instrument. In a final section, we illustrate these points by comparing two different IV strategies – one observational and the other experimental – for investigating the effect of price changes on demand for coffee.

## IV IN STRUCTURAL EQUATION MODELS

The use of instrumental variables originated in simultaneous equation models, in which researchers sought to estimate supply and demand curves from equilibrium values of price and quantity (Angrist and Krueger, 2001; Stock and Trebbi, 2003: 179). Because supply and demand curves map how quantity supplied and demanded responds to changes in prices, they can be considered ‘response

schedules’ or ‘structural equations’, where the regression of quantity,  $Q$ , on price,  $P$ , carries a causal interpretation (Freedman, 2009; Imbens, 2014, 9).<sup>1</sup> A researcher may stipulate, for instance, that demand is determined according to

$$Q_t = \beta_0 + \beta_1 P_t + \beta_2 X_t + \gamma_t, \quad (1)$$

where  $Q_t$  is the quantity of a product demanded at time  $t$ ,  $P_t$  is its price,  $X_t$  is a matrix of exogenous variables affecting demand, and  $\gamma_t$  is a random error (disturbance) term.

A challenge for estimating equation (1), however, is that the quantity of the good supplied is also a function of  $P_t$ . Suppose the supply curve is given by

$$Q_t = \beta_3 + \beta_4 P_t + \beta_5 Z_t + \gamma_t, \quad (2)$$

where  $Z_t$  is a matrix of variables affecting supply.<sup>2</sup> Were the supply curve to remain fixed while the demand curve shifted, data on equilibrium levels of price and output could allow a researcher to trace out the demand equation. Yet, both curves may shift as a function of shared market conditions. In an early analysis of the impact of tariffs in markets for butter and flaxseed, the mathematician and economist Philip G. Wright noted this problem: ‘If both supply and demand conditions change, price-output data yield no information as to either curve. Unfortunately ... [this case] is the more common’ (Wright, 1928: 296). Indeed, if  $X_t = Z_t$  in equations (1) and (2) – that is, the same variables affect the quantity of the good demanded and supplied – then data on quantities and prices cannot uniquely identify the supply and demand curves.

Wright (1928) proposed an initial solution to this problem by using variables that affected supply without independently shaping demand (and vice versa).<sup>3</sup> When such variables can be found, the columns of the matrix  $X_t$  in equation (1) are not identical to the columns of  $Z_t$  in equation (2). Using what came to be called ‘instrumental variables’ – that is, variables in  $X_t$  that are excluded from  $Z_t$ , and vice versa – Wright determined the elasticity of the

supply (and demand) functions of flaxseed. One instrument Wright used to estimate supply elasticity was the price of a flaxseed substitute, cottonseed. This example already suggests difficulties in finding viable instrumental variables, however: shocks to substitutes might affect not only the demand for, but also the supply of flaxseed, perhaps because producers anticipate shifts in the demand curve.

Estimating equations (1) and (2) raises related difficulties. Manipulation of the price of the good affects quantity in both equations: supply and demand are jointly determined within a system of structural equations. Moreover, unmeasured variables that affect the quantity of demand may also affect supply, resulting in endogeneity – that is, correlation between disturbances and an explanatory variable (Freedman, 2006: 699; Freedman, 2009; Imbens, 2014: 9). In that case, the Ordinary Least Squares (OLS) estimate of  $\beta_1$  in equation (1) is biased by  $(P'P)^{-1}P'E(\gamma|P)$ , when  $E(\gamma|P) \neq 0$  (Freedman, 2009: 181). Yet, as long as cottonseed is correlated with flaxseed price but uncorrelated with the disturbance term from the demand equation, IV analysis can provide a consistent estimator of demand elasticity (Angrist and Krueger, 2001: 70).

Wright's work went largely unnoticed and played little role in the development of the IV method in econometrics.<sup>4</sup> In fact, there was no further work on instrumental variables until the 1940s, when Reiersøl's (1945) dissertation demonstrated that model parameters can be identified using the additional 'instrumental set of variables' (Angrist and Krueger, 2001; Morgan, 1990; Aldrich, 1993). Building on the further work of Geary (1949) and Durbin (1954), Sargan (1958) demonstrated the consistency of the IV estimator. Wald (1940) had previously shown the consistency of an equivalent 'grouping' estimator.<sup>5</sup>

While some of this early research sought to address measurement error in independent variables, the IV framework has gained its most prominent use in addressing the problem of omitted variable bias. A researcher interested in a causal effect of an explanatory

variable  $X_i$  on an outcome variable  $Y_i$  may stipulate the response schedule,

$$Y_i = \beta_0 + \beta_1 X_i + \epsilon_i. \quad (3)$$

If unmeasured variables not included in equation (3) are correlated with the explanatory variable, such that  $\epsilon_i$  and  $X_i$  are statistically dependent, OLS will yield biased and inconsistent estimates of  $\beta_1$ . However, a third variable,  $Z_i$ , that is correlated with  $X_i$  but not  $\epsilon_i$ , offers a way to identify  $\beta_1$ . Specifically, consistent estimation of  $\beta_1$  can be obtained from the 'first-stage' regression of  $X_i$  on  $Z_i$  and then a second-stage regression of  $Y_i$  on the fitted values of  $X_i$ , or  $\hat{X}_i$ , from the first stage.<sup>6</sup> In matrix notation, this 'two-stage least squares' (2SLS) estimation of  $\beta_1$  can be written as

$$\hat{\beta}_{1,2SLS} = (\hat{X}'\hat{X})^{-1}\hat{X}'Y, \quad (4)$$

where  $\hat{X} = Z(Z'Z)^{-1}Z'X$ .

Other derivations of the multivariate IV least squares (IVLS) estimator can be rearranged to show their equivalence with equation (4) (Freedman, 2009: 178–9). In the bivariate model in equation (3), equation (4) is equivalent to dividing the regression coefficient of the 'reduced-form' regression of  $Y_i$  on a variable  $Z_i$  by the regression coefficient obtained in the first-stage regression of  $X_i$  on  $Z_i$ .<sup>7</sup>

$$\hat{\beta}_{1,2SLS} = \frac{\widehat{\text{Cov}}(Y_i, Z_i)}{\widehat{\text{Cov}}(X_i, Z_i)} = \frac{\widehat{\text{Cov}}(Y_i, Z_i)}{\widehat{\text{Cov}}(X_i, Z_i)} \cdot \frac{\widehat{\text{Cov}}(X_i, Z_i)}{\widehat{\text{Cov}}(X_i, Z_i)}. \quad (5)$$

We return to equation (5) in the next section on IV analysis in design-based inference, where the reduced-form regression of  $Y_i$  on  $Z_i$  is referred to as 'intent-to-treat' (ITT) analysis.

IV analysis requires several crucial assumptions for consistent estimation of  $\beta_1$  by the method in equations (4) or (5). Some of these assumptions are mechanical, meaning that the calculation of the 2SLS estimator requires

them to be true. To solve equation (4), the number of units must be at least as large as the number of independent variables (i.e.,  $n > q \geq p$  where  $n$  is the number of observations,  $q$  is the number of columns in  $Z$  and  $p$  is the number of columns in  $X$ ); and  $Z'X$  and  $Z'Z$  must have full rank of  $p$  and  $q$  respectively.<sup>8</sup>

Additionally, we require in practice a sufficiently strong covariance between  $X_i$  and  $Z_i$ : the so-called ‘weak instrument’ problem exacerbates finite-sample bias in the IV estimator.<sup>9</sup> Indeed, in finite samples with instruments that are only weakly related to the endogenous regressors, the asymptotic unbiasedness of the 2SLS estimator in a hypothetical, infinitely large sample – i.e., its consistency – may be of limited practical utility (Staiger and Stock, 1997). We can diagnose weak instruments by examining the relationship between  $X_i$  and  $Z_i$  in the data; as a rule of thumb, F-statistics of less than 10 indicate a weak instrument (Staiger and Stock, 1997).

Other key assumptions of structural equation models are more difficult or impossible to test. Each assumption merits careful consideration in applications of the method. First, and perhaps most fundamentally, valid IV analysis of structural equation models requires that the data were generated according to the posited response schedule – that is, a regression model such as equation (3):

$$Y_i = \beta_0 + \beta_1 X_i + \epsilon_i.$$

Because the model stipulates the effect of hypothetical interventions to alter values of  $X_i$ ,  $\beta_1$  is said to carry a causal interpretation: it is the causal effect of  $X_i$  on  $Y_i$ . However, in observational studies – by definition – no researcher intervened in the system to manipulate the value of  $X_i$  (Freedman, 2009). Whether the model captures what would happen if, say, a researcher varied  $X_i$  experimentally is usually a matter of conjecture. We return to this idea of invariance to manipulation in our discussion of design-based inference.

The stipulation of this model embeds several auxiliary postulates, with specific implications

for IV estimation. First – as often noted in methodological discussions of IV analysis, and as sometimes discussed in applications as well – the assumption that the response schedule is correctly specified implies an ‘exclusion restriction’. That is, the instrument is *excluded* from equation (3). Thus,  $Z_i$  does not have a ‘direct’ effect on  $Y_i$ : it does not itself belong in the response schedule and, if it is related to  $Y_i$ , it is only through its effect on  $X_i$ . We refer here to the exclusion restriction, although some scholars use this term to refer to the combination of this assumption and the independence of  $Z_i$  and  $\epsilon_i$ ; we treat the latter as a distinct assumption (Angrist and Pischke, 2008: 117).<sup>10</sup> Additional collection of qualitative and quantitative data can help to rule out plausible alternative channels through which  $Z_i$  might have a direct effect on  $Y_i$ . Yet, for reasons we discuss further below, convincingly demonstrating that the instrument only affects the outcome through the endogenous regressor of interest raises considerable difficulties.

In addition, the structural model critically implies a set of linearity and constancy assumptions. Equation (3) stipulates that the response schedule is linear in the parameter  $\beta_1$ : thus, the effect is proportional to the value of  $X_i$ . In addition, for each unit  $i$ , the response  $Y_i$  only depends on the value of the regressor  $X_i$ : the exposure to this treatment of other units  $j \neq i$  is irrelevant. This is an analogue to the ‘non-interference’ assumption, a component of the ‘stable-unit treatment value assumption’ (SUTVA), in the context of design-based inference under the potential outcomes model. Thus, for each unit  $i$ , the treatment effect is constant, in the sense that it does not depend on the treatment assignment of other units, which might be compromised by communication or learning from other subjects in a study. The response schedule also presumes a treatment effect that is constant *across* all units  $i$ :  $\beta_1$  is the same for every unit in the study. We further discuss these assumptions of linear and constant effects across units (and contrast it to the assumption of idiosyncratic unit effects in the potential outcomes framework) in the next section.<sup>11</sup>

Finally, models such as equation (3) assume a different kind of constancy assumption: effects are constant (or homogenous) across components of  $X$ . This assumption has received somewhat less attention yet is critical for understanding the leverage that IV analysis may – or may not – provide. Imagine a researcher who is interested in the effect of income ( $X_i$ ) on attitudes toward taxation ( $Y_i$ ). Among participants in a lottery, lottery winnings ( $Z_i$ ) can be used as an instrument for income. Income ( $X_i$ ) is the sum of winnings from the lottery and income from other sources ('earned income'): call these  $X_{1i}$  and  $X_{2i}$ . The model in equation (3) assumes that the effects of these two components of  $X_i$  are the same. If this is not the case, then, in calculating a 2SLS estimate of  $\beta_1$ , we are getting the effect of a particular type of income shock – specifically, windfall gains  $X_{1i}$  (Dunning, 2008). We are not getting the effect of an increase to earned income  $X_{2i}$ . Perhaps, then, the model we should be considering is, in fact,  $Y_i = \beta_0 + \beta_1 X_{1i} + \beta_2 X_{2i} + \epsilon_i$ . If  $\beta_1 \neq \beta_2$  in this equation, then assuming a constant effect of  $\beta_1$  in equation (3) is misleading. However, we cannot estimate the model with  $X_{1i}$  and  $X_{2i}$  without another instrument for  $X_{2i}$ . Were we to find such an instrument, concerns about the assumption that  $\beta_2$  is constant across components of  $X_{2i}$  may arise. Dunning (2008) gives additional examples where possible heterogeneous partial effects in IV analyses raise concerns about model specification. One way to reduce concerns of heterogeneous partial effects may be to define concepts more precisely a priori and limit causal claims to those aspects of a general concept that are actually measured through the IV analysis.<sup>12</sup> The point is that the stipulation of the response schedule is a key consideration for IV analysis.

If the many modeling assumptions hold – but  $X_i$  is endogenous, or statistically dependent on  $\epsilon_i$  – and there exists an instrumental variable such that

$$Z_i \perp \epsilon_i, \quad (6)$$

where  $\perp$  is read as 'is independent of', then the IV estimator in equation (5) consistently estimates  $\beta_1$  from equation (3). This too is a matter of model specification: like the exclusion restriction, statistical independence of the instrument and the disturbance term implies that  $Z_i$  does not belong in the response schedule. If it did, then the response schedule in equation (3) would be incorrectly specified. Given the model, however, random assignment of values of the instrument may imply  $Z_i \perp \epsilon_i$ . The assumption could also hold in a natural experiment where treatment is merely 'as-if' randomly assigned. Yet, the burden is then on the researcher to demonstrate why  $Z_i$  might be plausibly uncorrelated in expectation with pre-treatment causes of  $X_i$  and  $Y_i$ . Sovey and Green (2011) and Dunning (2012), among others, discuss tests that can be used to assess the validity of this assumption.

Relative to the design-based approach discussed next, the SEM framework adds additional complications for assessing the assumption in equation (6). Researchers often use multivariate IVLS regression – thus, the matrix form of the estimator in equation (4). They tend to focus on a single endogenous regressor and on whether a single instrumental variable is as good as randomly assigned; they also include putatively 'exogenous' columns of the matrix  $X$  in the matrix of independent variables,  $Z$ . Little attention is typically paid to assessing the assumption that those other columns of  $Z$  are exogenous – that is, as good as randomly assigned – as required for valid estimation by the 2SLS estimator for multiple regression. We return later to discussing these assumptions, after introducing the use of IV analysis in design-based analysis under the potential outcomes framework.

## IV ANALYSIS IN DESIGN-BASED CAUSAL INFERENCE

The rise of experimental social science has provided a new use for instrumental variables

as a tool for estimating complier average causal effects. When conducting an experiment, researchers randomly assign units to treatment or control conditions. Interest is often in estimating the average causal effect (ACE) for the group of units included in the experimental study (referred to variously as the ‘study group’ or ‘experimental population’). Scholars typically stipulate the Neyman potential outcomes model, also called the Neyman–Rubin–Holland model (Splawa-Neyman et al., 1990; Rubin, 1974; Holland, 1986). According to this model, each unit has a potential outcome under treatment,  $Y_i(1)$  – that is, the outcome that would materialize if it were assigned to the treatment group – and another potential outcome  $Y_i(0)$  that would materialize if it were assigned to control. The two potential outcomes cannot be simultaneously observed for the same unit, because a unit assigned to the treatment group cannot be assigned to control; this is the ‘fundamental problem of causal inference’ (Holland, 1986). Nor can a researcher observe the average of the potential outcomes under treatment for the experimental population without losing access to the average of the potential outcomes under control. In an experiment, however, units are assigned at random to treatment and control groups. It is as if the treatment group is a random sample from the experimental population; and the control group is another random sample from the same population. The mean of the treatment sample can therefore be used to estimate the average potential outcome under treatment for all units in the study group, and the mean of the control sample similarly estimates the average potential outcome under control. The difference of the means is an unbiased estimator for the average causal effect.

This mode of inference is sometimes called ‘design-based’, because the only stochastic element in the model is the random assignment to treatment and control groups – which is controlled by the researcher as a matter of research design (Cox, 2009).<sup>13</sup> Scholars have also used the term more broadly to denote

strategies for controlling for confounding variables that depend centrally on research design – rather than on regression adjustment, as in standard SEM frameworks (Freedman, 2009; Dunning, 2012). Design-based approaches are thus sometimes contrasted with ‘model-based’ research, even though models for causal and statistical inference play a central role in both. The key difference, as we discuss in the next section, concerns the nature of the assumptions that must be made.

In design-based inference in experiments, the CACE – and IV analysis – enters the picture when some units, despite having been assigned to the treatment condition, do not actually receive the treatment. Differential take-up of treatment generates a problem of non-compliance with treatment assignment. Imagine a case where a government offers a temporary employment program to unemployed citizens; many citizens apply, far more than the program can fund. The government decides to use a lottery to decide which applicants may participate. However, not all of those selected ultimately participate. Some have already located other employment, others may have already migrated elsewhere in search of employment, and still others may simply lose interest in participating. Similarly, some of those who were not offered enrollment may ultimately participate, say, if there is non-take-up by those originally selected to participate.

With non-compliance, the difference-of-means estimator is ITT analysis: it measures the effect of assignment to the program.<sup>14</sup> The effect of treatment assignment on outcomes, such as future employment or political support for the incumbent, may be of substantial policy as well as scholarly interest. Estimating it could tell us, for example, the likely marginal returns of offering the program to additional participants. Still, the estimator does not readily measure the effect of treatment receipt – that is, actual participation in the employment program. The assigned-to-treatment and assigned-to-control groups include non-compliers; this may ‘dilute’

the effect of treatment assignment. How to estimate the effect of program participation is not immediately obvious, however. We cannot naively compare those who received treatment to those who did not: those are self-selected groups, and participants may differ from non-participants in ways other than exposure to treatment. Put differently, these self-selected groups contain distinct mixes of compliers and non-compliers, and asymmetry may confound valid inference about the effect of treatment receipt.<sup>15</sup>

Here, IV analysis can assist in the estimation of an average causal effect among compliers – the CACE. To do so, we extend the potential outcomes model to allow for non-compliance.<sup>16</sup> Thus, we imagine that there are three types of subjects in the study pool: compliers, always-takers, and never-takers. Under the model, these types are fixed at the level of the subject; type is not affected by the assignment to levels of treatment. Compliers are those units who would receive the treatment if assigned to the treatment group – but otherwise receive the control. Always-takers receive the treatment, and never-takers receive the control, regardless of their assignment. A fourth type, defiers – who receive the treatment if assigned to the control group but receive the control if assigned to treatment – are ruled out; this assumption is required for identification of the CACE (Freedman, 2006).<sup>17</sup> The trick is then to separate the responses of compliers, always-takers, and never-takers – in order to isolate the effect of treatment assignment among compliers. At the unit level, we often cannot directly observe who is a complier and who is not, as these definitions involve counterfactuals – that is, potential outcomes (Imbens, 2014). For example, among those assigned to the control group who actually receive the control protocol, we do not observe whether they would have taken the treatment had they been assigned to the treatment group.

However, we can estimate the group-level distribution of compliance types—and the average responses by type. Imagine first that there are no always-takers: this is a situation

of ‘single crossover’ or ‘one-way non-compliance’ (Gerber and Green, 2012). In this case, we can tell which type is which among units assigned to the treatment group: the never-takers cross over to receive the control protocol while the compliers receive treatment.<sup>18</sup> Thus, we observe the average responses of the group of compliers in the assigned-to-treatment group. In the assigned-to-control group, however, the compliers and never-takers look the same: they both follow the control-group protocol.

Nonetheless, due to random assignment, we can estimate the proportion of each type in the study group. Indeed, the proportion of each type in the assigned-to-treatment group is an unbiased estimator for the corresponding proportions in the experimental population, since the treatment group is a random sample from the whole set of units in the experiment. In particular, the fraction of compliers in the treatment group – which we can observe in the case of single crossover from treatment to control – estimates the fraction of compliers in the experimental population. Moreover, the responses of never-takers in the treatment and control groups should be the same, in expectation: by assumption, treatment assignment has no effect on the response of never-takers, since they receive the control condition whether they are assigned to the treatment or the control group. Since we observe the overall response in the assigned-to-control group, and we impute the response of never-takers from the assigned-to-treatment group, we can therefore estimate the responses of the compliers in the control group. The assumption that treatment assignment does not affect the response of never-takers is akin to the exclusion restriction in the SEM framework, as we discuss further in the next section, though the potential outcomes framework helpfully clarifies the important distinction between the exclusion restriction and as-if random assignment. Together, random assignment and the exclusion restriction therefore allows us to estimate the responses of the never-takers in the assigned-to-control group – and thus the

compliers. An estimate of the CACE is just the average difference between the assigned-to-treatment and the assigned-to-control groups – that is, what ITT analysis gives us – divided by the estimated proportion of compliers in the study group.

The single-crossover model can be extended to the case of two-sided non-compliance, or ‘double crossover’ (Freedman, 2006; Dunning, 2012; Gerber and Green, 2012). In this case, we estimate the proportion of compliers by subtracting the proportion of the assigned-to-control group that actually receives the treatment from the proportion of the assigned-to-treatment group that receives treatment. Thus, when treatment assignment is a binary variable (e.g.,  $Z_i = 1$  when assigned to treatment,  $Z_i = 0$  when assigned to control), we can use the ‘Wald estimator’,

$$\hat{\beta}_{1,Wald} = \frac{\bar{Y}_1 - \bar{Y}_0}{\bar{X}_1 - \bar{X}_0}, \quad (7)$$

where  $\bar{Y}_1$  is the sample average in the assigned-to-treatment group,  $\bar{Y}_0$  is the sample average in the assigned-to-control group,  $\bar{X}_1$  is the proportion who receive treatment in the assigned-to-treatment group and  $\bar{X}_0$  is the proportion who receive treatment in the assigned-to-control group. The difference of means in the numerator of equation (7) is thus ITT analysis: it estimates the average causal effect of treatment assignment.<sup>20</sup> Note that  $\bar{X}_1$  includes both compliers and always-takers, while  $\bar{X}_0$  includes only always-takers. Effectively, the denominator subtracts off the proportion of always-takers in the control group from the joint proportion of compliers and always-takers in the treatment group. Because we expect the estimated proportion of compliers to be the same across the groups assigned to treatment and control (due to random assignment), the denominator of the Wald estimator estimates the proportion of compliers in the full study group.<sup>21</sup>

Why is equation (7) an IV estimator? Numerically, it is equivalent to a 2SLS procedure in which we regress  $Y$  on the fitted

values of  $X$ , which were obtained from a first-stage regression of  $X$  on  $Z$ . Indeed, with one treatment and one control group, and as we show in the appendix,

$$\hat{\beta}_{1,Wald} = \hat{\beta}_{1,2SLS}, \quad (8)$$

where  $\hat{\beta}_{1,2SLS}$  is given by equation (5). Conceptually, treatment assignment serves as an instrumental variable for treatment receipt in a similar sense to that developed in the previous section: it is correlated with an endogenous variable (treatment receipt), is randomly assigned, and by assumption does not influence outcomes, other than through its effect on treatment receipt. Indeed, the proof that  $\hat{\beta}_{1,Wald}$  is a consistent estimator for the CACE depends on both the randomization of the instrument and the stipulation that treatment assignment does not affect the responses of always-takers and never-takers – a kind of exclusion restriction.<sup>22</sup>

The beauty of the Wald estimator lies in its simplicity. If we have two potential treatment assignments, we can calculate an estimate for the complier average causal effect knowing only the first-stage difference in means (the numerator) and the estimated proportion of compliers in the study group (the denominator). This simplicity also rests on a model that seems reliably to capture core elements of the data-generating process: in any experiment, for example, the physical properties of the random assignment of units to treatment and control groups seem to justify the metaphor of drawing potential outcomes at random from an urn.

Nonetheless, as in all causal and statistical inference – and certainly as also in the SEM framework – design-based analysis under the potential outcomes model involves maintained hypotheses. A key assumption is the response schedule itself. The Neyman model assumes each unit has potential outcomes – in its simplest formulation, a potential outcome under control and a potential outcome under treatment. While potential outcomes are free to vary across units, they are considered fixed, deterministic properties of each

unit, and the treatment assignment of one unit does not affect the response of another. When extended to account for non-compliance, moreover, the model assumes that units are always-takers, never-takers, or compliers – but not defiers. In addition, assignment to treatment only affects outcomes for compliers; the response of always-takers and never-takers is invariant to treatment assignment. As in the SEM framework, such modeling assumptions merit careful consideration in applications of the design-based approach.

**SEM VS. DESIGN-BASED IV: A COMPARISON OF ASSUMPTIONS**

How, then, does the use of instrumental variables in the SEM framework compare to design-based approaches? The discussion so far highlights points of convergence – but also important areas of divergence. We detail similarities and contrasts in the core assumptions of the models in Table 40.1. Each row or set of rows in the table includes an assumption in the SEM framework (first column) and a corresponding or contrasting analogous assumption in the design-based approach (second column). Fundamental distinctions in the approaches

involve the assumed response schedule; the population for which key estimands are defined; stipulations on the stochastic process; and the manner of formulating validity conditions on instruments. In boldface, we indicate those assumptions that can be assessed, if at least partially, with data; we later explain the coding decisions.

First, for SEMs, the response schedule is a linear equation such as equation (3). Thus, the effect of  $X_i$  on  $Y_i$  is given by the constant of proportionality  $\beta$ . Linear structural equation models involve assumptions akin to potential outcomes because the response schedule traces out counterfactual responses at different values of  $X_i$  (Freedman, 2009). Yet, the levels of  $X_i$  (or  $Z_i$ ) are not typically directly manipulated, and linearity implies that the response surface varies smoothly as a function of  $X_i$ . By contrast, models in the Neyman tradition stipulate unit-level potential responses to two or several categorical treatment conditions. In experiments, assignment to these conditions is directly manipulated by a researcher.

Second, the response schedule under SEM also implies an assumption of a constant effect across units. By contrast, the design-based approach explicitly allows for treatment effects to vary across compliance types. This assumed unit-level heterogeneity of effects

**Table 40.1 SEM vs. design-based IV: a comparison of the assumptions**

<i>Structural equation modeling</i>		<i>Design-based IV</i>	
Linear response schedule	Linearity in parameters	Neyman potential outcomes	Unit-level potential responses to categorical treatment conditions
	Constant effect across units		Varying effect across units
	Constant effects across treatment components		Constant effect across treatment components
	Infinite (or undefined) population		<b>Finite experimental population</b>
	Random disturbance term (i.i.d)		Random sampling of potential outcomes (not i.i.d)
	$Y_i$ depends on $X_i$ , not on $X_{j \neq i}$		<b>Non-interference/SUTVA</b>
	$Z_i$ does not belong in response schedule (i.e., $Z_i \perp \square_i$ and exclusion restriction)		<b>(As-if) random treatment assignment</b>
	<b>Rank assumptions</b>		Exclusion restriction
	<b>Strength of instrument</b>		No defiers (monotonicity)
			<b>Strength of instrument</b>

Note: Bolded assumptions indicate those that can be potentially or partially tested from the data.

is useful because it readily illuminates key assumptions – for example, the idea of monotonicity, discussed momentarily – which are otherwise buried in the stipulation of common effects across units in the SEM framework (Imbens, 2014: 346). It also allows easy characterization of varying effects for specific sub-groups, including ‘local average treatment effects’ (LATE), such as the CACE.

This complier average causal effect is less readily characterized in an SEM model in which effects are presumed constant across units (Sovey and Green, 2011).

One apparent point of convergence among the SEM and design-based approaches is that both appear to stipulate constant effects across components of a treatment. Yet, the issues this raises, as we discuss later, appear less troublesome for the design-based approach than in structural equation modeling: that effects are constant across components of treatment in an experiment seems weaker and more plausible, compared to, say, the assumption that different types of income have the same effect on attitudes (Dunning, 2008).

Next, the two approaches further imply different assumptions about the population for which key estimands are defined. In the design-based approach, the target of inference is clear: it is the average of potential outcomes under treatment and control (and their difference) for the set of units in the study group – also known as the ‘experimental population’. Since this study group is typically (though not always) a convenience sample, there need be no broader population to which formal statistical inferences are drawn: the ACE is defined for the experimental population (and effects for sub-groups, such as the CACE, are similarly defined in reference to compliers in the study group).<sup>23</sup> Thus, in statistical treatments, the design-based approach is sometimes known as ‘finite population’ analysis. We code the presence of a finite experimental population as testable in Table 40.1, but, indeed, this is directly observable.

This clarity on the target population is not always present in the SEM approach. To be

sure, an equation such as (3) will be fit to data for a particular group of units; but the equation aspires to a level of generality that does not appear restricted to a particular set of data. This impression is heightened by assumptions on stochastic process. In the SEM framework, ‘Nature’ draws random disturbance terms,  $\epsilon_i$  in equation (3); in a classical regression model, these are independent and identically distributed (i.i.d). However, how ‘Nature’ draws error terms at random and with replacement, and from what broader population, is not clearly articulated. In contrast, the design-based approach assumes that potential outcomes are fixed in the particular study group at hand. Randomness enters only in the metaphor of sampling potential outcomes from an urn – that is, in sampling from this experimental population. Thus, random assignment to treatment or control groups determines which potential outcomes are observed. Moreover, these draws from the urn are not generally i.i.d: they are made without replacement, and the treatment and control samples are statistically dependent.

Both approaches require that the outcome for a given individual depends only on whether that individual received treatment – and not on the assignment of other individuals. Thus, under an SEM, such as equation (3),  $Y_i$  depends only on  $X_i$  and not on any other unit’s value of the endogenous regressor,  $X_j$ . The design-based framework makes an analogous stipulation: a unit’s potential outcomes are fixed and do not depend on the treatment receipt of any other unit. This is ‘non-interference’, or a component of what Rubin (1978) calls the Stable Unit Treatment Value Assumption (SUTVA). In the design-based framework, for example, a common concern is that units that were assigned to receive the treatment may talk with or otherwise affect units that were assigned to control. The stipulation of non-interference can be seen as an identifying restriction: if potential outcomes depend only on a given unit’s treatment receipt, but also on the treatment receipt of other units, the number of

parameters (potential outcomes) in the model multiplies quickly, and this increases the difficulty of identifying key causal parameters of interest. However, unlike in the SEM tradition, manipulation of an experimental design can provide the means to test the existence of such spillovers between treatment and control groups. For example, a researcher might assign clusters of households to the treatment and control group but then further assign individuals at random to treatment and control within the treatment households. Comparison of the responses of control individuals in the treatment and control households allows assessment of the presence of spillovers; see, for example, Nickerson (2008). For this reason, in Table 40.1, we code the non-interference assumption as potentially testable in the design-based approach.

Next, the two approaches differ in their approach to key validity assumptions on the instrument. The SEM framework assumes that the instrument  $Z_i$  does not belong in the response schedule given by equation (3). This, in turn, implies both  $Z_i$  independent of  $\epsilon_i$  – as secured by randomization of the instrument – and what we call the exclusion restriction. Yet, SEM does not clearly separate these two assumptions (Imbens, 2014: 346), while the design-based IV approach treats each assumption as distinct. An instrument needs to be, on the one hand, (as-if) randomly assigned, which allows for a causal interpretation of the first-stage regression of  $Y_i$  on  $Z_i$  (i.e., the ITT) (Angrist and Pischke, 2008: 152–153). The second assumption requires that the instrument only affects the outcome through the endogenous regressor. This exclusion restriction implies that potential outcomes for a given level of  $X_i$  do not change based on the value of  $Z_i$ .<sup>24</sup> Angrist and Pischke (2008: 153) use the example of the Vietnam draft lottery, a ‘natural’ experiment, to illustrate why these two validity assumptions should be treated as distinct. To serve in Vietnam, young men were randomly assigned a number based on their birthday; lower numbers were selected first to serve. The random assignment of draft order

fulfills the first validity assumption (i.e., statistical independence of  $Z_i$  and  $\epsilon_i$ ). Yet, being assigned a low draft number might affect the outcome (i.e., future earnings) not only through the endogenous regressor of interest (i.e., higher probability of military service), but also through other channels (e.g., enrolling in a university in hopes of getting a deferment). Compared to the stipulation that  $Z_i \perp \epsilon_i$  in SEMs, the assumption of as-if random assignment in the design-based approach can be directly, if only partially, tested. In addition to a priori knowledge or theory about the randomization process, this assumption can be assessed using balance and placebo tests, which answer the question of whether the data are consistent with randomization to treatment conditions. By contrast, in neither approach (SEM or design-based) can the exclusion restriction be directly assessed.

Note, then, that none of the assumptions of the SEM framework discussed so far can be readily tested from data. Others, however, must be true in order to calculate the 2SLS estimator. We refer to these as ‘rank assumptions’ in Table 40.1. For example, the number of units,  $n$ , must exceed the number of instruments,  $q$ , which must also be at least as large as the number of endogenous covariates,  $p$ ; also, the matrices  $Z'X$  and  $Z'Z$  must be full rank,  $p$  and  $q$ , respectively. In the first section, we referred to these assumptions as ‘mechanical’: given particular matrices  $X$  and  $Z$ , they can be readily tested. We therefore put this item in boldface in Table 40.1. More deeply, however, the rank of the matrices also reflects substantive modeling decisions – such as the exclusion of covariates that might otherwise be included in  $X$  or  $Z$  but cannot because if they were, the number of independent variables would outstrip the number of observations. Thus, identification is accomplished through model specification. As Freedman (2009: 144) puts it, ‘Many statisticians frown on under-identified models: if a parameter is not identifiable, two or more values are indistinguishable, no matter how much data you have. On the

other hand, most applied problems *are* under identified. Identification is achieved only by imposing somewhat arbitrary assumptions’.

In the design-based approach, the no-defiers (monotonicity) assumption can similarly be seen as an identification restriction. Defiers are those who receive the opposite treatment from the one they were assigned: that is, they receive the control if assigned to treatment, and the treatment if assigned to control. If there exist defiers, the relationship between treatment assignment and treatment receipt is non-monotonic. The existence of both defiers and compliers also means there are more structural parameters than we can estimate from the data. While we can estimate the proportions of compliers – using data on the proportions of never-takers (i.e., non-compliers in the treatment group) and always-takers (i.e., non-compliers in the control group) – we cannot estimate the proportion of defiers. Thus, if there are indeed defiers, the IV model will be under-identified (Freedman, 2006: 706). In that case, the Wald estimator in equation (7) does not consistently estimate the complier average causal effect. The no-defier condition is not directly testable, so we do not bold it in Table 40.1. Nonetheless, the assumption is often viewed as one of the more plausible in design-based IV applications (Freedman, 2006: 700). Certainly, when defiers constitute a very small proportion of the study group, identification and estimation issues from violations of the monotonicity assumption should be limited (Angrist et al., 1996, 451), and certain designs allow for us to dismiss the monotonicity assumption entirely. In cases of one-sided non-compliance, where researchers (or governments, nature, etc.) prevent the control group from having access to the treatment, there are, by construction, neither always-takers nor, more importantly, defiers.

Finally, both the SEM and design-based approaches require a sufficiently strong relationship between the instrument(s) and endogenous regressor(s). Because weak instruments explain little of the systematic

variation in  $X$ , the predicted values of  $X$ , that is  $\widehat{X}$ , approach  $X$ . The 2SLS estimator in equation (4) is thus biased in the same direction as the OLS estimator (Bound et al., 1995). In both IV approaches, this assumption can be tested directly from the data by examining the strength of the relationship between  $X$  and  $Z$  – see the discussion in our first section.

Overall, the discussion in this section suggests several conclusions. First, design-based approaches to IV tend to be more modest in terms of the underlying assumptions. The potential outcomes framework relaxes certain assumptions stipulated in the linear response schedule under SEM (e.g., linearity in parameters, constant effects across units). Moreover, the target of inference – the average causal effect for a particular study group or the average effect for a sub-group of compliers – is readily characterized and estimated; the model does not presume to extrapolate those effects to units outside the experimental population. Next, while many IV assumptions under SEM remain implicit in the assumption of the response schedule, IV analysis under the potential outcomes framework does a clearer job of disaggregating the key assumptions. Finally – as indicated by the greater number of bolded items in the second column of Table 40.1 – the assumptions of design-based analyses tend to be more directly testable, for example, by assessing balance on pre-treatment covariates across treatment and control groups or through modification of design. The next section illustrates these points through an empirical example.

## **AN ILLUSTRATION: THE DEMAND FOR COFFEE**

How do changes in prices affect demand for coffee? The question recalls those motivating Wright’s original work on IV, in which a key issue is the identification of the demand curve for agricultural goods. Yet, one could also approach this question experimentally, by

randomly assigning prices to coffee products and assessing how the demand changes in response. Here, we therefore describe two different approaches to answering this question: one in the SEM tradition, another in the design-based framework. The example further illustrates tradeoffs and limitations, as well as areas of convergence between the approaches.

Thus, as in Wright (1928), one option for studying this relationship would be to find an instrument that affects demand but not supply. A researcher might seek to use, say, rainfall as an instrument for coffee prices. Researchers have used rainfall (or deviations from average rainfall) as an instrument in a variety of settings, for example, estimating the effects of economic growth on dependent variables including civil war in Africa (Miguel et al., 2004) and land invasions in Brazil (Hidalgo et al., 2010). Scholars have also increasingly used rainfall to estimate the effects of turnout on support for certain political parties in the United States (Hansford and Gomez, 2010; Horiuchi and Kang, 2018; Fujiwara et al., 2016), Germany (Arnold and Freier, 2016), and Spain (Artés, 2014).

Imagine, then, a researcher wants to use changes in rainfall patterns in Uganda to instrument for changes to world coffee prices. Ultimately, she wants to test whether higher prices reduce the demand for coffee. Because Ugandan rainfall should only affect coffee demand through its effect on coffee supply and thus prices, the researcher thinks it might be a valid instrument. If the researcher were to use rainfall as an instrument to estimate a model in the form of equation (3), what assumptions must be met for a causal interpretation?

The key stipulations are found in the first column of Table 40.1. Each might raise concerns in this example. We mention only several. The demand schedule might be non-linear – that is, a demand ‘curve’ – rather than proportional to coffee prices. The elasticity of demand might vary across units, as a function of the availability of substitutes (say, tea), violating the assumption of constant

effects across units, and the assumption of constant partial effects – according to which the treatment effect does not vary across the components of the endogenous regressor – might especially suggest issues. In this case, prices can change in response to a variety of events, for example, changes induced by variation in weather patterns may have very different effects than price changes induced by a merger between two large coffee producers.<sup>25</sup> Thus, in the rainfall example, we may not be identifying the effect of price changes generally but, rather, price changes induced by a particular impetus – rainfall. Additionally, the assumption that demand in unit  $i$  does not depend on the exposure to coffee prices in unit  $j$  may also be suspect: in an interdependent world economy, spillover is perhaps much more common than non-interference.

Next, concerns might focus on the validity assumptions on the instrument – specifically, that rainfall does not belong in the response schedule. These validity assumptions entail that rainfall is independent of the disturbance term in the response schedule linking price changes to demand and that rainfall only affects coffee demand through price changes. Researchers may be able to argue that changes to rainfall in Uganda are as good as randomly assigned, adding credibility to the assumption of  $Z_i \perp \epsilon_i$ . However, the exclusion restriction assumption is considerably more difficult to test. Rainfall may change demand for coffee through channels other than supply and, thus, price. Angrist and Krueger (2001: 79) discuss the possibility that ‘sophisticated commercial buyers at the New York Coffee, Sugar and Coca Exchange, where coffee futures are traded, use weather data to adjust holdings in anticipation of price increases that may not materialize in fact’.<sup>26</sup>

This last point raises a final, empirical question regarding the strength of the instrument: is a change in rainfall patterns in Uganda enough to change world coffee prices? We could test this assumption using data from rainfall in Uganda and world coffee prices. An F-statistic greater than 10

in the regression of world coffee prices on Ugandan rainfall may suggest the latter is a sufficiently strong instrument. Yet, this rule-of-thumb has weaknesses. The ideal range of rainfall for coffee production is 45–70 inches per year; less than 30 inches is considered too dry, while more than 100 inches is considered too wet for coffee to successfully grow (Shaw, 1955: 278). Thus, we might expect the relationship between rainfall in Uganda and coffee prices to be U-shaped. The first-stage regression in equation (4) is the linear projection of  $X$  onto  $Z$ , however. While non-monotonicity in the relationship between rainfall and prices may not affect our interpretation of  $\beta$  (Imbens, 2014, 346) – given the modeling assumption of a constant effect – estimating a linear first stage for data that is non-linear may lead us to dismiss an instrument as weak even if it, in fact, has a strong relationship to the endogenous regressor.

The example of rainfall-induced variation in coffee prices thus illustrates several challenges of IV analysis under the SEM framework. Particularly troublesome is the assumption of correct specification of the linear response schedule, which gives rise to a number of other assumptions that must be carefully addressed but often cannot be directly tested – and which are not very clearly illuminated by the model. The design-based approach may provide a way of addressing some of these concerns a priori. Through robust experimental designs, researchers can attempt to reduce many of the issues that arise in the SEM framework. This approach has its own limitations and unverifiable assumptions. A feature and perhaps virtue of this approach, however, is that limited generalizability is baked into the estimand rather than obfuscated by an apparently general structural equation.

Consider, then, the direct experimental manipulation of coffee prices. Drawing partially on the innovative study of Hainmueller et al. (2014), we imagine a case in which researchers would like to work with supermarkets to manipulate coffee prices and

ultimately derive the price elasticity of demand for coffee.<sup>27</sup> The hypothetical researchers work with 100 supermarkets. Managers from 50 of the supermarkets are told to raise their prices while managers from the other 50 are told to hold their prices constant. The researchers track coffee sales in the 100 grocery stores for four weeks and then compare how sales changed across the treatment and control groups. How might the researchers analyze their experiment?

One option is ITT analysis: coffee sales in the 50 supermarkets that were told to raise prices may be compared with the 50 that were told to keep their prices constant. This approach takes advantage of the element of the design over which the researcher had most control – the initial randomization of units to treatment and control conditions. Moreover, it can be analyzed with a simple and transparent difference-in-means estimator that relies on relatively weak assumptions. In cases where researchers can engage in extensive monitoring to reduce non-compliance, as Hainmueller et al. (2014) do, this strategy provides a robust manner of estimating the treatment effect of interest. However, when such monitoring is not present and/or non-compliance is high, researchers may wish to estimate a complier average causal effect.

What might non-compliance look like in our hypothetical price-manipulation experiment? Never-takers are defined as those stores that never raise prices; always-takers are those that always raise prices; and defiers are those that raise prices when told not to raise and that do not raise when told to raise. The CACE would thus constitute the treatment effect for stores that would raise their coffee prices when instructed to and would not raise their prices otherwise. Under the potential outcomes framework, we could estimate a CACE using the ratio in equation (7). What assumptions are required?

A first assumption in valid estimation of the CACE is that the instrument is (as good as) randomly assigned. In the hypothetical case here, researchers controlled

random assignment, which they can subsequently check using balance tests.<sup>28</sup> A second assumption is that treatment assignment affects the outcome only through treatment receipt. In this case, does telling a supermarket manager to raise coffee prices affect coffee sales other than through the actual increase in coffee prices? Perhaps telling a store to raise coffee prices will result in the store not only increasing coffee prices, but also lowering tea prices. Or perhaps the price increase will lead managers to change the placement of merchandise, such that lower priced coffee is moved to occupy a more visible place in the store. The researchers may send monitors to check whether coffee prices are, in fact, being changed, which serves as both a test of the instruments' strength and also a measure of compliance. However, it would be difficult, if not impossible, for the researchers to account for all the changes made in response to the coffee price change announcement that might also affect coffee sales. Finally, we assume absence of defiers, or monotonicity. Is it plausible that there exist stores in the sample that raise prices when told not to and do not raise prices when told to? It seems unlikely in this case, although we might imagine some managers might look to defy an outside researcher who tells them how to control prices in their own store.

Both implicit and explicit in the discussion above are a number of tradeoffs regarding IV under the SEM and design-based approaches. In the SEM framework, many of the assumptions are embedded in the response schedule itself. Researchers should carefully justify ex-post the correct specification of the response schedule, including the assumptions that follow from it—but they may fail to do so. The design-based approach under potential outcomes allows for a weakening of the constant unit-level effects assumption but clarifies a new assumption – monotonicity.<sup>29</sup> This approach also draws on the potential outcomes framework, which relaxes the assumption of the linear response schedule and disaggregates

the assumptions otherwise implied by the model into distinct parts. Concerns about these assumptions are addressed through careful research design; natural and field experiments provide a way to find or develop robust instruments that are plausibly exogenous and that only affect the outcome through the endogenous regressor. The design-based approach thus has a number of desirable properties which include both the clear statement of and the possibility to test key assumptions.

A key limitation to both approaches, however, involves generalizability of interpretation, which the coffee demand example illustrates well. Often, IV analysis involves an intervention that addresses only one component of the treatment of interest. For example, it is hard to know exactly what the price manipulation experiment tells us about the relationship between coffee price and demand. Artificial manipulation of a coffee price may truly isolate the general effect of interest, but more likely, it tells us about only one component of a 'price' treatment – the actual changing of prices by a store. This change occurs at the end of the supply chain and tells us little about the result of price changes due to farming, tariffs, increased fuel prices, etc. The same can be said of using rainfall as an instrument for coffee price changes. However, in the SEM model, this claim is particularly muddled by the specification of the linear model, where the researcher is claiming to identify through  $X_i$  in equation (3) the effect of 'prices'. In reality, and as discussed above, price changes induced by rainfall may have a very different effect than price changes induced by other 'interventions'. From this perspective, an advantage of the design-based approach is then not just the clarity and relative testability of the key assumptions – but that the framework makes clear its limitations. Here, modesty is a virtue: the SEM approach is subject to the same kinds of weaknesses but, because of the lack of specificity embedded in the model specifications, it tends to overstate its ability to deliver on its ambitions.<sup>30</sup>

## CONCLUSION

Since Wright's initial work on supply and demand, social scientists have used instrumental variables to study the effects of independent variables that would otherwise be difficult (if not impossible) for the researcher to randomly assign. Some instruments, like rainfall, rely on plausibly exogenous natural variation that affects an endogenous independent variable of interest. Ramsay (2011) studies as-if random variation in natural disasters to understand how a country's level of democracy responds to a change in oil prices. Other instruments rely on lotteries, where the instrument is – due to actual randomization – independent of pre-treatment causes of  $X$  and  $Y$ . Researchers have used the Vietnam draft lottery as an instrument for military service (Angrist, 1990; Erikson and Stoker, 2011) and lottery winnings as an instrument for income (Doherty et al., 2006). While these cases assure that the instrument,  $Z$ , is – in expectation – uncorrelated with the disturbance term from the regression, there remain important concerns about both violations of the exclusion restriction and the correct specification of the response schedule.

In observational work, challenges often arise for validating the identifying assumptions, which researchers have shown varying degrees of willingness to acknowledge and address (Sovey and Green, 2011: 194; Staiger and Stock, 1997: 597, fn. 2). While certain assumptions can be directly tested from the data (relevance, rank, identifiability of parameters) and others may be plausible by design (independence of instrument and pre-treatment causes of  $X$ ,  $Y$ ), the remaining assumptions of structural equation modeling generally raise concerns that often cannot be fully allayed. The exclusion restriction and specification of the response schedule remain particularly troublesome.

IV analysis in the structural equation modeling framework offers a potential solution to

a key problem: identifying the causal effect of  $X$  on  $Y$  given the stipulation of a particular structural equation in which the model is presumed but  $X$  is assumed to be endogenous. However, the SEM framework may also prove restrictive; it imposes an assumption of a linear response schedule that does not allow for estimation of heterogeneous treatment effects. It further builds monotonicity into the estimand rather than addressing it as an assumption (Imbens, 2014: 346).

The potential outcomes framework overcomes some of these limitations by making more explicit the key underlying assumptions, which are often more plausible, less restrictive, and easier to test from the data. Linearity and constant effects assumptions are relaxed under this approach, and other assumptions, like the exclusion restriction and random assignment of units to values of the instrument, are directly stated, such that they might be separately addressed and evaluated. The monotonicity assumption, which is added under heterogeneous treatment effects, is generally viewed to be plausible, although its credibility should be judged based on the specific intervention.

Ultimately, despite the promise of IV, there remain key limitations. Both the SEM and design-based approaches suffer a common challenge of generating results that generalize beyond the intervention that gave rise to the instrument. Often, instruments affect the independent variable of interest through a specific (and perhaps narrow) channel. Generalizing from that particular component of the treatment to formulating broader claims about the treatment as a whole should be done only after consideration of other factors that may have induced change in the independent variable. Robust IV analysis thus requires that researchers consider both the story that can be told from the data given the assumptions and the story that *cannot* be told, given the inherent difficulties of generalization under the IV framework.

## Notes

- 1 We refer in this paper to 'structural equation models' in this sense. One stream of research uses the term more specifically to refer to systems of equations linking unobservable 'latent' constructs: see, for example, Bollen (1989).
- 2 We use the typical language of supply and demand 'curves' here, even though the response schedules in equations (1) and (2) are linear in  $P_i$ .
- 3 While Philip G. Wright's name is on the piece, the key finding is in Appendix B, which some believe was written by his son, Sewall. The elder Wright also discusses his son's closely related methods of causal path analysis. However, Stock and Trebbi (2003), using stylometric analysis, conclude that Philip was the most likely author.
- 4 Wright's innovation was only recognized in the 1970s when Goldberger (1972) highlighted Wright's contribution to structural equation methods (Aldrich, 1993: 270, fn. 34).
- 5 We show the equivalence of the IV estimator and Wald's grouping estimator below.
- 6 The fitted values  $\hat{X}_i$  are sometimes called 'predicted' values of  $X_i$ , though 'post-dicted' is usually more accurate. Importantly, we cannot simply use the values of  $\hat{X}$  to calculate the variance-covariance matrix of  $\hat{\beta}_1$ , as this produces inconsistent estimation of  $\sigma^2$  (Greene, 2003: 79).
- 7 A derivation can be found in the Appendix – see (A.1).
- 8 A model in which  $q = p$  is 'just-identified' while the case with  $q > p$  is 'over-identified'.
- 9 There is, of course, also a mechanical reason for this, related to the previous paragraph and the rank condition; if  $\text{Cov}(X_i, Z_i) = 0$ , then the estimator of  $\beta_1$  found in equation (5) is undefined.
- 10 Given a model like equation (3), the unconfoundedness of the instrument and the exclusion restriction are implied by  $\square_i \perp\!\!\!\perp Z_i$  (Imbens 2014).
- 11 Heckman and Robb (1986), Imbens and Angrist (1994), Angrist et al. (1996), Rosenzweig and Wolpin (2000), Freedman (2006) and Heckman et al. (2006) all draw attention to this IV assumption.
- 12 To be sure, improving conceptual precision by moving down Sartori's (1970) 'ladder of abstraction' may lessen the perceived impact of the research: a paper on the effects of windfall earnings on political attitudes may generate less interest than one that purports to estimate the effect of income more generally.
- 13 This usage of 'design-based' in statistics differs from a related but distinct use of the term in educational research.
- 14 As we discuss below, the ITT analysis is equal to the reduced-form estimate discussed above.
- 15 Relatedly, while manipulation checks can provide a useful measure of whether subjects understood or experienced the treatment in the way the researcher expected, treatment effects should not be calculated as conditional on having passed a manipulation check, because the check is necessarily post-treatment (Aronow et al., 2015; Montgomery et al., 2018).
- 16 See, *inter alia*, Angrist et al. (1996); Freedman (2006); Gerber and Green (2012); Dunning (2012); Imbens (2014).
- 17 Angrist et al. (1996) call the no-defiers assumption 'monotonicity': being assigned to treatment should never make it *less* likely that a unit actually receives treatment (see also Imbens 2014, 17).
- 18 This also assumes we can observe who receives the treatment, for example, who follows the protocol in a drug trial (which is distinct from the even harder problem of observing counterfactual compliance types).
- 20 Numerically, the value is equivalent to the reduced-form regression of  $Y$  on  $Z$ .
- 21 This is equivalent algebraically to the first-stage regression of  $X$  on  $Z$ .
- 22 Note that equation (7) suffers from ratio-estimator bias: the denominator is a random variable. However, by Slutsky's theorem, the estimator is consistent (asymptotically unbiased) – see Freedman (2006) or Dunning (2012).
- 23 Some work does nonetheless distinguish, though not always with clarity, between a sample average treatment effect (SATE) and a population average treatment effect (PATE), where the study group is itself viewed as a sample from a broader population.
- 24 Both of these assumptions, along with monotonicity and a strong instrument, are necessary for valid estimation of the CACE (Angrist and Pischke, 2008: 154)
- 25 Similar critiques have arisen around the use of rainfall as an instrument for economic growth. Dunning (2008) suggests that rainfall may induce a very specific type of economic growth that is quite different from growth induced by, for example, technological change in agriculture or an increase in foreign aid.
- 26 Research using rainfall as an instrument for economic growth and turnout has often been critiqued with respect to the exclusion restriction. In the case of Miguel et al. (2004), rainfall may lead to flooding on roads and bridges, making it difficult to transport soldiers and thus decreasing the likelihood of conflict (Sovey and Green, 2011; Dunning, 2012). Sarsons (2015) shows that the relationship between rainfall and conflict in India is strongest in areas downstream of dams, where agricultural income is less susceptible to rainfall shocks due to access to irrigation. As for research on turnout and party support, Horiuchi and Kang (2018) demonstrate that

weather directly changes voter support for parties, with rainfall making voters more likely to support Republicans. In fact, most of the benefit obtained by Republicans in rainy elections can be attributed to voters changing their preferences, rather than differential levels of turnout.

- 27 Using a randomized control trial with 26 grocery stores in New England, Hainmueller et al. (2014) manipulate both the price and labeling of coffee to understand whether consumers are willing to pay a higher price for fair trade coffee.
- 28 Unlike the analysis, which was performed using store-weeks as units, the balance tests were performed at the store level, giving a sample size of only 26, which may limit their power.
- 29 However, as we noted, the assumption of monotonicity exists implicitly in the SEM framework. Allowing for defiers would imply more structural parameters than can be estimated from the data.
- 30 For a related point in the context of fixed effects regressions, see Aronow and Samii (2016).

## APPENDIX

We derive the algebraic equivalence of the two-stage least-squares (equivalently, the IV) estimator in equation (5) and the Wald estimator of the Complier Average Causal Effect for a finite population in equation (7) in the bivariate case with one treatment and one control group. Here,  $Y_i$  is the outcome variable;  $X_i = 1$  if unit  $i$  receives treatment and otherwise  $X_i = 0$ ; and  $Z_i = 1$  if unit  $i$  is assigned to treatment and otherwise  $Z_i = 0$ . The number of units is given by  $N$ , and the number of units assigned to treatment is  $m < N$ . Without loss of generality, index the units assigned to treatment by  $i = 1, \dots, m$  and the units assigned to control by  $i = m + 1, \dots, N$ . Thus, we have

$$\begin{aligned}
 \hat{\beta}_{1,2SLS} &= \frac{\widehat{Cov}(Y_i, Z_i)}{\widehat{Cov}(X_i, Z_i)} \\
 &= \frac{\sum_{i=1}^N (Y_i - \bar{Y})(Z_i - \bar{Z})}{\sum_{i=1}^N (X_i - \bar{X})(Z_i - \bar{Z})} = \frac{\sum_{i=1}^N (Y_i Z_i) - \bar{Y} \sum_{i=1}^N Z_i - \bar{Z} \sum_{i=1}^N Y_i + N \bar{Y} \bar{Z}}{\sum_{i=1}^N (X_i Z_i) - \bar{X} \sum_{i=1}^N Z_i + \bar{Z} \sum_{i=1}^N X_i + N \bar{X} \bar{Z}} \\
 &= \frac{\sum_{i=1}^N (Y_i Z_i) - m \bar{Y}}{\sum_{i=1}^N (X_i Z_i) - m \bar{X}} \left( \text{because } \sum_{i=1}^N Z_i = m, \bar{Z} = \frac{m}{N} \right) \\
 &= \frac{m(\bar{Y}_1 - \bar{Y})}{m(\bar{X}_1 - \bar{X})} \left( \text{because } \sum_{i=1}^m Y_i Z_i = m \bar{Y}_1 \right) \\
 &= \frac{m \left( \bar{Y}_1 - \frac{m}{N} \bar{Y}_1 - \frac{N-m}{N} \bar{Y}_0 \right)}{m \left( \bar{X}_1 - \frac{m}{N} \bar{X}_1 - \frac{N-m}{N} \bar{X}_0 \right)} \left( \bar{Y} = \frac{\sum_{i=1}^m Y_i + \sum_{i=m+1}^N Y_i}{N} = \frac{m}{N} \bar{Y}_1 + \frac{N-m}{N} \bar{Y}_0 \right) \\
 &= \frac{\frac{m(N-m)}{N} (\bar{Y}_1 - \bar{Y}_0)}{\frac{m(N-m)}{N} (\bar{X}_1 - \bar{X}_0)} \\
 &= \frac{\bar{Y}_1 - \bar{Y}_0}{\bar{X}_1 - \bar{X}_0}
 \end{aligned}
 \tag{A.1}$$

The first step uses the definition of the sample covariance; we divide through by  $n / n$ . Next, we multiply out terms, then use the definition of  $Z = 1$  as the units assigned to treatment (and thus, the sum,  $\sum Z_i$ , is  $m$ , while the mean,  $\bar{Z}$ , is  $m / N$ ) and cancel terms. In the following step, we use the fact that the product,  $Y_i Z_i$ , will be zero when  $Z_i = 0$  and  $Y_i$  when  $Z_i = 1$ . The sum of this product will thus equal the mean outcome for the treated units,  $\bar{Y}_1$ , times the number of treated units,  $m$ . The next step uses the fact that the mean,  $\bar{Y}$ , is simply a weighted average of the mean outcome under treatment,  $\bar{Y}_1$ , and the mean outcome under control,  $\bar{Y}_0$ . The final steps factor out common terms and reduce the equation to the Wald estimator.

# Causality and Design-Based Inference

Jake Bowers and Thomas Leavitt

## DESIGN-BASED CAUSAL INFERENCE

No one knows the true causal effect of an intervention. In an experiment, a researcher can assign some units to treatment and others to control; yet, one cannot see how treatment units would have acted were they assigned to control nor how the control units would have acted were they assigned to treatment.<sup>1</sup> In the face of this fundamental ignorance, statisticians have developed two prominent approaches to inferring unobservable causal effects using data that can be observed. An analyst can either (1) generate a guess about (usually average) treatment effects or (2) posit a hypothesis about the effects of a treatment (such as the hypothesis that a treatment had no effects) and then assess the consistency of observable data with that null hypothesis, relative to a class of alternative hypotheses (such as the hypothesis that a treatment had a positive effect).

In what follows, we will define criteria by which a procedure qualifies as ‘good’ in the

context of both estimation and testing and subsequently explain the role that research design plays in whether estimators and tests satisfy these criteria. We consider estimators and tests about causal effects first in the context of a randomized study design under full control of the researcher and second in cases in which the researcher does not fully control the study design. We show the ways in which either complete knowledge or assumptions (and the ways in which they could be violated) about the study design constitute what Fisher (1935, 14) referred to as a ‘reasoned basis’ for inference.

## CAUSALITY AND RESEARCH DESIGN

### *Defining Causal Effects*

Consider a study in which there are  $1, \dots, N$  units and the index  $i \in \{1, \dots, N\}$  runs over these units. Each individual,  $i$ , can be in

either the treatment condition,  $z_i = 1$ , or the control condition,  $z_i = 0$ . Under the Stable Unit Treatment Value Assumption (SUTVA) (Cox, 1958; Rubin, 1980, 1986), each individual has a treatment potential outcome,  $y_{t,i}$  (unit  $i$ 's outcome if given the intervention), and a control potential outcome,  $y_{c,i}$  (unit  $i$ 's outcome if not given the intervention).<sup>2</sup> An individual causal effect,  $\tau_i$ , for each of the  $i \in \{1, \dots, N\}$  units is a function of each unit's two potential outcomes,  $\tau_i \equiv f(y_{c,i}, y_{t,i})$ , such as  $\tau_i \equiv \frac{y_{t,i}}{y_{c,i}}$  or  $\tau_i \equiv y_{t,i} - y_{c,i}$ . For this chapter, we focus specifically on the additive, individual causal effect defined as  $\tau_i \equiv y_{t,i} - y_{c,i}$ . Researchers, however, can never observe both potential outcomes for each unit; instead, one can observe only  $y_i$ , which can be equal to either  $y_{c,i}$  or  $y_{t,i}$ , depending on whether unit  $i$  is assigned to treatment ( $z_i = 1$ ) or control ( $z_i = 0$ ). We therefore represent observed outcomes by the function  $y_i = z_i y_{t,i} + (1 - z_i) y_{c,i}$ . Researchers may want to make an inference about the  $1, \dots, N$  individual causal effects, which we collect into the vector  $\boldsymbol{\tau}' = [\tau_1 \ \tau_2 \ \dots \ \tau_N]$ , or about a function of these individual causal effects, such as the average causal effect,

$$\bar{\tau} = \left( \frac{1}{N} \right) \sum_{i=1}^N \tau_i.$$

We say that researchers want to 'make an inference' because neither  $\boldsymbol{\tau}$  nor  $\bar{\tau}$  can be directly observed. Researchers, of course, don't simply want to 'make an inference': they want to make inferences that can reliably track the true causal quantity of interest. This chapter shows how inferential procedures based on the research design can have such a reliable relationship with true causal quantities and explains what it means for a procedure to be 'based on research design'.

### **Defining a Research Design**

Although a research design can certainly be more than this, for the purposes of this chapter

a research design refers to the process by which units come to be in one study condition instead of another, i.e., each  $z_i$  comes to equal 1 or 0. More formally, we denote the collection of the values of  $z_i$  for all  $i \in \{1, \dots, N\}$  units by the vector  $\mathbf{z}' = [z_1 \dots z_N]$  and define a research design as (1) a set of possible ways (events) in which the whole vector  $\mathbf{z}$  could occur and (2) a probability distribution on this set of possible events. In a controlled study design (i.e., an experiment), we think of a researcher as 'assigning' conditions to all units in the study. When a researcher does not control how a unit  $i$  takes on a value of  $z_i$ , we think of that unit as 'selecting' into its own condition. As we lay the groundwork of concepts and notation, we write 'assignment' and assume control by the researcher, but we will apply the general framework later to uncontrolled research designs in which units 'select' into study conditions.

The set of possible ways in which  $\mathbf{z}$  can occur depends on the process by which units are assigned to study conditions. If individuals can be in either the treatment or control condition irrespective of any other individual in the population, then we call this process individual assignment. As a simple example, consider the 'coin flip' assignment process: in this case, the proportion of  $N$  individuals in either the treatment or control condition can vary across different assignments. We refer to this process as *simple* individual assignment. A researcher can implement simple individual assignment via an actual physical, stochastic process, such as  $N$  flips of a (potentially biased) coin – although in practice researchers will typically use random number generators (RNGs).

Under completely unconstrained simple individual assignment, the number of units in the treatment condition can range from 0 to  $N$  and the number of units in the control condition can likewise range from  $N - 0$  to  $N - N$ . More formally, we write the set,  $\Omega$ , of possible ways that a researcher can

assign all individuals to study conditions as follows:

$$\Omega = \{0,1\}^N = \left\{ \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 1 \\ 0 \\ \vdots \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \\ \vdots \\ 0 \\ 0 \end{bmatrix}, \dots, \begin{bmatrix} 1 \\ 0 \\ \vdots \\ 1 \\ 1 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \\ \vdots \\ 1 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 \\ 1 \\ \vdots \\ 1 \\ 1 \end{bmatrix} \right\}. \tag{1}$$

We can write the number of possible assignments in the set  $\Omega$  by  $|\Omega|$  (the ‘cardinality of Omega’), under simple assignment as follows:

$$|\Omega| = \binom{N}{0} + \binom{N}{1} + \dots + \binom{N}{N-1} + \binom{N}{N} = \sum_{n_t=0}^N \binom{N}{n_t},$$

where  $n_t = \sum_{i=1}^N z_i$  is the number of units in the treatment condition, which can range from 0 to  $N$ , and  $\binom{N}{n_t} = \frac{N!}{n_c!n_t!}$  is the number of ways to choose  $n_t$  units from a total of  $N$  units. Conversely,  $n_c = \sum_{i=1}^N (1-z_i)$  is the number of units in the control condition, which can range from  $N - 0$  to  $N - N$ . In practice, researchers who control the assignment process will typically forbid assignments in which all units are in either condition (the first and last assignments in Equation (1)), in which case  $|\Omega| = \sum_{n_t=1}^{N-1} \binom{N}{n_t}$ .

The ‘coin flipping’ design helps us introduce the formal elements of a research design. In practice, individual coin flips can lead to lopsided designs in which many units are in one condition or another. An alternative design that enables the researcher to control the numbers of units in each condition is *complete* assignment.

Complete individual assignment differs from simple, individual assignment only in that the value of  $n_t$  is fixed across all possible assignments. We have described simple individual assignment via the example of coin flips. Complete individual assignment can

be thought of as draws from an urn. Imagine, for example, that an urn contains  $N$  balls, of which  $n_t$  are blue balls and  $N - n_t = n_c$  are red balls. The researcher could draw the first ball from the urn and assign the first unit in the study to the treatment condition if the ball is blue and to the control condition if the ball is red. The second draw could follow the same rule for the assignment of the second unit, and so on and so forth until no more balls remain in the urn. This form of assignment ensures that exactly  $n_t$  units are in the treatment condition and  $N - n_t = n_c$  units are in the control condition. More formally, complete individual assignment excludes any assignment,  $\mathbf{z}$ , with more or less treatment units,  $n_t$ , than that which is predetermined by the researcher. Therefore, under complete assignment, the number of possible assignments is simply  $|\Omega| = \binom{N}{n_t}$ .

Simple and complete assignment can also happen at the *cluster* (as opposed to the *individual*) level. In this setup, we not only have a set of  $1, \dots, N$  individuals, but also a set of  $1, \dots, K$  clusters, where each cluster,  $k \in \{1, \dots, K\}$ , contains  $N_k \geq 1$  individual units and  $N = \sum_{k=1}^K N_k$ . In cluster assignment

designs, all of the units in the  $k$ th cluster are assigned to either the treatment condition,  $z_{i,k} = 1$ , or the control condition,  $z_{i,k} = 0$ . In simple cluster assignment, the number of possible assignments is given by  $|\Omega| = \sum_{k_t=0}^K \binom{K}{k_t}$ ,

where  $k_t$  denotes the number of treatment clusters, although (just as in simple individual assignment) researchers will typically ensure that  $k_t \notin \{0, K\}$ . Under complete cluster assignment, the number of treatment clusters is fixed, such that the number of assignments is  $|\Omega| = \binom{K}{k_t}$ .

Lastly, *blocked assignment* is when individuals or clusters are assigned (either simply or completely) to study conditions within

blocks, which we index from  $b \in \{1, \dots, B\}$ . Blocks are typically constructed on the basis of individuals' or clusters' values of baseline covariates. Baseline covariates are measured prior to assignment and hence their values are fixed regardless of the condition to which a unit or cluster is assigned. Under simple individual block assignment, the number of possible assignments is  $|\Omega| = \prod_{b=1}^B \left( \sum_{n_{t,b}=1}^{N_b-1} \binom{N_b}{n_{t,b}} \right)$ , where

$N_b$  is the number of units in block  $b$ ,  $n_{t,b}$  is the number of units in the treatment condition in block  $b$  and  $n_{t,b} \notin \{0, N_b\}$  for all  $b$ . Under complete individual block assignment, the number of possible assignments is  $|\Omega| = \prod_{b=1}^B \binom{N_b}{n_{t,b}}$ . One can analogously deduce the number of possible assignments under either simple or complete cluster block assignment. As we will explain in subsequent sections, block assignment carries important implications for properties of both estimators and hypothesis tests.

Given a set of possible assignments,  $\Omega$ , arising from an assignment mechanism, the remaining component of a research design is a probability distribution on this set of assignments. In a *uniform randomized experiment*, the probability of each assignment is simply  $\frac{1}{|\Omega|}$  for all  $\omega \in \Omega$ , whereby each assignment has an identical probability of realization. Yet the probability distribution on  $\Omega$  need not be uniform, even in a randomized experiment. Design-based inference means only that the stochastic properties of estimators and tests be based on this probability distribution on  $\Omega$ , regardless of whether that distribution is uniform or not. As we now move to discussions of both estimation and testing, notice throughout that whenever we refer to random quantities, the randomness of those quantities stems solely from the probability distribution on  $\Omega$ .

**An Illustrative Example**

In the sections to follow, we demonstrate our arguments via a simple hypothetical example

that consists of  $N = 6$  units and an individual assignment process (complete individual assignment) in which three units are assigned to treatment ( $n_t = 3$ ) and to control ( $n_c = 3$ ). Let's further imagine that (unbeknownst to the researcher) the six units' potential outcomes and individual causal effects are as follows in Table 41.1.

Based on the complete individual assignment process in which there are  $N = 6$  units and of which  $n_t = 3$  are assigned to treatment, the set of  $|\Omega| = \binom{6}{3} = 20$  possible assignments is given by Equation (2):

$$\Omega = \left\{ \begin{bmatrix} 1 \\ 1 \\ 1 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 1 \\ 1 \\ 0 \\ 1 \\ 0 \\ 0 \end{bmatrix}, \dots, \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \\ 1 \\ 1 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 0 \\ 1 \\ 1 \\ 1 \end{bmatrix} \right\}. \quad (2)$$

The assignment that one draws from the set,  $\Omega$ , determines which potential outcomes one observes. One can observe treatment potential outcomes only for units assigned to treatment, and control potential outcomes only for units assigned to control (recall the function  $y_i = z_i y_{t,i} + (1 - z_i) y_{c,i}$ , which determines the potential outcome that one observes for each individual  $i$ ). As Table 41.2 shows, for each of the  $\binom{6}{3} = 20$  possible assignments, there are  $\binom{6}{3} = 20$  corresponding possible

realizations of observed data, where ‘?’ throughout this chapter denotes an unobserved and hence unknown potential outcome.

Only one such possible realization of data in Table 41.2 can be observed; but, knowing that there are 20 possible realizations allows the researcher to use procedures – e.g., estimators or hypothesis tests – to make inferences about unobservable causal quantities based on the single observed realization. We want procedures for drawing causal inferences to have properties that are ‘good’ (a notion that we will define more precisely in later sections). These properties describe or measure a procedure’s performance in two contexts: (1) studies with a fixed, finite size (number of units) and (2) a hypothetical scenario in which the size of a given study increases towards  $\infty$  while all other relevant factors remain constant. We refer to the latter context as one of *asymptotic growth*, which we conceptualize below.

If we have an experimental pool of six units, which is not a sample using a known procedure from a well-defined population, what does ‘asymptotic growth’ mean? We follow Brewer (1979) and Middleton and Aronow (2015) in using the idea of ‘copies’ as a way to talk about how estimators and tests behave as study sizes increase. In short, this conception of asymptotic growth states that (1) the original population of  $N$  units is copied  $h-1$  times such that there are  $h$  copies in total, (2) within each of the  $h$  copies, exactly  $n_t$  units are assigned to the treatment condition and the remaining  $n_c = N - n_t$  units

are assigned to the control condition and (3) the  $h$  copies are then collected into a single population with  $hN$  total units,  $hn_t$  treatment units and  $hn_c$  control units.

In the context of our working example, this conception of growth stipulates that the study population of  $N = 6$  units is embedded in a sequence of populations of increasing sizes in which the initial population is simply copied  $h - 1$  times.

Notice that over this sequence of increasing finite populations shown in Table 41.3, all relevant factors other than  $N$  remain constant: the proportions of treatment and control units remain fixed and the mean of control and treatment potential outcomes remain fixed, as do their variances and their covariance. Notice, however, that the number of possible assignments increases over this sequence of increasing

finite populations from  $\binom{6}{3} = 20$  to  $\binom{12}{6} = 924$

and from  $\binom{18}{9} = 48620$  to  $\binom{24}{12} = 2704156$

and so forth.

We will show that, in either the finite context – given in Table 41.1 – or in the asymptotic context – given in Table 41.3 – whether a procedure is ‘good’ depends on whether it maintains fidelity to the research design – i.e., the probability distribution on the set  $\Omega$ . In other words, we will show that in a randomized experiment, a ‘good’ procedure is one that heeds the dictum of Senn (2004, 3729) who, in the voice of R. A. Fisher, states that ‘[a]s ye randomise so shall ye analyse’.

**ESTIMATION**

As we have mentioned above, no one can observe both potential outcomes for any given unit in a given study population. One can, however, generate a guess about some function of the study population’s individual causal effects (e.g., the mean causal effect) using observed outcomes. We call this unobservable causal quantity the *estimand*. The *estimator*, by contrast, refers to the procedure that generates a guess about the

estimand. An *estimate* is the actual output of the estimator once it is applied to a given data set.

One estimand is the mean causal effect,  $\bar{\tau} = \left(\frac{1}{N}\right) \sum_{i=1}^N \tau_i$ , which, to return to the example from Table 41.1, is  $\bar{\tau} = \frac{2+4+0+5+4+3}{6} = 3$ .

A procedure for generating a guess about  $\bar{\tau}$  is the Difference-in-Means estimator, which we can define in terms of observable quantities as follows:

$$\hat{\tau}(Z, Y) = \frac{Z'Y}{Z'Z} - \frac{(1-Z)'Y}{(1-Z)'(1-Z)} = \left(\frac{1}{\sum_{i=1}^N Z_i}\right) \sum_{i=1}^N Z_i Y_i - \left(\frac{1}{\sum_{i=1}^N (1-Z_i)}\right) \sum_{i=1}^N (1-Z_i) Y_i \tag{3}$$

In the example from Table 41.1, the random vectors<sup>3</sup> of  $\mathbf{Z}$  and  $\mathbf{Y}$  can take on any of the possible values,  $(\mathbf{z}_1, \mathbf{y}_1), \dots, (\mathbf{z}_{20}, \mathbf{y}_{20})$ , given in Table 41.2. If we apply the estimator in Equation (3) to the possible realizations of data in Table 41.2, then there are 20 possible estimates that correspond to each of the 20 possible realizations of data:

$$\hat{\tau}(\mathbf{z}_1, \mathbf{y}_1) = 6.6667, \dots, \hat{\tau}(\mathbf{z}_{20}, \mathbf{y}_{20}) = -0.6667.$$

The researcher can observe only one of these 20 possible estimates and this single estimate should be generated by an estimator that is ‘good’. More specifically, three ‘good’ properties of an estimator are *unbiasedness*, *consistency* and *precision*. An unbiased estimator is one in which, although any single estimate may be close to or far from the true value of the estimand, the *expected value of the estimator* – i.e., the probability-weighted mean of all possible estimates – is equal to the value of the estimand. Consistency states that as the number of units in the study increases asymptotically, holding all other factors constant, the probability distribution of an estimator concentrates increasingly around the truth. (For any fixed  $\varepsilon > 0$ , the probability that the estimate and its target differ by no more than  $\varepsilon$  tends to 1.) Lastly, a precise estimator is one in which the expected distance of an estimate from the true causal estimand is small.

In the following discussion, we show the role that research design plays in whether the Difference-in-Means estimator is unbiased, consistent and/or precise with respect to the estimand  $\bar{\tau} = \left(\frac{1}{N}\right) \sum_{i=1}^N \tau_i$ . We also show how designs can yield estimators that are more or less precise. Researchers may want to estimate quantities other than  $\bar{\tau}$ . Although we do not discuss such cases, the general principles for determining whether an estimator is unbiased, consistent and/or precise with respect to the causal quantity of interest is the same: researchers can define an estimand that they seek to infer, define an estimator by which they would estimate this quantity

under all possible realizations of data and subsequently assess whether this estimator is unbiased, consistent and/or precise based only on the probabilities with which possible data are realized.

### Unbiasedness

We now show that a ‘good’ estimator of the unknown estimand,  $\bar{\tau}$ , is the estimator given in Equation (3),  $\hat{\tau}(\mathbf{Z}, \mathbf{Y})$ . In particular, we will show that this estimator satisfies the criterion of no systematic error – i.e., unbiasedness – in a *uniform randomized experiment*, when the numbers of treatment and control units are both fixed.<sup>4</sup> Whether the Difference-in-Means estimator is unbiased with respect to  $\bar{\tau}$  depends solely on the known research design, i.e., whether or not there is a uniform probability distribution on the set of assignments.

Returning to the example from Table 41.1, recall that if we apply the estimator in Equation (3) to the possible realizations of data in Table 41.2, then there are 20 possible estimates that correspond to each of the 20 possible realizations of data:

$$\hat{\tau}(\mathbf{z}_1, \mathbf{y}_1) = 6.6667, \dots, \hat{\tau}(\mathbf{z}_{20}, \mathbf{y}_{20}) = -0.6667.$$

Informally, an unbiased estimator produces a guess about the estimand with no systematic error. Slightly more formally, an estimator is unbiased if the average of all possible estimates is equal to the true value of the estimand. This average of estimates, however, must be weighted by the probabilities of observing each possible estimate; we call this average the ‘expected value’ and denote the expected value of the Difference-in-Means estimator by  $\mathbb{E}[\hat{\tau}(\mathbf{Z}, \mathbf{Y})]$ .

To calculate the expected value of the Difference-in-Means estimator to assess properties like bias and consistency, we need to know the probability associated with each of these 20 possible estimates. We know that the estimator is a function of two random quantities,  $\mathbf{Z}$  and  $\mathbf{Y}$ ,

but  $\mathbf{Y}$  inherits randomness only from  $\mathbf{Z}$ , since  $Y_i = Z_i y_{1,i} + (1 - Z_i) y_{c,i}$  for all  $i \in \{1, \dots, N\}$  units. Therefore, each probability associated with its corresponding estimate depends only on  $\mathbf{Z}$ . So, we calculate the expected value of the estimator in general as follows:

$$\mathbb{E} \left[ \hat{\tau}(\mathbf{Z}, \mathbf{Y}) \right] = \hat{\tau}(\mathbf{z}_1, \mathbf{y}_1) \Pr(\mathbf{Z} = \mathbf{z}_1) \\ + \dots + \hat{\tau}(\mathbf{z}_{|\Omega|}, \mathbf{y}_{|\Omega|}) \Pr(\mathbf{Z} = \mathbf{z}_{|\Omega|}).$$

In the context of the running example, there are 20 possible estimates corresponding to each of the  $\mathbf{z}_1, \dots, \mathbf{z}_{20}$  possible assignments, and the probability of each of those possible assignments is  $\frac{1}{20}$ . Therefore, the expected value of the Difference-in-Means estimator is

$$\mathbb{E} \left[ \hat{\tau}(\mathbf{Z}, \mathbf{Y}) \right] = \hat{\tau}(\mathbf{z}_1, \mathbf{y}_1) \Pr(\mathbf{Z} = \mathbf{z}_1) \\ + \dots + \hat{\tau}(\mathbf{z}_{20}, \mathbf{y}_{20}) \Pr(\mathbf{Z} = \mathbf{z}_{20}) \\ = 6.6667 \left( \frac{1}{20} \right) \\ + \dots + -0.6667 \left( \frac{1}{20} \right) \\ = 3.$$

In this example, the expected value of the estimator,  $\mathbb{E}[\hat{\tau}(\mathbf{Z}, \mathbf{Y})]$ , is exactly equal to the true mean causal effect,  $\bar{\tau}$ . The estimator is unbiased given the design. If  $\Pr(\mathbf{Z} = \mathbf{z})$  did not equal  $\frac{1}{20}$  for all  $\mathbf{z}$  – i.e., if some assignments were more or less probable than others – then the Difference-in-Means estimator might not be unbiased. In general, the equality between  $\mathbb{E}[\hat{\tau}(\mathbf{Z}, \mathbf{Y})]$  and  $\bar{\tau}$  holds when (1) units are assigned to study conditions as individuals (not as groups, i.e., *clusters*), (2) there is always at least one unit in the treatment condition and one in the control condition and (3) each possible assignment has an identical probability of realization. In other words, the Difference-in-Means estimator is

unbiased with respect to the mean additive causal effect in a uniform randomized experiment under either complete individual assignment or simple individual assignment so long as there is always at least one unit in each of the study conditions.

Notice that the Difference-in-Means estimator did not require large numbers of units or assumptions about the distributions of potential outcomes to be unbiased. The potential outcomes could have been any set of values and the property of unbiasedness would still have held. However, the unbiasedness property did require that there be a uniform probability distribution on the set of possible assignments. But in a controlled research design, like a randomized experiment, the researcher knows whether or not this condition is true.

### Consistency

‘No systematic error’ is not the same as ‘close to the truth’. Achen (1982, 36) explains the need for another conception of a ‘good’ estimator when he writes ‘[u]nbiasedness is too weak a property, since it says nothing about approximating the truth’. While we know that an unbiased estimator yields estimates that are, on average, equal to the true value of the estimand, any single estimate might be far from the truth. In our running example, not one of the 20 possible estimates is actually equal to the true mean causal effect of  $\bar{\tau} = 3$ , even though the probability-weighted average of those 20 estimates is equal to 3. Another ‘good’ characteristic of an estimator is to produce values close to the truth as more information is supplied to the estimator from the design.

In contrast to unbiasedness, consistency states that as the number of units in the study grows asymptotically, holding all other factors constant, the probability of an estimate within an arbitrarily small distance,  $\epsilon$ , from the truth is equal to 1. More formally, we can define consistency as follows:

$$\lim_{h \rightarrow \infty} \Pr \left( \left| \hat{\tau}(\mathbf{Z}, \mathbf{Y}) - \bar{\tau} \right| < \varepsilon \right) = 1 \text{ for all } \varepsilon > 0 \quad (4)$$

or equivalently as

$$\lim_{h \rightarrow \infty} \Pr \left( \hat{\tau}(\mathbf{Z}, \mathbf{Y}) \in (\bar{\tau} - \varepsilon, \bar{\tau} + \varepsilon) \right) = 1 \text{ for all } \varepsilon > 0, \quad (5)$$

where, referring back to the conception of asymptotic growth in Table 41.3,  $h$  is the number of copies of the original finite population from Table 41.1.

To unpack Equations (4) and (5), Figure 41.1 shows what happens to the distribution of the Difference-in-Means estimator under complete random assignment as  $h \rightarrow \infty$ .

The general trend is that the probability of estimates close to the true mean causal effect,  $\bar{\tau} = 3$ , grows larger and larger and ultimately converges in probability (over the sequence of increasing finite populations) to 1. For example, following Equation (5), consider the probability that an estimate lies on

the interval  $(3 - \varepsilon, 3 + \varepsilon)$  and let  $\varepsilon = 1$ . The respective probabilities of an estimate on this interval for  $h \in \{1, 2, 3, 4\}$  are 0.1, 0.2359, 0.2559 and 0.2994, and as  $h \rightarrow \infty$ , that probability tends to 1. This property holds for  $\varepsilon = 1$  as well as for any positive value of  $\varepsilon$  that one could choose. For example, we could have let  $\varepsilon = 0.5$ , in which case the corresponding probabilities for  $h \in \{1, 2, 3, 4\}$  are 0.1, 0.1234, 0.1522 and 0.1643, and the limiting probability as  $h \rightarrow \infty$  is also 1. In general, it is not necessary that each probability be greater than its predecessor for  $h \in \{1, 2, 3, 4, \dots\}$ . Consistency states only that there exists some number in which, for any  $h$  greater than that number, the estimator will lie within an arbitrarily small interval (of distance  $\forall \varepsilon > 0$ ) around the true mean causal effect.

In this particular case, consistency follows (in part) from unbiasedness. As the size of  $N$  increases towards  $\infty$  while all other factors remain constant, the probability of an estimate

**Figure 41.1** Distribution of Difference-in-Means estimator as  $h \rightarrow \infty$ . The dashed lines denote the expected value of the estimator.

arbitrarily close to the estimator’s expected value is equal to 1. Unbiasedness ensures that the expected value of the estimator is equal to the true value of the estimand. Therefore, as the size of the study population grows towards  $\infty$ , the estimator produces a value arbitrarily close to the truth (not just to the estimator’s expected value) with a probability of 1. Both the unbiasedness and consistency of the Difference-in-Means estimator, moreover, arise solely from the research design. Even though the distribution of the estimator starts to look more and more normal as the size of the study population increases to  $\infty$ , we made no such distributional assumptions to show the estimator’s unbiasedness and consistency.

**Precision**

While unbiased and consistent estimators are desirable, such estimators may yield estimates far from the truth, with high probability in actual experiments with fixed study populations. One estimator is more precise than another estimator for a given study design if it produces estimates that are closer to the truth on average. In other words, a ‘good’ estimator also has a low variance; in our case, a more precise estimator than the Difference-in-Means estimator would make the 20 possible estimates in Table 41.2 closer to the true mean causal effect, on average. We now consider first the factors that make the Difference-in-Means estimator produce guesses with lower expected distance from the true mean causal effect and second the procedure one can use to conservatively estimate the variance of the Difference-in-Means estimator.

Neyman (1923) derived an exact analytic expression for the variance of the Difference-in-Means estimator based solely on the research design of a randomized experiment, as follows:

$$\sigma_{\bar{\tau}}^2 = \frac{1}{N-1} \left( \frac{n_t \sigma_{y_c}^2}{n_c} + \frac{n_c \sigma_{y_t}^2}{n_t} + 2\sigma_{y_c, y_t} \right), \quad (6)$$

where  $\sigma_{y_c}^2$  is the variance of control potential outcomes,  $\sigma_{y_t}^2$  is the variance of treatment potential outcomes and  $\sigma_{y_c, y_t}$  is the covariance of control and treatment potential outcomes.

Equation (6) suggests that one can increase the precision of the Difference-in-Means estimator (i.e., reduce the estimator’s variance) by increasing the number of treatment units and/or the number of control units. Precision can also be increased by decreasing the variances of treatment,  $\sigma_{y_t}^2$ , and control,  $\sigma_{y_c}^2$ , potential outcomes. For a simple and clear account of the factors that increase precision, see Gerber and Green (2012, section 3.2).

A standard design choice that researchers can make to increase precision is blocking. That is, a researcher can first construct blocks that are similar in terms of covariates related to potential outcomes and second assign units to study conditions within blocks. Blocked assignment works by excluding assignments that, on average, yield estimates far from the true mean effect. To see this point, we return to the example in Table 41.1 and introduce  $\mathbf{x}$ ,  $\mathbf{x} \in 0,1^N$  which is a vector of baseline covariate values for all  $i \in 1, \dots, N$  units. The vector  $\mathbf{x}$  is a fixed quantity that is measured for all units prior to assignment; hence,  $\mathbf{x}$  cannot change as a function of whichever assignment is realized.

From Table 41.4, we can see that  $\mathbf{x}$  is related to both  $y_c$  and  $y_t$ . The treatment potential outcomes are greater, on average, among units whose baseline covariate values are equal to 1 compared to units whose baseline covariate values are equal to 0. The same is

**Table 41.4 True values of  $y_c$ ,  $y_t$ ,  $\tau$  and the baseline covariate  $\mathbf{x}$**

$y_c$	$y_t$	$\tau$	$\mathbf{x}$
20	22	2	1
8	12	4	1
11	11	0	0
10	15	5	1
14	18	4	1
1	4	3	0

true for control potential outcomes. If the researcher puts units whose covariate values are equal to 1 in one block and units whose covariate values are equal to 0 in another, and then assigns half of the units to treatment and control within blocks, the set of possible assignments,  $\Omega_b$ , would be as follows:

$$\Omega_b = \left\{ \begin{bmatrix} 1 \\ 1 \\ 1 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 1 \\ 1 \\ 0 \\ 0 \\ 1 \end{bmatrix}, \dots, \begin{bmatrix} 0 \\ 0 \\ 1 \\ 1 \\ 1 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 1 \\ 1 \\ 0 \end{bmatrix} \right\}. \quad (7)$$

The set  $\Omega_b$  above has only 12 possible assignments as opposed to the 20 possible assignments in Equation (2) under complete random assignment without blocks. In particular, the

assignments of  $\mathbf{z}_2, \mathbf{z}_3, \mathbf{z}_7, \mathbf{z}_8, \mathbf{z}_{13}, \mathbf{z}_{14}, \mathbf{z}_{18}, \mathbf{z}_{19} \in \Omega$  are excluded from  $\Omega_b$ .

Figure 41.2 shows the eight estimates corresponding to the eight assignments that were included in unblocked assignment but excluded in blocked assignment. On average, these eight estimates are farther from the true mean effect than are the other 12 estimates. More concretely, the average squared distance of the eight excluded estimates from the truth is 36.91667 and the same average squared distance of the 12 included assignments is 18.12963. Hence, this blocked design increases precision by reducing the probability (to 0) of estimates that are, on average, far from the truth and by increasing the probability of estimates that are, on average, closer to the truth.<sup>5</sup>

Thus far, we have focused on design choices that can decrease the variance of the Difference-in-Means estimator. But, note

**Figure 41.2** Distribution of Difference-in-Means estimates under (a) unblocked and (b) blocked assignment. The dashed lines denote the expected value of the estimator.

that the variance of the Difference-in-Means estimator is, like the true mean causal effect, a fixed, unobservable quantity. As we can see from Equation (6), the variance of the Difference-in-Means estimator depends on the variance of treatment and control potential outcomes as well as their covariance, none of which can be directly observed. We need a ‘good’ procedure by which we can estimate the variance of the Difference-in-Means estimator if we are to reasonably infer its precision. We will use such a variance estimator in the context not only of evaluating estimators but also hypothesis testing.

One can unbiasedly and consistently estimate two of the three unknown quantities in Equation (6). Following Cochran (1977), unbiased and consistent estimators of  $\sigma_{y_c}^2$  and  $\sigma_{y_t}^2$ , respectively, are:

$$\hat{\sigma}_{y_c}^2 = \left( \frac{N-1}{N(n_c-1)} \right) \sum_{i:Z_i=0}^N (y_{c,i} - \hat{\mu}_{y_c})^2$$

$$\text{and } \hat{\sigma}_{y_t}^2 = \left( \frac{N-1}{N(n_t-1)} \right) \sum_{i:Z_i=1}^N (y_{t,i} - \hat{\mu}_{y_t})^2, \text{ where}$$

$$\hat{\mu}_{y_c} = \left( \frac{1}{n_c} \right) \sum_{i=1}^N (1-Z_i)y_{c,i} \text{ and } \hat{\mu}_{y_t} = \left( \frac{1}{n_t} \right) \sum_{i=1}^N Z_i y_{t,i}$$

We cannot write an unbiased and consistent estimator for  $\sigma_{y_c, y_t}$  since no two potential outcomes for any unit can be jointly observed. Neyman (1923) noted, however, that one could use a conservative procedure for estimating the quantity in Equation (6) by assuming the largest possible value of  $2\sigma_{y_c, y_t}$ , which, by the Cauchy–Schwarz inequality and the AM–GM inequality (i.e., inequality of arithmetic and geometric means), is  $\sigma_{y_c}^2 + \sigma_{y_t}^2$ .

After substituting  $\sigma_{y_c}^2 + \sigma_{y_t}^2$  for  $2\sigma_{y_c, y_t}$ , the analytic expression for the variance of the Difference-in-Means estimator (assuming  $2\sigma_{y_c, y_t} = \sigma_{y_c}^2 + \sigma_{y_t}^2$ ) is

$$\frac{1}{N-1} \left( \frac{n_t \sigma_{y_c}^2}{n_c} + \frac{n_c \sigma_{y_t}^2}{n_t} + \sigma_{y_c}^2 + \sigma_{y_t}^2 \right),$$

which can be simplified to

$$\frac{N}{N-1} \left( \frac{\sigma_{y_c}^2}{n_c} + \frac{\sigma_{y_t}^2}{n_t} \right). \tag{8}$$

Now there are only two unknown quantities in Equation (8), each of which can be unbiasedly estimated. Hence, one can now unbiasedly estimate the quantity in (8) via the conservative variance estimator of

$$\hat{\sigma}_{\hat{\tau}}^2 = \frac{N}{N-1} \left( \frac{\hat{\sigma}_{y_c}^2}{n_c} + \frac{\hat{\sigma}_{y_t}^2}{n_t} \right). \tag{9}$$

This estimator is conservative because, since it unbiasedly estimates the quantity in (8), its expected value is equal to or greater than the true variance of the estimator given in (6).<sup>6</sup>

Thus far, we have explained the role that research design – i.e., the probability distribution on the set of assignments,  $\Omega$  – plays in determining whether estimators are unbiased, consistent and precise. We have also explained how one can infer the variance of an estimator via a conservative procedure. We have used a simple example of complete uniform assignment to illustrate these points; yet an estimator that is unbiased, consistent and/or relatively precise in this design may not be so in another design. For example, the Difference-in-Means estimator is not necessarily unbiased when there is a non-uniform probability distribution on  $\Omega$ ; however, the Horvitz–Thompson (i.e., inverse probability weighted) estimator (Horvitz and Thompson, 1952) is unbiased in such a design (see Aronow and Middleton, 2013). Such design-based inference differs from model-based inferences in that the former remains reliable without the need to impose a probability model on potential outcomes or to model the functional form (e.g., a linear model) that links the treatment variable to potential outcomes. The only probability model in design-based inference is the assignment process itself, which, in the case of a randomized experiment, is known to be the true model of the data-generating process.

## HYPOTHESIS TESTING

Focusing on  $\bar{\tau}$  engages with the fundamental problem of causal inference by aggregation across units in the study and  $\hat{\bar{\tau}}$  can be shown to be an unbiased, consistent and, depending on the study design, relatively precise estimator. An alternative approach begins with claims about causal effects rather than guesses about them, stating hypotheses about  $\bar{\tau}$  or even about individual effects,  $\tau$ . This approach then tests those claims, and so the procedures that we will assess in this section are properties of tests rather than of estimators. A researcher who performs a hypothesis test for causal inference first states a null hypothesis about a relationship between unobserved potential outcomes and a (usually composite) alternative hypothesis, which we will define more precisely below. The researcher can then assess the probability that the research design generates data under the null hypothesis that are more extreme than the actually observed data. The observed data and data under the null hypothesis are summarized via a test statistic that maps the data — the observed outcome and treatment assignment — to a single number. For example, the test statistic calculated on whichever data are generated by the design,  $t(\mathbf{Z}, \mathbf{Y})$ , could be

$$\left( \frac{1}{\sum_{i=1}^N Z_i} \right) \sum_{i=1}^N Z_i Y_i - \left( \frac{1}{\sum_{i=1}^N (1 - Z_i)} \right) \sum_{i=1}^N (1 - Z_i) Y_i,$$

which is the same formula that we labeled  $\hat{\bar{\tau}}$  in Equation (3) but, in the context of hypothesis testing, is not an estimator but a data summary. We call the probability of a test statistic under the null more extreme than the observed test statistic a probability-value or  $p$ -value. Typically, when the  $p$ -value is less than or equal to a pre-specified ‘significance level’ of the test, which we denote by  $\alpha \in (0,1)$ , a researcher *rejects* the null hypothesis, meaning that the researcher declares that the observed data are not consistent with the null

hypothesis relative to an alternative hypothesis. When the  $p$ -value is greater than the significance level of the test, the researcher *fails to reject* the null hypothesis relative to an alternative hypothesis — meaning that the researcher declares that there is not enough information to state that the observed data are inconsistent with the hypothesized state of the world. Sometimes, we talk about hypothesis testing as an attempt to distinguish signal from noise; a high  $p$ -value tells us that we cannot distinguish signal from noise, and a low  $p$ -values tells us that we can do so.

Hypothesis tests are subject to at least two types of errors: first, one could reject the null hypothesis when it is true (a type I error) or, second, fail to reject the null hypothesis when it is false (a type II error). Two features of hypothesis tests related to these two potential errors are the  $\alpha$  size of the test and the *power* of the test. We now define the  $\alpha$  size (distinct from the  $\alpha$  level) and power-of-hypothesis tests.

A test’s  $\alpha$  level is, in the words of Rosenbaum (2010), that test’s ‘promise’ that the probability of a Type I error (i.e., the probability of a  $p$ -value that is less than  $\alpha$  when the null hypothesis is true) is less than or equal to the  $\alpha$  level. The test’s  $\alpha$  size, on the other hand, is the test’s true probability of a Type I error, which, in general, can be greater than, equal to or less than the  $\alpha$  level ‘promised’ by the test. In contrast to the  $\alpha$  level and size of a test, a test’s power is the probability of a  $p$ -value that is less than the  $\alpha$  level when the null hypothesis is false. In other words, power is 1 minus the Type II error probability; hence, as the power of a test increases, the Type II error probability decreases.

In the subsections to follow, we first define ‘good’ properties of hypothesis tests. We then describe tests of causal hypotheses in two distinct traditions traceable to Fisher (1935) (subsequently developed most extensively by Rosenbaum, 2002, 2010), and Neyman and Pearson (1933). We then explain the role that research design plays in justifying whether tests in either of these two traditions have good properties.

### **What Makes a Hypothesis Test a 'Good' Test?**

We have already discussed three properties of good estimators – namely, unbiasedness, consistency and precision – but what makes a test of a null hypothesis relative to an alternative hypothesis a 'good' test? Just as we did for estimation, we describe 'good' features of hypothesis tests in the context of a fixed, finite population and in the context of a hypothetical scenario in which a study's size increases towards  $\infty$  by increasing the number of copies of the study. The first two 'good' properties (a Type I error probability less than the  $\alpha$  level and an unbiased test) refer to the former context, and the third property (a consistent test) refers to the latter context. Informally, a good hypothesis test should rarely mislead us: it should rarely encourage us to declare that we have discovered a signal in the noise when no signal exists and it should often find signals when they do exist.

Regardless of the size of a given study population, a hypothesis test first ought to control its  $\alpha$  size (true Type I error probability) such that it is less than or equal to the test's  $\alpha$  level. Second, a hypothesis test ought to be an *unbiased test* (not to be confused with an *unbiased estimator*), i.e., the probability of rejecting the null hypothesis when it is false and the alternative hypothesis is true should be at least as great as the probability of rejecting the null hypothesis when it is true and the alternative hypothesis is false (see Lehmann and Romano, 2005, chapter 4). Intuitively, we want to *reject* something that is *false* and we want to *not reject* something that is *true*. A test that leads us to reject true nulls with greater probability than we reject false nulls does not yield inferences that track the true causal effect. A good hypothesis test ought to be an unbiased test in this sense.

Turning now to the asymptotic context described in the section 'An Illustrative Example', a hypothesis test ought to be a

*consistent test* (not the same as a *consistent estimator*); that is, as the size of the study population increases asymptotically while all other relevant factors remain constant, the probability of rejecting the null hypothesis when it is false and the alternative is true should tend to 1 (see Lehmann and Romano, 2005, chapter 11). We now show the role that research design plays in enabling 'good' hypothesis tests in two different design-based traditions: Fisherian (Fisher, 1935) and Neymanian (Neyman and Pearson, 1933).

### **Fisherian Hypothesis Testing**

Hypothesis testing in the tradition of Fisher (1935), later developed most extensively by Rosenbaum (2002, 2010), assesses the consistency of the observed data with a null hypothesis vis-à-vis an alternative hypothesis. A strong null hypothesis,<sup>7</sup> which we denote by  $\tau_0$ , postulates an individual treatment effect for all  $i \in \{1, \dots, N\}$  units in a given study population. For example, one strong null hypothesis is  $\tau'_0 = [5 \ 5 \ \dots \ 5 \ 5]$  and another might be  $\tau'_0 = [0.5 \ -10 \ \dots \ 200 \ -74.25]$ . The *strong null hypothesis of no effect* (which we henceforth refer to as 'the strong null of no effect') specifically postulates that  $\tau_i = 0$  for all  $i \in \{1, \dots, N\}$  units – i.e., that  $\tau'_0 = [0 \ 0 \ \dots \ 0 \ 0]$ .

The consistency of the observed data with a strong null hypothesis vis-a-vis an alternative is typically assessed via  $p$ -values. To reiterate, a  $p$ -value is the probability of a test statistic at least as extreme as the observed test statistic from the perspective of the null hypothesis: as we will show below, the hypothetical world of the null generates, along with the known research design, the probability distribution that we compare against our single observed test statistic. In the context of Fisherian hypothesis tests, we can formally represent upper ( $p_u$ ), lower ( $p_l$ ) and two-sided ( $p_t$ )  $p$ -values as follows:

$$\begin{aligned}
 p_u &= \sum_{m=1}^{|\Omega|} \mathbb{1} \left[ t(\mathbf{z}_m, \mathbf{y}_{0_j}) \geq T \right] \Pr(\mathbf{Z} = \mathbf{z}_j) \\
 p_l &= \sum_{m=1}^{|\Omega|} \mathbb{1} \left[ t(\mathbf{z}_m, \mathbf{y}_{0_j}) \leq T \right] \Pr(\mathbf{Z} = \mathbf{z}_j) \quad (10) \\
 p_t &= \min\{1, 2 \min\{p_u, p_l\}\},
 \end{aligned}$$

where the index  $m \in \{1, \dots, |\Omega|\}$  runs over all possible assignments in the set of assignments  $\Omega$ ,  $\mathbb{1}$  is an indicator function that is 1 if the argument  $[\cdot]$  is true and 0 if false,  $t(\mathbf{z}_m, \mathbf{y}_{0_m})$  is the null test statistic (using  $\mathbf{y}_{0_m}$  to refer to the vector of observed outcomes for the  $m$ th assignment implied by the null hypothesis,  $H_0$ ) and  $T$  is the observed test statistic.<sup>8</sup>

To provide an illustration of Fisherian  $p$ -values, we return to the example in Table 41.1 and imagine that the assignment  $\mathbf{z}'_8 = [1 \ 0 \ 0 \ 1 \ 1 \ 0]$  happened to be the one randomly selected. In this case, the realization of data would be as in Table 41.5.

If the researcher uses the Difference-in-Means test statistic to provide a single, numerical summary of the observed data in Table 41.5, then the observed test statistic would be  $t(\mathbf{z}_8, \mathbf{y}_8) = 11.6667$ . Let's assume that the researcher wants to assess the consistency of this observed test statistic with the strong null of no effect – i.e., that  $\tau_i = 0$  for all  $i$  – relative to the alternative hypothesis of a positive effect – i.e., that  $\tau_i$  is non-negative for all  $i$  and positive for at least one  $i$ .

Potential outcomes are only partially observed, but the researcher can ‘fill in’ the

missing potential outcomes according to the strong null hypothesis  $H_0 : y_{t,i} = y_{c,i}$  for all  $i$ . Below, we can also show what this hypothesis implies for the observed outcomes  $y_t$ , recalling that  $y_i = Z_i y_{t,i} + (1 - Z_i) y_{c,i}$  and writing  $y_{c0,i}$  and  $y_{t0,i}$  to mean ‘value of  $y_{c,i}$  and  $y_{t,i}$  under a test of  $H_0$ ’:

$$\begin{aligned}
 y_{c0,i} &= y_i - z_i \tau_{0_i}, \\
 y_{t0,i} &= y_i + (1 - z_i) \tau_{0_i},
 \end{aligned} \quad (11)$$

which in the case of the strong null of no effect implies that units’ null potential outcomes and observed outcomes are as they appear in Table 41.6.

Assuming for the sake of argument that the strong null of no effect is true, the researcher knows exactly what all other possible realizations of data would look like under each possible assignment in  $\Omega$ . Hence, the researcher can summarize all other possible realizations of data under the null with the same Difference-in-Means test statistic – generating a probability distribution of those null test statistics – and then calculate the probability of a null test statistic greater than or equal to the observed test statistic of 11.6667 (see Figure 41.3).

In this case, the upper  $p$ -value –  $p_u$  from Equation (10) – is 0.05. Assume that the value of  $\alpha$  has been pre-set to a level greater than 0.05, which leads the researcher to reject the strong null of no effect in favor of the alternative of a positive effect. Table 41.1 shows that the strong null of no effect is

**Table 41.5 Realization of Data if  $\mathbf{z}_8$  were the randomly drawn assignment**

false ( $y_{t,i} \neq y_{c,i}$  for all  $i$ ) and the alternative of a positive effect is true; hence, this particular choice to reject the strong null of no effect relative to the alternative of a positive effect happened to be a good one.

To assess whether the hypothesis-testing procedure is a good one overall, we want to establish that the test (1) has a true Type I error probability less than the  $\alpha$  level, (2) is unbiased and (3) is consistent. We will now illustrate these three properties in turn.

Let's return to the example given in Table 41.1, where the true vector of individual causal effects is  $\tau' = [2\ 4\ 0\ 5\ 4\ 3]$ , and Table 41.2 describes the 20 possible realizations of data. When the null hypothesis,  $\tau_0$ , is false, the potential outcomes implied by the null hypothesis vary depending on which data are realized. However, when the null hypothesis,  $\tau_0$ , is true, i.e.,

when  $\tau_0 = \tau$ , the potential outcomes implied by the null hypothesis are fixed across all possible realizations of data, as shown by Table 41.7.

If we set the significance level of the test to, say,  $\alpha = 0.10$ , then it is true by definition that the probability that an observed test statistic lies in the lower tail of its distribution is less than or equal to 0.10, and the same is true for the probability that an observed test statistic lies in the upper tail of its distribution. Figure 41.4 shows the distribution of this test statistic, in which both the lower and upper tails according to  $\alpha = 0.10$  are shaded darker.

Notice that no matter which of the 20 possible realizations of data is actually realized, the null potential outcomes when the null hypothesis is true are identical to the true potential outcomes in Table 41.1, and hence each of the 20 possible null distributions of

**Table 41.7 Null potential outcomes for all possible realizations of data when the null hypothesis is true.**

$z_1$	$y_{c0}$	$y_{t0}$	$y_1$	$z_2$	$y_{c0}$	$y_{t0}$	$y_2$	$z_{19}$	$y_{c0}$	$y_{t0}$	$y_{19}$	$z_{20}$	$y_{c0}$	$y_{t0}$	$y_{20}$

**Figure 41.4 Distribution of observed test statistic. The upper and lower tails containing 10% of the of the probability mass are in the darker shade.**

the test statistic are identical to the distribution of the observed test statistic. Since all 20 possible null distributions are identical to the distribution of the observed test statistic, the probability that an observed test statistic lies in one of the tails of the null distribution must also be less than or equal to 0.10. This means that the probability of a null test statistic that is more extreme than the observed test statistic must be less than or equal to  $\alpha$ .

Fisherian hypothesis tests possess the property that the Type I error probability is less than or equal to the test's  $\alpha$  level. Yet such a property does *not* imply that the power of the test is greater than the test's Type I error probability (i.e., that the test is unbiased). To show that a test is unbiased relative to a specific class of alternative hypotheses, we now need to more precisely define the alternative to the null hypothesis.

In the previous sections, we referred to causal effects by the vector  $\tau$ , but now we define the size of causal effects using the vectors of control and treatment potential outcomes:  $y_c$  and  $y_t$ , respectively. More specifically, following Rosenbaum (2002), we define a treatment effect that is ‘larger’ than another treatment effect as follows:

**Definition 1.** *One treatment effect  $(y_c^*, y_t^*)$  has a larger effect than another treatment effect  $(y_c, y_t)$  if and only if  $y_{t,i}^* \geq y_{t,i}$  and  $y_{c,i}^* \leq y_{c,i}$  for all  $i \in \{1, \dots, N\}$  units, where  $y_t^* \neq y_t$  or  $y_c^* \neq y_c$ .*

Such an ordering of causal effects is consistent with many models of treatment effects, such as additive, multiplicative, tobit and dilated effects (Rosenbaum, 1999, 2002, 2010), not solely with the model of a constant, additive effect.

We now use this formal definition of a ‘larger effect’ in terms of potential outcomes to define a desirable property of a test statistic: ‘larger’ effects yield test statistic values greater than those produced by ‘smaller’ effects. Rosenbaum (2002, chapter 2) shows that an ‘effect-increasing’ test statistic with respect to two possible realizations of data,  $(z, y)$  and  $(z, y^*)$ , satisfies this property. Following Rosenbaum (2002), we define an effect-increasing test statistic as follows:

**Definition 2.** *A test statistic,  $t(\cdot, \cdot)$ , is effect increasing when  $t(z, y) \leq t(z, y^*)$  whenever  $y_i \leq y_i^*$  for all  $i \in \{1, \dots, N\} : z_i = 1$  and  $y_i^* \leq y_i$  for all  $i \in \{1, \dots, N\} : z_i = 0$ .*

An effect-increasing test statistic ensures that, when the null hypothesis is false and the alternative of a larger effect is true, each possible realization of data yields a test statistic value that is greater than or equal to the corresponding test statistic value when the null hypothesis is true and the alternative of a larger effect is false. To understand this property, consider the following example in Table 41.8 of two possible causal effects,  $(y_c, y_t)$  and  $(y_c^*, y_t^*)$ , in which the former is a null effect and the latter is a larger, positive causal effect (see definition 1).

**Table 41.8** No-effects,  $(y_c, y_t)$ , and positive-effects,  $(y_c^*, y_t^*)$

$y_c$	$y_t$	$y_c^*$	$y_t^*$
20	20	20	22
8	8	3	12
11	11	10	11
10	10	10	15
14	14	9	19
1	1	1	4

For any  $z$ , regardless of whichever three out of the six units are assigned to treatment, the larger causal effect,  $(y_c^*, y_t^*)$ , will always yield a value of the observed outcome for all treatment units that is greater than or equal to the outcome we would see with the same  $z$  in the no-causal-effect state, and we would also see a value of the observed outcome for all control units that is less than or equal to what we would see in the no-causal-effect state. Table 41.9 shows that an effect-increasing test statistic ensures that the observed test statistic of a larger effect is always greater than or equal to the observed test statistic of a smaller effect.

In addition to the property that increasing causal effects map monotonically onto increasing test statistics, we also want the  $p$ -values for tests of the null hypothesis when the null is false and the alternative is true to be smaller compared to the  $p$ -values when the null is true and the alternative is false. An effect-increasing test statistic also suffices for this property (for a formal proof, see Rosenbaum, 2002, chapter 2).

Table 41.10 shows that for all  $z_1, \dots, z_{20}$  possible assignments the  $p$ -value of the strong null of no effect when the positive effect,  $(y_c^*, y_t^*)$ , is true is less than or equal to the strong null’s  $p$ -value when no-effect,  $(y_c, y_t)$ , is true.

We have just shown that Fisherian tests using effect-increasing test statistics are unbiased: they provide more evidence against false claims than against true claims. In addition to being unbiased, we would also like our tests

**Table 41.9 Observed difference-in-means test statistics under all possible assignments for both a no-effects and positive-effects true causal state**

to be consistent, i.e., as the size of the study population grows towards  $\infty$ , while other factors remain constant, the power of the test tends to 1. Returning to the example in Table 41.1, notice that the probability of a  $p$ -value less than  $\alpha$  increases along the sequence of finite populations of increasing size, given in Table 41.3. For example, with an  $\alpha$  level of  $\alpha = 0.10$ , Figure 41.5 shows that the probability of a  $p$ -value less than  $\alpha = 0.10$  grows greater and greater.

Figure 41.5 shows that when the study population size grows from 6 to 12 and 18 units while all other factors are held constant, the power increases from 0.15 to roughly 0.2933 and 0.3741, respectively. As the population size increases along the sequence given in Table 41.3, the power of the test of the strong null of no effect will tend to 1. In other words, as we draw upon more and more data, we *reject* a *false* null with greater and greater probability.

We used the Difference-in-Means estimator as a test statistic for our example data in order to demonstrate the properties of Fisherian hypothesis tests in randomized experiments. However, we could have also used rank-based test statistics, standardized mean differences or many other functions of treatment and outcomes, most of which are effect increasing like the Difference-in-Means test statistic. In fact, one of the challenges of Fisherian testing is its flexibility in terms of test statistics. We do not engage with those decisions here but encourage interested readers to see (Rosenbaum, 2010, chapter 2), as well as Caughey et al. (2018), for some discussion on using this flexibility to assess substantively interesting hypotheses about pareto optimal causal effects, and Bowers et al. (2013, 2016) for examples on the propagation of causal effects on networks.

**Figure 41.5** Distribution of Fisherian  $p$ -values for test of strong null of no effect under all realizations of data as the size of the experimental pool grows from one copy of the study,  $h = 1$  ( $n = 6$ ); to two copies of the study,  $h = 2$  ( $n = 12$ ); to three copies of the study,  $h = 3$  ( $n = 18$ ). The dashed lines denote the significance level of  $\alpha = 0.10$ .

### *Hypothesis Testing in the Neymanian Tradition*

While Fisherian tests allow the use of many different kinds of test statistics, Neymanian hypothesis tests are much more closely related to the estimation of mean causal effects (see the third section). In any given study, one can observe only a single estimate, now interpreted as a test statistic. However, a researcher can postulate (provisionally, for the sake of argument) a weak null hypothesis,  $H_0 : \bar{\tau} = \bar{\tau}_0$ , relative to some alternative hypothesis, such as  $H_a : \bar{\tau} > \bar{\tau}_0$ , and subsequently assess the probability of a test statistic under the weak null more extreme than the test statistic the researcher actually observed. Such Neymanian hypothesis tests differ from Fisherian tests in several fundamental ways. Neymanian hypothesis tests

(1) hypothesize about the mean causal effect, not the individual causal effect for each unit in the study, (2) require that the Difference-in-Means estimator be unbiased such that a hypothesis about the mean causal effect implies the same value for the mean (i.e., expected value) of the estimator, (3) require that the researcher estimate the variance of the Difference-in-Means estimator (recall that the distribution of the test statistic in the Fisherian test is known under random assignment and a strong null hypothesis) and (4) draw upon the finite population central limit theorem (Erdős and Rényi, 1959; Hájek, 1960; Li and Ding, 2017), which implies that the product of  $\sqrt{N}$  multiplied by the difference between the estimator and its expected value converges to a normal distribution with mean equal to 0 and variance equal to  $\sigma_{\bar{\tau}}^2$ , which, Due to Slutsky's theorem, one can

equivalently state this property as . . .  $\frac{\hat{\tau} - \mathbb{E}[\hat{\tau}]}{\sqrt{\hat{\sigma}_{\hat{\tau}}^2}}$ , which is known as the z-score, converges in distribution to a standard normal (i.e., normal distribution with mean 0 and variance equal to 1).

We can see points (1)–(4) by looking at the common expressions for Neymanian  $p$ -values:

$$\begin{aligned} p_u &= 1 - \Phi\left(\frac{\hat{\tau} - \bar{\tau}_0}{\sqrt{\hat{\sigma}_{\hat{\tau}}^2}}\right) \\ p_l &= \Phi\left(\frac{\hat{\tau} - \bar{\tau}_0}{\sqrt{\hat{\sigma}_{\hat{\tau}}^2}}\right) \\ p_t &= 2\left(1 - \Phi\left(\frac{|\hat{\tau} - \bar{\tau}_0|}{\sqrt{\hat{\sigma}_{\hat{\tau}}^2}}\right)\right), \end{aligned} \tag{12}$$

where  $\hat{\tau}$  is the familiar Difference-in-Means estimator (from the third section) now interpreted as a test statistic, not an estimator,  $\hat{\sigma}_{\hat{\tau}}^2$  is the conservative variance estimator (also from the third section) now used to describe the distribution of the Difference-in-Means test statistic under the weak null hypothesis rather than the precision of an estimator,  $\bar{\tau}_0$  is a weak null hypothesis and  $\Phi(\cdot)$  is the standard normal cumulative distribution function (CDF).

The expressions in Equation (12) return the probability of Difference-in-Means test statistic at least as extreme as the observed test statistic if the weak null hypothesis,  $\bar{\tau}_0$ , were true. Notice, though, that the weak null hypothesis,  $\bar{\tau}_0$ , is technically a claim about the mean of the Difference-in-Means test statistic, which we can denote by  $\mathbb{E}_0[\hat{\tau}]$ . However, because the Difference-in-Means estimator is unbiased, its expected value is always equal to the mean causal effect; this is why we use  $\bar{\tau}_0$  in Equation (12) rather than  $\mathbb{E}_0[\hat{\tau}]$ . Finally, note that the true variance of the Difference-in-Means test

statistic is unknown, but the normal CDF requires two arguments – a value for the mean and a value for the variance – to assign a probability to null test statistics as least as extreme as the observed test statistic. Rather than postulate a hypothesis about the variance of the estimator, like one does for the mean of the estimator, Neymanian tests use an estimate from the conservative variance estimator in Equation (9) to calculate a  $p$ -value via the standard normal CDF.

In many situations, we can easily justify the assumption that  $\frac{\hat{\tau} - \bar{\tau}_0}{\sqrt{\hat{\sigma}_{\hat{\tau}}^2}}$  is well approximated by a standard normal distribution by appealing to the aforementioned finite population Central Limit Theorem (CLT) and associated theory (see, e.g., Hogg, 1978). The Difference-in-Means test statistic scaled by  $\sqrt{N}$  is indeed asymptotically normal and the  $p$ -values in Equation (12) are all asymptotically valid – roughly meaning that, as . . .  $N$  grows towards  $\infty$ , the probability of a Type I error is less than or equal to the  $\alpha$  level of the test.

However, in small experiments in which the normal approximation is poor, tests of a weak null hypothesis relative to an alternative may have either a Type I error probability greater than the test’s  $\alpha$  level (when the null is true) or low power (when the null is false). Table 41.5 and Figure 41.3 demonstrate Neymanian  $p$ -values, in which the assignment  $\mathbf{z}_8$  happened to be the one randomly drawn by the researcher. In this example, the observed Difference-in-Means test statistic is 11.6667 and the conservatively estimated variance is 12.8889. If we were to test the weak null hypothesis of no effect, i.e., that  $\bar{\tau}_0 = 0$ , against the alternative hypothesis that  $\bar{\tau}_a > 0$ , then the upper one-tailed  $p$ -value would be as follows:

$$\left(1 - \Phi\left(\frac{11.6667 - 0}{\sqrt{12.8889}}\right)\right) \approx 0.0006, \tag{13}$$

**Figure 41.6** Distribution of Neymanian  $p$ -values under all realizations of data. The dashed line is the observed  $p$ -value

which yields a smaller  $p$ -value than the upper  $p$ -value we calculated via the Fisherian test of the strong null of no effects (which was  $p = 0.05$ ). Figure 41.6 illustrates all upper  $p$ -values for a test of the weak null over all 20 possible realizations of data when the true effects are as given in Table 41.1.

In this particular case in which the weak null hypothesis is false, we can see that the Neymanian hypothesis test has high power. But in general, Neymanian tests can have bad properties in small experiments, such as a Type I error probability greater than  $\alpha$ . For example, imagine that the weak null hypothesis of no effect were true as is depicted in Table 41.11.

In this hypothetical experiment in which the weak null is true (and the strong null also happens to be true but need not be), Figure 41.7 shows that for some  $\alpha$  levels like  $\alpha = 0.05$ , the type I error probability is greater than the test's  $\alpha$  level (the solid line is above the dotted line). For other  $\alpha$  levels, the

**Table 41.11** Values of  $y_c$ ,  $y_t$  and  $\tau$  when weak null hypothesis is true

$y_c$	$y_t$	$\tau$
22	22	0
8	8	0
11	11	0
15	15	0
18	18	0
1	1	0

type I error probability is less than the  $\alpha$  level (the solid line is below the dotted line), which makes the test at that level a conservative test. In short, although Neymanian hypothesis tests are asymptotically valid, such tests (particularly in small experiments) may yield type I error probabilities that do not fulfill the 'promise' made by a given  $\alpha$  level.

An additional implication of the differences between Neymanian and Fisherian hypothesis tests is that, although the former is consistent,<sup>9</sup> it is not necessarily unbiased in finite contexts,

**Figure 41.7** Distribution of type I error probabilities for different  $\alpha$  levels

even when the Difference-in-Means test statistic is well approximated by a normal distribution. For intuition on this point, note that when the alternative of a larger effect is true and the null of no effects is false, the Difference-in-Means test statistic will yield values that are systematically larger than the values it would produce if the null of no mean effect were true – larger causal effects lead to larger test statistic values. Yet the alternative of a larger effect could be such that when it is true, the *variance estimates* are systematically larger than what the same variance estimates would be if the null were true – e.g., if a positive mean causal effect is caused by a few outliers that react strongly to treatment. Since the  $z$ -score scales the Difference-in-Means test statistics by the variance estimates, the systematically greater variance estimates when the alternative is true could yield *smaller*  $z$ -scores compared to when the null is true. Smaller  $z$ -scores yield larger  $p$ -values; hence, Neymanian hypothesis tests of weak causal hypotheses are not necessarily unbiased in finite contexts, even when the

assumption of normality approximately holds. For more on Fisherian versus Neymanian hypothesis tests, see Ding (2017), as well as the discussion from Aronow and Offer-Westort (2017), Chung (2017), Bailey (2017) and Loh et al. (2017).

Up to this point, we have discussed the role that research design plays in the quality of procedures for causal inference: estimation and testing. To simplify the exposition, we have been referring to situations in which the researcher completely controls and thus knows the research design. We now consider situations the researcher does not control or only partially controls the research design.

### **PARTIALLY CONTROLLED RESEARCH DESIGNS: NON-COMPLIANCE AND ATTRITION**

We refer to designs with imperfect compliance and/or attrition as partially controlled

designs, in that the researcher *does* control the probability distribution on the set of possible assignments but does *not* control whether units actually comply with the assigned treatment or report their outcomes. Causal inferences in such partially controlled designs often require more assumptions to make causal inferences, which are typically defined no longer on the whole study population but a specific stratum of units in the study.

**Non-compliance**

Non-compliance occurs when units who are assigned to receive treatment or control do not actually receive it, where the random variable  $D_i \in \{0,1\}$  is an indicator variable for whether unit  $i$  has received or not received the assigned treatment. We are often substantively interested in the causal effect of actual receipt of treatment and not its mere assignment. Under complete uniform random assignment, we have shown above that the probability  $Z_i = 1$  is identical for all  $i = 1, \dots, N$  units. Yet, we're interested in the causal effect of  $D_i$ , and since  $D_i$  is an outcome of  $Z_i$  (i.e., measured after  $Z_i$ ), the probability that  $D_i = 1$  is not necessarily identical for all units. Hence, a naive estimator of the difference in observed outcomes between those who did and did not receive the treatment (i.e., the per-protocol estimator) is not necessarily unbiased.

Since whether or not units actually receive (or comply with) the treatment is an outcome variable measured after assignment, we can define units' compliance status in terms of their unobservable potential outcomes (Table 41.12).

**Table 41.12 Compliance strata**

$z_i = 0$	$z_i = 1$	Stratum
$d_{c,i} = 1$	$d_{t,i} = 1$	<i>Always Taker</i>
$d_{c,i} = 0$	$d_{t,i} = 1$	<i>Complier</i>
$d_{c,i} = 1$	$d_{t,i} = 0$	<i>Defier</i>
$d_{c,i} = 0$	$d_{t,i} = 0$	<i>Never Taker</i>

Notice that the probability that  $D_i = 1$  for an *Always Taker* is 1 and the probability that  $D_i = 1$  for a *Never Taker* is 0. The only strata within which the probabilities of receiving treatment are identical and on the interval  $(0, 1)$  are *Compliers* and *Defiers*.

Angrist et al. (1996) show that scholars can reliably infer the mean causal effect among *Compliers* under three further assumptions in addition to SUTVA and a uniform probability distribution on the set of assignments,  $\Omega$ , which is sometimes referred to as the exogeneity of the instrument,  $\mathbf{Z}$ . These three assumptions, in addition to SUTVA and uniform random assignment, are:

- 1 Exclusion restriction – i.e., the instrument affects the outcome only through the receipt of treatment.
- 2 No Defiers – i.e., that there are no units for which  $d_{c,i} = 1$  and  $d_{t,i} = 0$ .
- 3 At least one Complier – i.e., there exists at least one unit in the study for which  $d_{c,i} = 0$  and  $d_{t,i} = 1$ .

To see this point, note that one can write the mean causal effect as a sum of the mean causal effects among the four strata (*Always-Takers*, *Compliers*, *Defiers* and *Never-Takers*), weighted by the proportion of units in each stratum:

$$\bar{\tau} = \delta_{AT}\pi_{AT} + \delta_C\pi_C + \delta_D\pi_D + \delta_{NT}\pi_{NT},$$

where  $\delta_s, \pi_s: s \in \{AT, C, D, NT\}$  represent the mean causal effect in each stratum and the proportion of units in that stratum, respectively.

By the exclusion restriction assumption, the causal effect of  $Z$  on  $Y$  must be 0 for *Always Takers* and *Never Takers* (i.e.,  $\delta_{AT} = 0$  and  $\delta_{NT} = 0$ ). By the assumption of no *Defiers*, the proportion of *Defiers*,  $\pi_D$ , is 0. Hence, the mean causal effect among *Compliers* is

$$\bar{\tau} = \delta_C\pi_C$$

$$\frac{\bar{\tau}}{\pi_C} = \delta_C,$$

i.e., the mean causal effect on all units scaled by the proportion of Compliers is equal to the mean causal effect among Compliers.

We showed in the section on unbiasedness that under complete uniform random assignment, the Difference-in-Means estimator is unbiased regardless of the distributions of potential outcomes. Both  $\mathbf{Y}$  and  $\mathbf{D}$  are outcomes of  $\mathbf{Z}$ ; hence, the Difference-in-Means estimators of  $\hat{\tau}(\mathbf{Z}, \mathbf{Y})$  and  $\hat{\tau}(\mathbf{Z}, \mathbf{D})$  unbiasedly estimate  $\bar{\tau}$  and  $\pi_c$ , respectively. The Wald (or IV) estimator (Wald, 1940), which is also sometimes referred to as the Bloom estimator (Bloom, 1984) or the CACE (Complier Average Causal Effect) estimator (Gerber and Green, 2012), is defined as  $\frac{\hat{\tau}(\mathbf{Z}, \mathbf{Y})}{\hat{\tau}(\mathbf{Z}, \mathbf{D})}$ . In

short, it is the ratio of these two unbiased estimators. This ratio estimator consistently, though not necessarily unbiasedly, estimates  $\frac{\bar{\tau}}{\pi_c}$  (see Angrist and Pischke, 2008, chapters 4.6 and 4.7).

A design-based test of the hypothesis of no mean causal effect among *Compliers* is difficult due to the absence of an analytic expression for the variance of the CACE ratio estimator (for more on this topic, see Imbens and Rosenbaum, 2005; Kang et al., 2018). On the other hand, tests of the null hypothesis that the causal effect is 0 for all Compliers is relatively straightforward.

The null hypothesis of no causal effect among Compliers implies the strong null of no effect for all units under the assumptions of the exclusion restriction and no Defiers. Since these two assumptions jointly imply that the individual causal effect is 0 for all Always Takers and Never Takers, and that there are no Defiers, then no causal effect among Compliers implies no causal effect among all units. For example, let's imagine that (like in Table 41.5)  $\mathbf{z}_8$  was the assignment that the researcher happened to randomly

**Table 41.13 Realization of data if  $\mathbf{z}_8$  were the randomly drawn assignment**

$z_8$	$y_c$	$y_t$	$y_8$	$d_8$	$d_c$	$d_t$
1	?	22	22	0	?	0
0	8	?	8	0	0	?
0	11	?	11	0	0	?
1	?	15	15	1	?	1
1	?	18	18	0	?	0
0	1	?	1	1	1	?

draw, except that now we observe the following imperfect compliance, as shown in Table 41.13.

We know that if  $d_{t,i} = 0$ , then, by the no-Defiers assumption, that unit must be a Never Taker, and if  $d_{c,i} = 1$ , then, by the same assumption, that unit must be an Always Taker. We don't know, however, whether a unit  $i$  such that  $z_i = 1$  and  $d_{\{t,i\}} = 1$  is a Complier or Always Taker, and we don't know whether a unit  $i$  such that  $z_i = 0$  and  $d_{\{c,i\}} = 1$  is a Complier or Never Taker. Yet under the null hypothesis of no causal effect among Compliers, the individual causal effect is 0 regardless of whether a given unit is a Complier, Always Taker or Never Taker. Hence, we can fill in missing potential outcomes without knowing those units' compliance strata, as in Table 41.14.

One can now use an effect-increasing test statistic, such as the Difference-in-Means test statistic, to test the hypothesis of no Complier causal effect against either the alternative of a positive Complier causal effect or a negative Complier causal effect. Hansen and Bowers

**Table 41.14 Null potential outcomes for a test of the strong null of no effect if  $\mathbf{z}_8$  were realized assignment**

$z_8$	$y_{c,0,8}$	$y_{t,0,8}$	$y_8$	$d_8$	$d_c$	$d_t$
1	22	22	22	0	0	0
0	8	8	8	0	0	?
0	11	11	11	0	0	?
1	15	15	15	1	?	1
1	18	18	18	0	0	0
0	1	1	1	1	1	1

(2009) present an application of this idea in the context of the one-sided compliance in a cluster-randomized get-out-the-vote campaign with a binary outcome, replacing what would be a complex two-stage logistic multilevel model with a relatively simple Fisherian hypothesis test. Imbens and Rosenbaum (2005) show how the Fisherian approach produces valid confidence intervals, where the Neyman-style approach using two-stage least squares fails to control the type I error probability when the instrument is weak (i.e., there are few Compliers).

Under the assumptions of the exclusion restriction and no Defiers, we do not need to know which units are Compliers in order to assert the hypothesis of no Complier causal effect. However, if one were to posit a hypothesis other than no Complier causal effect, one would also need to posit a hypothesis about which units are Compliers and which are not. Hypothesis testing with imperfect compliance is therefore more complicated when testing hypotheses other than that of no Complier causal effect (for more on Fisherian approaches to instrumental variable analysis, see Kang et al., 2018; Rosenbaum, 1996, among others).

**Attrition or Missing Outcomes**

Our second step away from the ideal case of complete control over the research design is to allow for the possibility of missing outcomes. Let  $r_{t,i}$  be an indicator, i.e.,  $r_{t,i} \in \{0,1\}$ , for whether subject  $i$  would respond to an attempt to measure an outcome if assigned to treatment, and let  $r_{c,i} \in \{0,1\}$  be an indicator for whether subject  $i$  would respond if assigned to control. We can represent whether an individual’s outcomes are missing or not, based on Equation (14):

$$Y_i = \begin{cases} y_{c,i} + [y_{t,i} - y_{c,i}]Z_i & \text{if } R_i = 1 \\ \text{NA} & \text{if } R_i = 0, \end{cases} \quad (14)$$

where  $R_i = Z_i r_{t,i} + (1 - Z_i)r_{c,i}$ .

From Equation (14), we can see that if  $R_i = 1$ , then the researcher will observe  $y_{c,i}$  for unit  $i$  if  $Z_i = 0$  and  $y_{t,i}$  for unit  $i$  if  $Z_i = 1$ . By contrast, if  $R_i = 0$ , then  $Y_i$  will be unobserved – i.e., NA.

We can define four distinct strata of subjects (see Table 41.15) with regard to attrition in order to help us understand how attrition can affect the properties of estimators and hypothesis tests. Just as in the case of imperfect compliance, we can only infer the causal effects on certain subgroups when outcomes are missing (even when assignments are randomized).

In the context of attrition, can we define a set of assumptions, as we did under imperfect compliance, in which estimators and tests satisfy good’ properties on some subset of the experimental data? It turns out that we can only do so if the question of whether a unit attrits or not is independent of treatment assignment. Without further assumptions, we know only that the random variable  $R_i$  is independent of the random variable  $Z_i$  among only *Always Reporters* and *Never Reporters*.<sup>10</sup> Therefore, if we assume that all experimental units belong to one of these two types, then our estimators and tests maintain the properties they should among the set of *Always Reporters*.<sup>11</sup> (We cannot observe outcomes for *Never Reporters* and hence cannot estimate or test hypotheses about causal effects on units that are *Never Reporters*.) On this set of *Always Reporters*, one can estimate causal effects and test strong or weak causal hypotheses, as we did above.

**Table 41.15 Attrition strata**

$Z_i = 0$	$Z_i = 1$	Stratum
$r_{c,i} = 1$	$r_{t,i} = 1$	<i>Always Reporter</i>
$r_{c,i} = 0$	$r_{t,i} = 1$	<i>If Treated Reporter</i>
$r_{c,i} = 1$	$r_{t,i} = 0$	<i>If Untreated Reporter</i>
$r_{c,i} = 0$	$r_{t,i} = 0$	<i>Never Reporter</i>

## UNCONTROLLED RESEARCH DESIGNS: OBSERVATIONAL STUDIES

In this section, we finally relax the assumption that the researcher has control over how the treatment variable is assigned. The key distinction between experimental and observational studies is that in a randomized experiment, the researcher knows the probabilities with which units are *assigned* to treatment and control conditions; however, in an observational study, the researcher observes units only after they have *selected* into study conditions with unknown probabilities. How, then, is one to generate statistical inferences using estimators and tests focusing on causal effects when the probability distribution on the set of assignments,  $\Omega$ , is unknown? A common design-based approach to this problem is to define units' treatment assignment probabilities as an unknown function of a set of baseline covariates. In the ideal (and often unattainable) case, by appropriate conditioning on these baseline covariates, the researcher can estimate and test hypotheses about causal effects via procedures that meet the desirable properties described at the outset of this chapter. Much of the work on observational studies emphasizes appropriate conditioning on baseline covariates, as well as methods to diagnose the success of such conditioning strategies (e.g., Hansen and Bowers, 2008; Hartman and Hidalgo, 2018, among others). Realistically, the design-based approach in observational studies might be called an 'as-if-randomized' approach, e.g., a researcher might make choices about comparison groups such that within a group, treatment selection *appears* random.

The model of an observational study states that units are individually assigned to treatment or control by  $N$  *independent* (but not necessarily *identically distributed*) coin tosses. More specifically, for all

$i \in \{1, \dots, N\}$  units, we let  $\Pr(Z_i = 1)$  be equal to  $\lambda(\mathbf{x}_i)$ , where  $\lambda(\cdot)$  is an unknown function and  $\mathbf{x}_i$  is unit  $i$ 's fixed vector of baseline covariate values. Even if we don't know  $\lambda(\cdot)$ , if  $\mathbf{x}_i = \mathbf{x}_j$  for any two units  $i$  and  $j \neq i$ , then it follows that  $\Pr(Z_i = 1) = \Pr(Z_j = 1)$ . Of course, we still don't know the function  $\lambda(\cdot)$  and hence don't know the actual values of  $\Pr(Z_i = 1)$  and  $\Pr(Z_j = 1)$ ; we know only that these two values are equal. Therefore, if we construct a block,  $b$ , that consists of treatment unit  $i$  and control unit  $j \neq i$  (or vice versa) then each possible assignment within that block has an equal probability of realization. If each possible assignment has an equal probability, then an observational study can be analyzed as if it is a uniform, block randomized experiment (for more on the analysis of block, randomized experiments, see Gerber and Green, 2012, chapter 4). This approach does not directly estimate  $\lambda(\cdot)$ , although there are alternative approaches that do so and subsequently use these estimated values (known as estimated propensity scores) as a basis for inference (see, e.g., Robins et al., 2000).

Scholars can therefore attempt to make an observational study as experiment-like as possible by creating matched blocks on the basis of observed covariates that the researcher believes to determine units' treatment assignment probabilities. A range of matching algorithms exist to improve covariate balance and hence make observational studies like experiments as much as possible (at least on the basis of observed covariates). For more on this topic, see Hansen (2004), Diamond and Sekhon (2013), Sävje et al. (2017) and Zubizarreta (2012), among others. After matching (or some other form of covariance adjustment) and favorable comparisons with randomized designs, researchers then must confront the fact that their observational studies are not randomized studies. This leads directly to the topic of sensitivity analyses.

**SENSITIVITY TO ASSUMPTIONS  
IN UNCONTROLLED RESEARCH  
DESIGNS**

Thus far, we have considered cases in which either the probability distribution on  $\Omega$  is known by random assignment or units' assignment probabilities are a function of only *observed* covariates. But in an observational study, we rarely know – let alone observe – all relevant covariates. We now consider deviations from the assumption that units' assignment probabilities are determined by only observed covariates and subsequently assess how one's inferences would change under violations of this assumption.

A powerful, design-based framework for such a sensitivity analysis is given by Rosenbaum (2002, chapter 4). Before explaining this framework, we need to define a few additional terms. First, the *treatment odds* for unit  $i \in \{1, \dots, N\}$  is  $\frac{\pi_i}{(1 - \pi_i)}$ , which is simply the

$i$ th unit's probability of assignment to treatment divided by that unit's probability of assignment to control. The *treatment odds ratio* for any two units  $i$  and  $j \neq i$  is simply the ratio of the  $i$ th unit's treatment odds and the  $j$ th unit's treatment odds. If units' treatment odds are a function of only observed covariates and the researcher is able to obtain balance on all of these observed covariates, then the treatment odds for units  $i, j \neq i : \mathbf{x}_i = \mathbf{x}_j$  is identical and their treatment odds ratio is 1.

Rosenbaum (2002, chapter 4) considers what happens when units' treatment odds are a function not only of observed covariates,  $\mathbf{x}$ , but also an unobserved covariate,  $\mathbf{u}$ . Under the assumption of a logistic functional form between all units' treatment odds and baseline covariates, as well as the constraint that  $0 \leq u_i \leq 1$  for all  $i$ , one can write the treatment odds of the  $i$ th unit as follows:

$$\frac{\pi_i}{(1 - \pi_i)} = \exp\{\kappa(\mathbf{x}_i) + \gamma u_i\}$$

$$\log\left(\frac{\pi_i}{(1 - \pi_i)}\right) = \kappa(\mathbf{x}_i) + \gamma u_i,$$

where  $\kappa(\cdot)$  is an unknown function and  $\gamma$  is an unknown parameter, and the treatment odds ratio for units  $i$  and  $j$  is  $j \neq i$ :

$$\frac{\left(\frac{\pi_i}{1 - \pi_i}\right)}{\left(\frac{\pi_j}{1 - \pi_j}\right)} = \frac{\exp\{\kappa(\mathbf{x}_i) + \gamma u_i\}}{\exp\{\kappa(\mathbf{x}_j) + \gamma u_j\}}$$

$$= \exp\left\{\left(\kappa(\mathbf{x}_i) + \gamma u_i\right) - \left(\kappa(\mathbf{x}_j) + \gamma u_j\right)\right\}.$$

If  $\mathbf{x}_i = \mathbf{x}_j$ , then  $\kappa(\mathbf{x}_i) = \kappa(\mathbf{x}_j)$  and, hence, the treatment odds ratio is simply:

$$\exp\left\{\gamma(u_i - u_j)\right\}.$$

Since  $u_i, u_j \in [0, 1]$ , the minimum and maximum possible values of  $(u_i - u_j)$  are  $-1$  and  $1$ . Therefore, the minimum and maximum possible values of the treatment odds ratio are  $\exp\{-\gamma\}$  and  $\exp\{\gamma\}$ . After noting that  $\exp\{-\gamma\} = \frac{1}{\exp(\gamma)}$ , we can bound the treatment

odds ratio between  $i$  and  $j$  as follows:

$$\frac{1}{\exp(\gamma)} \leq \frac{\left(\frac{\pi_i}{1 - \pi_i}\right)}{\left(\frac{\pi_j}{1 - \pi_j}\right)} \leq \exp\{\gamma\}. \quad (15)$$

We can denote  $\exp\{\gamma\}$  by  $\Gamma$  and subsequently consider how one's inferences would change for various values of  $\Gamma$ .

For example, let's say that a researcher obtains balance via stratification on all observed covariates – such that the

design closely resembles a uniform, block randomized experiment – and subsequently tests a strong null hypothesis under the assumption that all units’ treatment odds are identical. Now the researcher considers deviations from this assumption. Different assumptions about  $u$  and  $\gamma$  imply differing probabilities of possible assignments, which, as Rosenbaum (2002, chapter 4) shows, can be represented by

$$\Pr(\mathbf{Z} = \mathbf{z}) = \frac{\exp\{\gamma \mathbf{z}' \mathbf{u}\}}{\sum_{\mathbf{z} \in \Omega} \exp\{\gamma \mathbf{z}' \mathbf{u}\}}. \quad (16)$$

To return to the working example from Table 41.1, let’s imagine that the realized assignment was  $\mathbf{z}_8$ , which yielded an observed test statistic of 11.6667 and a  $p$ -value of 0.05 (see Figure 41.3). We calculated that

$p$ -value under the assumption that all units had identical probabilities of assignment. However, in an observational study, it could be the case that the strong null of no effects is true and that there is an unobserved covariate,  $u$ , such that units do not have identical assignment probabilities. A sensitivity analysis permits us to directly assess how our inferences would change under such a scenario. For example, we might first assume that  $\Gamma = 2$ , which implies that  $\gamma = \log(2) \approx 0.6931$ . The quantity  $\gamma$  is the coefficient of a unit’s unobserved baseline covariate  $u_i$ . If all units have the same value of this unobserved covariate — i.e.,  $u_i = u_j$  for all  $i \neq j$  — then all units’ assignment probabilities will remain identical. A conservative approach therefore might instead find a vector  $\mathbf{u}$  that, given a value of  $\gamma$ , will maximize the  $p$ -value of a test

**Figure 41.8** Distributions of Difference-in-Means test statistic under strong null of no effect when  $\mathbf{z}_8$  is the realized assignment under (a) a model where an unobserved covariate has no effect on odds of treatment,  $\Gamma = 1$ , and (b) a model where an observed covariate doubles the odds of treatment,  $\Gamma = 2$ . The dashed lines denote the value of the observed test statistic.

of the strong null hypothesis of no effect. In this particular example,  $\mathbf{u}' = [1\ 0\ 0\ 1\ 1\ 0]$  maximizes the  $p$ -value for an upper one-sided test of the strong null hypothesis of no effect. In general, different procedures exist for finding the vector  $\mathbf{u}$  that maximizes (or minimizes) the  $p$ -value for a given value of  $\Gamma$  (see Gastwirth et al., 2000; Rosenbaum, 2018; Rosenbaum and Krieger, 1990). Figure 41.8 illustrates how the respective null distributions would differ under  $\Gamma = 1$  and  $\Gamma = 2$  in which  $\mathbf{u}' = [1\ 0\ 0\ 1\ 1\ 0]$ .

Notice that under  $\Gamma = 1$  and  $\Gamma = 2$ , the observed test statistic remains fixed at 11.6667. The set of 20 null test statistic also remains fixed for  $\Gamma = 1$  and  $\Gamma = 2$ . The value of  $\Gamma$  changes only the probability associated with each of the null test statistics. As we can see, when  $\Gamma = 1$ , the  $p$ -value is 0.05, but when  $\Gamma = 2$ , the  $p$ -value increases to approximately 0.1270. The researcher is no longer able to reject the strong null of no effect at a level of  $\alpha = 0.10$  when  $\Gamma = 2$  compared to when  $\Gamma = 1$ , and this is one way in which researchers can assess the sensitivity of their inferences to assumptions about the research design.

This approach is not the only way to formalize the impact of the assumptions underlying the ‘as-if randomized’ research designs used for causal inference when researchers have little to no control over the selection process of the main explanatory variable. See also Hosman et al. (2010) for an approach focusing on regression coefficients and regression-based adjustment, as well as an application by Chaudoin et al. (2018) of ideas like these to problems in international relations.

## CONCLUSION

Statistics and research design help us learn about general and abstract social science theory using concrete and specific observations. Observation helps us learn about

theory, but observation occurs using the tools of research design and they are summarized, described and interpreted using the tools of statistics. In fact, we have shown that certain counterfactual causal quantities can never be directly observed, and that our ability to report with confidence about such unobserved causal effects depends heavily on statistical tools, which, in turn, depend on research design for their operation. The persuasiveness of claims about links from an estimate or  $p$ -value to an unobserved causal effect and general theory depends on the clarity of each step. At the most nitty-gritty level, we want our tools to work well – our estimators and tests should err in known and controlled manners and should err rarely.<sup>12</sup> We have asked, ‘How can we know that tools do the work that we want them to do?’ Additionally, we have shown how to use the facts of research design to answer that question and to justify use of these common tools. This means that when we want to persuade an audience that our findings support a given theory (or urge modification of it), we do not need our audiences to believe that (1) we have a random sample from a well-defined population, (2) that the outcome arises from some known probability process (like a normal or zero-inflated Poisson distribution) or (3) that the treatment or selection process relates to background covariates in some known (often linear and additive) fashion. Instead, in a randomized experiment, we ask that a reader believe that our research design correctly describes the physical processes that occurred in the research (a request that is not hard to verify and assess). In an observational study, we ask readers to agree that the as-if randomized approach is reasonable, and we present direct evidence comparing observational designs to randomized experiments in order to make the provisional as-if randomized approach easier to assess.

In explaining reliable procedures, we have used a very simple set of examples.

Our simplifications include the use of only two experimental conditions (treatment and control); yet the general modes of inference described in this chapter can be straightforwardly applied to factorial experiments and other contexts with multiple treatments (see Dasgupta et al., 2015). A second such simplification has been the Stable Unit Treatment Value Assumption (SUTVA) (Cox, 1958; Rubin, 1980, 1986), which, in the case of a binary treatment variable, implies that all units have only two potential outcomes. Yet both estimation (see Aronow and Samii, 2017; Hudgens and Halloran, 2008) and testing (see Bowers et al., 2013, 2016; Rosenbaum, 2007) are possible when units have more than two potential outcomes due to interference between units, for example, in the context of experiments on networks. Furthermore, we have focused on randomized experiments and only briefly pointed to the strategy of ‘as-if randomized’ approaches to estimation and testing in observational studies. We explained that such approaches, when paired with sensitivity analyses, can enable persuasive statistical inferences about causal effects when the researcher lacks control over the design. In other words, once an observational research design compares favorably to the standard of an equivalent experiment (the way that a matched design can be compared to a block-randomized experiment), statistical inference about causal effects can use the same procedures, provisionally justified in the same way, as in a randomized experiment if also followed by a sensitivity analysis.

This focus on the basics – on ensuring that our statistical tools do what they should – leaves larger questions unexplored. For example, some researchers would prefer to make inferences about not only counterfactual causal effects among units in a given study but also about future units in data contexts that differ from the one under study. One might desire unbiased and consistent estimators, as well as valid and powerful

tests, not only based on the research design generating the data collected here and now, but also for unknown future research designs guiding data collection elsewhere and at other times. Forecasting causal effects is an active research area (for only a few recent works on the topic, see Bisbee et al., 2017; Coppock et al., 2018; Dehejia et al., 2019; Pearl, 2015; Stuart et al., 2015). Whether or not a researcher or policy-maker would like a formal forecast of the causal effects of an intervention from one study to a new context (in time, space and/or units), information provided by a single study to the motivating theoretical question still depends on the reliability of the tools used to conduct and analyze the study. We have focused on showing how the reliability of such procedures is based on the research design itself and leave questions about the properties of procedures for forecasting causal effects as a separate, though important, topic.

Design-based causal inference emphasizes inferring a counterfactual quantity, not a quantity in a population or of an outcome-generating model. Such an emphasis arises naturally from a wide range of social science research contexts, such as (1) when units are not a random sample, e.g., when the units are administrative units like schools or countries or convenience samples arising without a known chance process, or (2) when probability models of outcomes – and their structural relationship to explanatory variables – are difficult to write or justify, e.g., when an outcome can be plausibly described by multiple different probability models. In such contexts, simple comparisons based on the research design can advance social science theory and avoid debates about data models. When strong theory generates clear probability and structural models, a model-based justification for statistical inference might be preferred, although we would want this mode of inferences to satisfy the same properties discussed in this chapter: tests should not mislead and estimators

should produce estimates close to the truth. The model-based approach to showing whether these characteristics hold is well described in most statistics textbooks, and we recommend Cox (2006) for an overview.

A general question nevertheless remains: are design-based procedures better or worse than model-based procedures for advancing social science theory or policy learning? Design-based inference is simple, easily interpretable and can ensure that estimators and tests are reliable based on few assumptions, where the assumptions tend to be easily defended in terms of the known features of the research design. But does design-based inference possess reliable properties only for narrowly defined research questions? To be sure, there is nothing intrinsic to design-based inference that requires scholars to use only specific estimators that focus only on specific estimands, such as mean causal effects, or to test only certain hypotheses about no causal effects instead of others. And, although we did not show it here, it is straightforward to assess the properties of non-standard estimators and tests by representing the research design and simulating from it (see Blair et al., 2019, for an example of a framework for simulation based assessment of estimators and tests). For only one example of the flexibility of design-based approaches, imagine that we wondered whether a certain non-linear structural model described well a relationship between a causal driver (like an experimental treatment) and an outcome. In this case, Bowers et al. (2013, 2016) show how the evidence against structural models of unobserved potential outcomes can be generated and hypothesis tests created, i.e., there is nothing about design-based approaches that precludes the use of structural models. That said, a clear difference of means can often teach enough about a complicated structural theory such that there is no need to complicate the research design or statistical inference tasks. In the end, all else equal, reliable procedures advance scientific knowledge

more than unreliable procedures do. For this reason, one of the benefits of engaging with design-based inference is that it brings clarity to the task of judging and choosing our statistical tools and provokes us to directly confront and grapple with the conditions under which evidence can be reliably interpreted as evidence for or against causal claims.

## Notes

- 1 Holland (1986, 947) refers to the inability to observe both potential outcomes for a single unit at the same moment in time as the ‘fundamental problem of causal inference’.
- 2 For simplicity, we consider studies in which there are two conditions – treatment and control – although the same general principles apply to studies with multiple conditions (see Dasgupta et al., 2015).
- 3 To distinguish between fixed quantities and quantities that can take on different values with certain probabilities (i.e., random quantities), we now use uppercase letters for random quantities and lowercase letters for fixed or realized quantities.
- 4 When the numbers of treatment and control units are *not* fixed, such as in simple, individual assignment, the Difference-in-Means estimator remains unbiased in a uniform randomized experiment so long as at least one unit is always in the treatment and control conditions, respectively. In general, when the numbers of treatment and control are *not* fixed, the Difference-in-Means estimator is not necessarily unbiased, such as in cluster uniform random assignment when clusters are of unequal sizes (see Middleton and Aronow, 2015).
- 5 Note that, if treatment assignment probabilities differ *across* blocks (but are uniform *within* blocks), then the standard Difference-in-Means estimator may be biased. In such cases, an unbiased estimator would be the Difference-in-Means estimator that generates an estimate within each block and subsequently weights each block-specific estimate by the proportion of units in that block.
- 6 Recent work has derived a consistent estimator for an upper bound on the term  $2\sigma_{y_c, y_t}$  that is always less than or equal to  $\sigma_{y_c}^2 + \sigma_{y_t}^2$  (Aronow et al., 2014). Such an estimator enables

researchers to more precisely estimate the variance of the Difference-in-Means estimator and, as we will discuss later, increase the power of hypothesis tests about the mean causal effect.

- 7 We use the term 'strong' instead of 'sharp', as used by Fisher (1935), to contrast *strong* null hypotheses with *weak* null hypotheses which we discuss below.
- 8 The expression for a two-sided  $p$ -value,  $p_t = \min\{1, 2\min\{p_u, p_l\}\}$ , comes from Rosenbaum (2010, 33) who states that '[i]n general, if you want a two-sided P-value, compute both one-sided P-values, double the smaller one, and take the minimum of this value and 1'. The rationale is that doubling a one-sided  $p$ -value compensates for, in essence, testing twice.
- 9 We can see this property indirectly from Wu and Ding (2018) and Lin (2013).
- 10 Note that  $R_i$  is independent of  $Z_i$  if and only if the probability that  $R_i$  takes on any value in its sample space does not vary conditional on any value that  $Z_i$  takes on in its sample space – i.e., that  $\Pr(R_i = 1 | Z_i = 1) = \Pr(R_i = 1 | Z_i = 0)$  and  $\Pr(R_i = 0 | Z_i = 1) = \Pr(R_i = 0 | Z_i = 0)$ . The only two types of subjects who satisfy such independence are Always Reporters and Never Reporters.
- 11 Other approaches to estimation and testing relax the assumption that outcome missingness is independent of treatment assignment and devise procedures that bound inferences about treatment effects under best-or worst-case scenarios as they pertain to the true values of missing outcomes, e.g., 'trimming bounds' (Lee, 2009) and 'extreme value bounds' (Manski, 1990).
- 12 We did not assess software packages to implement randomization or sampling nor did we provide much guidance on the choice of which among many possible ways to randomize a treatment or sample from a population. Nevertheless, these topics are also important in the effort to advance theory through observation.

# Statistical Matching with Time-Series Cross-Sectional Data: Magic, Malfeasance, or Something in between?

Richard A. Nielsen<sup>1</sup>

In the beginning, there was history. If scholars of International Relations (henceforth IR) wanted to know why something happened, they consulted history for patterns. Under what conditions did that something happen? What if conditions had been different? What if choices had been different? What if timing had been different?

Then, spurred by a combination of factors, some IR scholars discovered that the field of statistics offered new ways to explore history. By compiling history into databases, wrangling it into numerical matrices, and applying mathematical models, these scholars abstracted away from the fine details to see broad patterns that are difficult for even the most systematic historian to pick out. Historical and statistical modes of inquiry seem entirely different: the data rearranged in unfamiliar ways, the skill sets distinct. Yet, the logic of inference can be surprisingly similar if the language barrier between traditions can be crossed.

Matching is a family of quantitative procedures for creating and analyzing a sample

of cases that differ on one key factor (called a ‘treatment’) and are ‘matched’ to be similar on others. It puts historical counterfactual comparison at the center of statistical analysis, providing one ‘border crossing’ between the historical and statistical traditions in IR.

Matching emerges naturally as the statistical analog to the qualitative tradition of paired case comparison (Tarrow, 2010). In a qualitative study of a puzzling phenomenon, our first move might be to identify a positive case: one in which the outcome of interest happens. We might then try to infer *why* the outcome happened from the historical record by considering possible counterfactual histories: if various factors had been different, would the outcome have been different also?

Relying on subjective intuition about counterfactual histories for a single case can lead us to merely confirm our prior assumptions. Comparison cases provide more objective information for inferring how the positive case might have turned out if some factor had been different. Following the logic of Mill’s

methods of difference, we might seek a comparison case that is similar to our positive case but differs in the factor that we suspect matters most. If our cases are otherwise identical and our theories are deterministic, then this comparison can tell us all we need to know. Any difference between the case outcomes is the causal effect of the differing factor. However, our theories are not usually deterministic and our paired cases rarely match in every respect, so the difference in outcomes could be due to something else. To be more certain that the factor explains the outcome, we might do another comparison, and another, to see if they support the same conclusion. Soon, we have too many pairs of cases to easily summarize qualitatively, so we might give a numerical summary: perhaps the average difference in outcomes across pairs of cases. We have arrived at matching. Typically, an analyst creates a matched sample by trimming down a quantitative data set, but a researcher employing the method of paired comparison could build the same matched sample ‘from the ground up’, as I have just described. The power of matching comes from the properties of the sample, not how the analyst obtains it.

After constructing a matched sample, an analyst typically estimates the causal effect of treatment on the outcome using a regression model. Regression is a method for calculating

correlations that does not, by itself, necessarily produce credible estimates of causal effects. Matching is a method for selecting cases to use in the regression calculation so that the assumptions necessary to infer causation from correlation are more plausible. Matching is case selection for quantitative studies.<sup>2</sup>

In the mid 2000s, matching burst into IR and Political Science in a series of high-profile publications. To chronicle its dramatic rise, I collected a comprehensive list of articles applying matching to IR data in the 12 leading IR journals.<sup>3</sup> Following the first application by Simmons and Hopkins (2005), the number of applications has risen exponentially. In 2017, a record high of 28 articles used matching (see Figure 42.1), and by mid 2018 there were 20, with the year only half-way over (the latest for which I could collect data). Matching now features in at least 10% of the approximately 200 quantitative IR articles published each year.

The rise of matching has been controversial. Proponents tout the benefits for making causal inferences with non-experimental data. Detractors argue that matching is over-hyped as a magic bullet for causal inference, and that it offers unscrupulous researchers another tool to ‘p-hack’ their way to false discoveries (Arceneaux et al., 2006, Arceneaux et al., 2010, Miller, 2019). The time-series cross-sectional (TSCS) data sets common in IR are especially challenging for matching. With little guidance from methodologists, researchers have developed ad hoc approaches to matching with TSCS data, a fact that is equally troubling for the credibility of research findings despite receiving less attention.

The critics are right that matching is not magic. It is helpful for causal inference, but only with strong assumptions. Existing matching methods do not adequately accommodate the complex structure of many IR data sets, and matching does not stop researchers from p-hacking. Like any other method, it can be misused, oversold, and misunderstood. But matching is not just hype either. Matching has proven to be a reliably useful

**Figure 42.1** The number of articles per year using statistical matching in the 12 leading IR journals

method for causal inference with messy, non-experimental data. It belongs in the toolbox of IR scholars.

In this chapter, I introduce matching for readers with no prior experience and weigh its merits and weaknesses in IR applications using time-series cross-sectional data. There are already several excellent introductions to matching (Ho et al., 2007, Sekhon, 2009, Stuart, 2010), which I aim to complement rather than reproduce. I first introduce the philosophy of causal inference underlying matching. I then explain the mechanics of matching that arise from this philosophy. Matching mechanics are not always well-suited to the time-series cross-sectional data structures common in IR, so I discuss the challenges and attempts to surmount them. I conclude by returning briefly to the controversies.

## THE PHILOSOPHY OF MATCHING

Matching rests on a counterfactual approach to causation. A variable  $T$  (for ‘treatment’) is a cause of variable  $Y$  if  $Y$  would have been different had  $T$  been different. Imagine all possible values of  $Y$  for a unit  $i$  and call these the potential outcomes of unit  $i$ . For simplicity, consider the case where  $T$  is a binary indicator for whether the event represented by  $T$  happened ( $T = 1$ ) or not ( $T = 0$ ). The causal effect of  $T$  on  $Y$  for unit  $i$  is the potential outcome when  $T$  is one minus the potential outcome when  $T$  is zero, denoted  $Y_i(T = 1) - Y_i(T = 0)$ .

The fundamental problem of causal inference is that for any unit, we cannot observe both potential outcomes because we cannot re-run history (Holland, 1986). For any causal inference, at least half of the data for our calculation are missing. Thus, we *infer* causal effects rather than *measuring* them; we are always guessing about the counterfactual outcome that we would see if  $T$  were different.

Experimental manipulation is the best way to learn about cause and effect (Bowers and Leavitt, Chapter 41, this *Handbook*). In an

experiment, we randomly assign  $T$  to learn whether it causes changes in  $Y$ . Yet even in an experiment, we cannot observe both potential outcomes for any individual. To impute the missing potential outcomes, most analysts estimate average causal effects over many individuals. With enough units and random assignment of  $T$ , we can average  $Y$  for the  $T = 1$  group and subtract the average of  $Y$  for the  $T = 0$  group to get an unbiased estimate of the average treatment effect (abbreviated ATE). We can write this difference in means estimator as  $\bar{Y}_{\text{treated}} - \bar{Y}_{\text{control}}$ .

Despite efforts to bring experiments into IR (Findley et al., 2013), there are many situations where randomization is impossible, unethical, or both. We are forced to infer cause and effect from an *observational study* using data observed in the natural world. In observational studies, units select their level of treatment or have it assigned to them non-randomly (called ‘selection effects’, ‘endogeneity’, and ‘reverse causality’). This results in *imbalance*: systematic differences between treated and control groups. If selection into treatment is correlated with potential outcomes of  $Y$ , then the average control unit provides a biased estimate of the missing potential outcome for the average treated unit, making the estimator  $\bar{Y}_{\text{treated}} - \bar{Y}_{\text{control}}$  biased as well. These factors that are related to both treatment status and the potential outcomes are called *confounders*, and often denoted with the matrix  $X$ .

Some observational studies feature a natural experiment in which treatment is assigned ‘as if’ randomly by nature for a subset of the data. Even if treatment assignment in the overall data set is correlated with possible confounding variables, comparing the subset of units that received as if random treatment assignment can produce credible causal inferences. Techniques such as instrumental variables (Carter and Dunning, Chapter 40, this *Handbook*) and regression discontinuity designs (Cattaneo et al., Chapter 44, this *Handbook*) facilitate these comparisons, depending on the type of natural experiment that occurred.

Often, there is no natural experiment for a researcher to exploit. The next-best strategy is to compare outcomes for units with similar values of the confounding variables. This is called a *conditioning strategy* because we condition on the values of  $X$  to infer the causal effect of  $T$  on  $Y$ . Matching is a conditioning strategy proposed by Rubin and collaborators in a series of papers starting with Rubin (1973).<sup>4</sup> As developed by Rubin, matching identifies treated and control units that have similar values of the confounding variables  $X$  in a data set and then removes the other units, hoping to approximate the data that would have resulted from a randomized experiment. In this matched sample, the variables in  $X$  are no longer correlated with treatment assignment so we can obtain unbiased estimates of the ATE using the difference in means:  $\bar{Y}_{\text{treated}} - \bar{Y}_{\text{control}}$ .

The core insight of matching is that a subset of data may be useful for credible causal inference, even if all available data are not. However, subsetting the data may limit the inferences a researcher can make. In a natural experiment, only some units have treatment randomized by nature, so the estimated quantity of interest is a *local average treatment effect* for only those units (Imbens, 2009). Analogously, matching only allows credible causal inference for the types of units retained in the matched sample; all other inferences rely on extrapolation. If an analyst's quantity of interest is the *sample average treatment effect* on the treated units (abbreviated SATT), then they cannot discard any treated units. This quantity of interest answers the question 'what would have happened if all treated units in this sample had instead received control?' Answering an alternative question such as 'what if all control units received treatment?' requires a different matching scheme that retains all control units but may discard treated units. Sometimes, an analyst may wish to estimate the SATT, but there are treated units that do not have good matches and discarding them would greatly reduce imbalance. Analysts may discard these treated observations, but their quantity of

interest is now the *feasible sample average treatment effect on the treated* (FSATT): the ATE in the subsample for which causal inference is feasible (King et al., 2017: 475).

## Assumptions

The assumptions necessary for causal inference with a conditioning strategy are stringent. First, we require the *stable unit treatment value assumption*, abbreviated SUTVA, which states that the fixed (but generally unknown) potential outcomes for each unit do not depend on the potential outcomes of the other units. Equivalently, this assumption states that there is no interference between units and no hidden versions of treatment.

Second, conditioning strategies require the assumption of *conditional ignorability*: that after conditioning on the  $X$ , treatment assignment is independent of the potential outcomes. Alternatively, this assumption is called 'selection on observables' or 'no omitted variables'. If unobserved confounders affect both treatment and outcome, conditioning on  $X$  cannot provide unbiased causal estimates. This requires that the analyst know which variables are confounders. Variables that are part of the *assignment mechanism* of  $T$  should be included in  $X$ . The most compelling matching applications carefully theorize the assignment mechanism of  $T$  and then exhaustively measure each variable.

Third, we require *common support*: there must be treated and control units at all levels of  $X$  for which we wish to make inference.

## CONSTRUCTING AND ANALYZING MATCHED SAMPLES

The core activity of matching is constructing a matched sample that plausibly satisfies the assumptions of stable unit treatment values, conditional ignorability, and common support. A *matching algorithm* is the procedure

for constructing a matched sample. Matching algorithms typically identify similar treatment and control units and match them to each other, discarding (or ‘pruning’) unmatched units from the data set. This is equivalent to giving discarded units a weight of zero in subsequent statistical calculations, so a matched sample is merely a reweighted version of an unmatched sample.<sup>5</sup> After constructing a matched sample, the analyst can calculate the effect of treatment by calculating the difference of the (weighted) average outcome of the treated units and the weighted average outcome of the control units ( $\bar{Y}_{\text{treated}} - \bar{Y}_{\text{control}}$ ). Or, the analyst may wish to further adjust via regression (Ho et al., 2007).

Although matching algorithms are the focus of much of the matching literature, from a certain perspective, the algorithm is not very important. What matters is getting the best possible matched sample by whatever means. What is the best possible matched sample? Matched samples are evaluated on two main criteria: the similarity of treated and control units in the sample (called *balance*) and sample size. A larger sample provides more statistical power for estimating precise results. A balanced sample is more likely to satisfy the assumptions of common support and conditional ignorability. These two criteria are in tension because the way to improve balance is to discard observations. Matching is a constrained optimization problem of maximizing balance subject to a sample size constraint (or maximizing sample size subject to a balance constraint).

Assessing sample size is straightforward, but the notion of balance deserves elaboration. When  $X_{\text{treated}} = X_{\text{control}}$ , the data set is unambiguously balanced. However, when  $X_{\text{treated}} \neq X_{\text{control}}$ , there is no universal definition of balance. Various balance metrics have been proposed and each may give different answers. Improvement on one balance metric may not correspond to improvements in other balance metrics. Applied scholars often fixate on justifying their choice of matching algorithm, but they should be more concerned

with justifying their choice of balance metric. As I show below, these are integrally connected, but the prevalence of nonsensical practices in the literature reveals that analysts may not fully appreciate this connection.

Each balance metric offers different answers to two questions: How should differences between  $X_{\text{treated}}$  and  $X_{\text{control}}$  be summarized? And which differences are small enough for a data set to be declared sufficiently balanced? Analysts must inescapably answer these questions by choosing a balance metric, and their choice reflects an implicit set of assumptions about how confounding threatens their inferences.

Analysts who believe that confounding is omnipresent worry that minor differences between  $X_{\text{treated}}$  and  $X_{\text{control}}$  could induce substantial confounding. These analysts prefer balance metrics that are sensitive to small differences in many possible dimensions. Other analysts might be less concerned about confounding from small differences between  $X_{\text{treated}}$  and  $X_{\text{control}}$  and prefer balance metrics that do not capture these small differences.

One set of balance metrics focus on the discrepancies between pairs (or groups) of treated and control units. The *Average Mahalanobis Imbalance* metric uses the average of the pairwise Mahalanobis distance<sup>6</sup> from each unit to the nearest unit of the opposite treatment status (King et al., 2017: 479). The *L1 Imbalance* metric is a discretized version of the same idea. The analyst selects a multivariate histogram binning, calculates the difference in the frequency of treated and control units in each bin, and averages over the bins of the histogram (King et al., 2017: 479). For both metrics, larger values indicate more imbalance. These discrepancy-based balance metrics are sensitive to small differences in many possible dimensions. Both of them have the highly desirable ability to detect an exactly matched subset of observations if such a subset exists. However, they offer no definitive threshold for declaring a data set ‘balanced’ short of zero difference ( $X_{\text{treated}} = X_{\text{control}}$ ).

An alternative style of balance metrics uses statistical tests to detect differences between  $X_{\text{treated}}$  and  $X_{\text{control}}$ . Some analysts calculate the difference in means of the covariates in  $X$  and declare the data set balanced if variable-by-variable t-tests fail to reject the null hypotheses that the means are the same. Some analysts prefer Kolmogorov–Smirnov tests for the difference in distributions to t-tests. Hansen and Bowers (2008) propose a global p-value for a test that the combined dimensions of  $X$  are detectably different from each other. The metrics rely on widely recognized significance thresholds for declaring a data set sufficiently balanced, even if  $X_{\text{treated}} \neq X_{\text{control}}$ . Unfortunately, hypothesis testing depends on the sample size, so ‘balance’ may be achieved once enough observations are removed whether the remaining observations in the matched sample are actually similar or not (Stuart, 2010). Also, optimizing these metrics will not reliably uncover an exactly matched subsample, even if one exists.

In addition to these formal approaches, analysts also inspect balance by plotting the difference in means between treated and control groups for each covariate before and after matching (akin to the variable-by-variable t-tests, but without a test).

### **Matching Algorithms**

It does not matter how one constructs a matched sample with sufficient balance and sample size. In theory, analysts could directly optimize their preferred balance metric subject to a sample size constraint. In practice, this is usually not possible because the optimization problem is intractable, though it can be done for some balance metrics (King et al., 2017). One could attempt brute-force optimization by randomly sampling all possible subsets of the data and finding the sufficiently sized subset with the best balance. However, this is infeasible for most data sets because the number of possible combinations is too large. Instead, analysts turn to

matching algorithms that dramatically reduce the time necessary to construct candidate matched samples and select the best one.

Ideally, matches should be exact: each treated unit paired to a control unit (or units) with identical values of all confounding pre-treatment covariates. Exact matches can be identified by checking whether each treated unit has a matching control unit with identical values of  $X$  (using, for example, the MatchIt library in R).

In most data sets, exact matching leaves too few observations for precise estimation in the subsequent statistical analysis. With continuous covariates, exact matches are unlikely to exist at all. Approximate matching methods offer a way to identify matched subsets of the data that plausibly satisfy the three key assumptions above, even if the treated and control units are not exactly matched.

Each approximate matching algorithm deals with the problem of inexact matches by explicitly or implicitly constructing a distance metric from each treated unit to each control unit and then attempting to identify a matched sample of sufficient size that minimizes that distance metric.

There is no established ‘best’ matching algorithm. Because each algorithm has a different distance metric, each is optimizing a different implied balance metric, and each potentially finds different matched samples. Standard practice is to match with one algorithm and then check balance with one or more metrics *not* implied by that algorithm. If one is lucky, optimizing the balance metric implied by the algorithm will lead to improvements with respect to other balance metrics. In this happy circumstance, the choice of balance metric does not matter much because they all move together.

However, in many cases, a matching algorithm does not lead to notable improvements on all balance metrics. Standard practice in this situation is to change the tuning parameters of the algorithm, rematch, and check balance again, repeating until balance on various balance metrics is satisfactory. More generally,

analysts often match using a method that minimizes one metric, and then evaluate balance by checking another metric. This is a strange form of indirect optimization. If balance on one metric is really the target, then iteratively optimizing it using hit-or-miss trials from an unrelated matching algorithm seems nonsensical. One justification might be that some balance metrics cannot be directly optimized, but even so, the standard practice of checking balance and manually adjusting the algorithm after each iteration of is inefficient.

Instead, analysts who cannot find exactly matched observations within their data sets must make a philosophical commitment to a particular balance metric and, if possible, chose a matching algorithm that optimizes it. Checking whether matching improves alternative balance metrics may be revealing about the sensitivity of matches to the choice of balance metric, but it is not dispositive about whether the data set is balanced. When two balance metrics diverge meaningfully, there is no way to optimize both at the same time. The choice of one over the other is philosophical.

There is a long and growing list of matching techniques.<sup>7</sup> I'll review the key families of algorithms which are the foundation for many, though not all, of the options available.

### ***Mahalanobis Distance Matching (MDM)***

The first matching approach proposed by Rubin (1980) matches treated and control units based on continuous distances from each other in the  $k$ -dimensional space defined by the  $k$  covariates in  $X$ . The basic matching machinery works for any continuous distance metric: First, calculate the distance from each treated unit to each control unit. Then, form matches by selecting the closest control observation to each treated observation. Finally, discard the unmatched control observations. Methodologists prefer Mahalanobis distance (Euclidian distance normalized by the covariance matrix) because it accounts for

correlations between the variables and makes them unit-less and scale-invariant. In order to avoid matched pairs that are not adequately similar, analysts often use a *caliper*: a defined maximum distance for a match. If a treated unit does not have a matching control unit within the specified caliper, it is discarded and the quantity of interest shifts from the SATT to the FSATT.

### ***Propensity Score Matching (PSM)***

Rubin and Rosenbaum (1983) introduce the *propensity score*, defined as the probability that unit  $i$  receives treatment, conditional on  $X$ . They show that the propensity score is a sufficient statistic for  $X$ ; all of the information about  $X$  necessary to make the potential outcomes independent of treatment is contained in this score. Assuming conditional ignorability, matching units exactly on their true propensity scores results in unbiased estimates, even if  $X_{\text{treated}} \neq X_{\text{control}}$ . The true propensity score is usually unknown, so we must estimate it – typically with predicted values from a logistic regression predicting treatment as a function of  $X$ . We then match treated and control units using the similarity of their propensity scores. Again, analysts often define calipers. A common rule of thumb is that observations should be within 0.25 of a standard deviation of the propensity scores to match (Rosenbaum and Rubin, 1985: 114; but see King and Nielsen, 2019).

The theory underlying PSM is elegant and intuitive, but it requires exact matches on the true propensity score. In practice, we typically must make do with inexact matches on estimated propensity scores, and this can sometimes make causal inferences worse, rather than better (King and Nielsen, 2019). Several methods combine information from the propensity score and some other covariate information (Diamond and Sekhon, 2013; Imai and Ratkovic, 2014), and these methods side-step the problem.

There are a host of complications that can be vexing for both MDM and PSM.

Methodologists assume a large pool of control observations from which to match (Rubin and Thomas, 1996), but this is not the case in many IR settings. Also, the same control might be the best available match for multiple treated units. Which should get it? Optimal matching (Rosenbaum, 1989), optimal full matching (Hansen, 2004), and optimal cardinality matching (Zubizarreta et al., 2014) are promising solutions that improve global balance as well as local balance.

### ***Coarsened Exact Matching (CEM)***

Coarsened exact matching is an extension of exact matching methods to situations where exact matches are not possible (Iacus et al., 2012) and is the most popular example of a class of matching methods that are monotonically imbalance bounding (Iacus et al., 2011). Monotonically imbalance bounding methods set a fixed bound on the imbalance that the analyst will permit and achieve that balance, though often at the expense of matched sample size.

CEM ‘coarsens’ each variable into categories that are less restrictive than the measured values. For example, if the democracy level of country is measured on a 21 point scale, as in the Polity IV scores (Marshall et al., 2002), we might coarsen this variable into five categories based on the scores: strongly democratic, leaning democratic, inchoate, leaning autocratic, and strongly autocratic. Then, we match units that fall in the same category, rather than requiring that matches have exactly the same score. Observations that do not have matches, both treated and control, are discarded, and the remaining observations are reweighted to account for the fact that matches may not be one-to-one. Then, the analyst ‘uncoarsens’ the data and estimates causal effects using weighted least squares on the matched data set.

### ***The Matching Frontier***

A new class of approaches seeks to improve inferences with each of the prior methods by

introducing the ‘matching frontier’ – a set of matched samples that are optimal according to the balance metric they maximize (King et al., 2017). Users of MDM and PSM often use *calipers*, which define the maximum allowable distance between a treated and control match. A stricter caliper will result in a smaller, but more balanced, matched sample. Analysts also tend to create one-to-one matched samples out of convenience. However, if more than one control unit is a good match for a treated unit, arbitrarily limiting the number of matches decreases the sample size and decreases the precision of causal estimates without removing bias.

The matching frontier generalizes the idea of a caliper and allows many-to-many matching. The frontier is defined by matched samples of various sizes, from  $n = N$  (the full unmatched sample) down to  $n = 2$  (the closest matching pair). At each possible sample size  $n$  between

$N$  and 2, there are  $\binom{N}{n}$  possible matched

samples. The frontier finds the optimal one for each  $n$ , resulting in a series of optimal matched samples of various sizes.

This continuum of matched samples defines the trade-off between bias and variance. Matched samples that discard all but a few extremely close matches will reduce bias the most but may lack the statistical power to precisely estimate effects. On the other end, those that retain most of the original sample will usually result in more precise estimates, but there may be more bias because the observations are less similar to each other. Any matching solution that is not on this frontier is suboptimal: there is an achievable matched sample that has either more observations or better balance.

Calculating matching frontiers for arbitrary balance metrics is hard because the number of possible matched samples for real-life data sets is extremely large. King et al. (2017) develop fast algorithms that calculate the matching frontier for MDM, PSM, and CEM-style methods.

### ***Categorical and Continuous Treatments***

All of these algorithms struggle to accommodate categorical and continuous treatment variables. The problem is philosophical as well as technical. As the number of treatment levels increases, so does the number of counterfactual questions we must answer to describe what would have happened to a given unit if it received each alternative treatment level. One possibility is to construct a matched sample for each possible treatment contrast, but this is difficult if each level of treatment is only assigned to a few observations. With a truly continuous treatment variable, each unit receives a unique level of treatment, so constructing a matched sample for each treatment level is impossible. Instead, methodologists have proposed matching methods that effectively consider similar levels of treatment to be equivalent (Imai and Van Dyk, 2004; Hirano and Imbens, 2004).

Regression appears to side-step this challenge, effortlessly estimating effects of categorical and continuous treatments. In fact, regression faces the same challenge but limits the analyst's ability to diagnose it; regression automatically fits a hyperplane that extrapolates between treatment levels while obscuring the fact that this extrapolation may be based on very little data at any single treatment level. Matching calls attention to the true degree of difficulty in making credible causal inferences when there are many versions of treatment.

### ***Inference***

After matching, analysts typically calculate their desired treatment effect by fitting a parametric regression model predicting  $Y$  as a function of  $T$ , possibly controlling for variables in  $X$  if matching was inexact. If the assumptions hold, this results in an unbiased estimate. But analysts are almost always interested in testing whether this estimate is statistically different from some null hypothesis

(typically that treatment has no effect). This requires estimates of the uncertainty surrounding an effect estimated via matching and there is substantial debate in the literature about how to do so.

Because it is convenient, the standard practice among practitioners is to report the standard errors from regression analysis as measures of uncertainty for the treatment effect. Methodologists worry that these standard errors do not account for the uncertainty of the matching procedure. Abadie and Imbens (2008) show that naive bootstrap standard errors are not asymptotically valid and propose a correction, though recent work proposes an asymptotically valid bootstrap (Otsu and Rai, 2017). Others propose algorithm-specific approaches such as a Bayesian estimate incorporating the uncertainty inherent in estimating propensity scores (An, 2010). However, Iacus et al. (2019) argue that these concerns are misplaced; if analysts are willing to change their axioms about sampling, then unaltered regression standard errors are correct.

One especially clever approach to justifying measures of effect size uncertainty comes from Imai and Kim (2019). They demonstrate an equivalence between linear models with unit fixed effects and a class of within-unit matching schemes. From this equivalence, they are able to show that accepted model-based standard errors are valid, without resorting to the more computationally intensive proposed alternatives. While this equivalence approach currently only applies to an uncommon subclass of matching approaches, it might be extensible.

### ***Comparison to Regression***

Regression is an alternative approach to conditioning on  $X$  that has a much longer history of use in IR. Regression conditions on  $X$  by calculating smooth hyperplanes that summarize the central tendency of the data at all levels of the variables in the regression.

To make causal inference, a researcher simply compares the average distance between the conditional central tendency for the treated units and the conditional central tendency of the control units. Regression without matching works well for causal inference if the assumptions listed above hold, and if the regression hyperplanes accurately reflect the central tendency of  $X$  – in other words, if the model fits well. However, matching offers several advantages over traditional regression.

Benefit 1: matching automatically conditions on complex interactions between covariates. Linear regression can do this in principle, but in practice, most applied researchers specify linear, non-interactive regression models and only check model fit haphazardly. In a balanced matched sample, treatment effect estimates are not dependent on whether the analyst includes interactions and nonlinear terms in a subsequent regression (Ho et al., 2007).

Benefit 2: matching identifies and corrects issues of ‘common support’, where some subset of treated or control units is so dissimilar from any units with other treatments that any inference about the outcomes of these units is determined almost entirely by modeling assumptions rather than data. Matching also draws attention to the related challenge of estimating the effects of categorical and continuous treatments. Linear regression obscures these challenges.

Benefit 3: analysts have intuitions about cases, but regression makes it difficult for analysts to tell which cases are really being compared. Analysts can examine matched cases to directly assess the quality of their counterfactual comparisons.

## **MATCHING WITH TIME-SERIES CROSS-SECTIONAL DATA**

IR researchers frequently use time-series cross-sectional (TSCS) data to estimate causal effects. With the exception of a few

working papers (Nielsen and Sheffield, 2009, Imai et al., 2020), there has been very little attention to TSCS data in the matching literature, leaving applied researchers with few guidelines. My survey of the applied matching literature in IR shows that 65% of IR articles that use matching use it on TSCS data, but only half of these do anything to account for the structure of the data, and few analysts defend their choices.

In this section, I explain the challenges of matching with TSCS data and describe current best practices. This is an area of active research (Imai et al., 2020), so future scholarship may offer amendments and improvements to the approach I endorse here.

To match TSCS data, IR scholars must be attentive to their unit of analysis. Outside of IR, matching is typically applied to cross-sectional data, in which each row in a data matrix records information about a single unit (e.g., a patient in a medical study). Analysts generally assume that these units are independent, so each row of the matrix is exchangeable. If this assumption holds, then every treated unit may be matched to any control unit without fear of violating the stable unit treatment value assumption or the assumption of conditional ignorability. Virtually all matching algorithms have been designed to take the data matrix provided by the analyst and match each treated row to the nearest available control row without constraint. In this setting, each row of the data set matches the analyst’s conceptual unit of analysis.

TSCS data are typically formatted in a ‘long’ format matrix where each column is a variable and each row contains information about a given unit in a given time period, such as a country-year. These rows are no longer plausibly independent observations. Repeated observations of the same unit are probably correlated, as are observations of different units in the same time period. Applying standard matching algorithms to these data sets often results in matches that are likely to be dependent (e.g., if the country of Ghana received a treatment in the year

2005, the row of the data matrix with the most similar  $X$  values is likely to be Ghana in 2004). This is not necessarily bad. In fact, Imai and Kim (2019) show that estimates from a within-unit matched sample are equivalent to a popular fixed effects model. Generally, however, if countries (rather than country-years) are the analyst's unit of analysis, then I advise modifying the TSCS data matrix to correspond. For most TSCS matching applications, the fix is simple: transform the data matrix from 'long' to 'wide' format and then perform matching.

The cross-sectional data sets used in traditional matching applications can be thought of as TSCS data sets in 'wide' format with only two time-periods: pre-treatment (covariates) and post-treatment (outcome). Extending matching methods to data sets with a longer pre-treatment time-series component merely requires appending this information in the right way.<sup>8</sup> Each prior time period simply adds to the available set of covariates on which to match treated and control units. Rather than representing this additional time-period with a new row in the data matrix  $X$ , represent it with a new column. Similarly, lagged values of the outcome variable should be represented as additional columns on the data matrix.

Analysts may be interested in long-range outcomes. If so, long-range measurements of the outcome variable should be included in a single row as well. However, analysts should not adjust for post-treatment covariates that might affect the outcome, because they might also be a result of treatment, and would then bias the estimated treatment effect. The difficulty of adjusting for post-treatment confounding means that inferences about immediate outcomes will be much more precise than inferences about long-range outcomes.

Several complications remain. First, should TSCS matching include every observed lag of every covariate? Can units provide multiple observations? And if so, how should treatment and control units be defined? Finally, should

analysts remain concerned about interference between units inducing SUTVA violations? I discuss each of these issues in turn.

### ***Should Matching Include Every Lag of Every Covariate?***

With a TSCS set in 'wide' format, analysts will suddenly feel that they have 'lost' most of their data because they have exchanged a data matrix with many rows and few columns for one with few rows and many columns. This 'loss' is illusory; the ' $N$ ' of the data matrix in 'long' format gives a highly inflated sense of the effective number of observations. The 'wide' data matrix encodes the same information but reflects dependencies between repeated observations of the same unit.

With TSCS data in 'wide' format, the analyst may have more variables than observations. Suppose they observe 180 countries over, say, 74 years since the end of World War II and wish to 'control for' 20 variables (e.g., GDP, Democracy, Trade). Structured as country-years, the  $X$  matrix would have 13,320 observations and 20 variables, but when reformatted to be 'wide', the same data set now has 180 observations and 1,480 variables (e.g.,  $GDP_{1946}, \dots, GDP_{2019}; Democracy_{1946}, \dots, Democracy_{2019}; Trade_{1946}, \dots, Trade_{2019}$ ). Most matching methods fail when the number of covariates exceeds the number of observations (Roberts et al., forthcoming).

If a country receives treatment in 2015, does the analyst really need to consider each observation of each control variable back to the end of World War II? Probably not. Determining how many lags of a given covariate to use depends on how treatment is assigned. Analysts should choose the smallest set of lags that ensures conditional ignorability. Ideally, theory and prior evidence should guide this choice, but they are rarely precise enough to dictate whether  $democracy_{t-4}$  is a confounder after including  $democracy_{t-1}$ ,  $democracy_{t-2}$ , and  $democracy_{t-3}$ . Without strong theory to guide the choice about lags,

analysts can reasonably turn to heuristics. For example, if the analyst assumes that treatment assignment is largely a function of recent events, she might match placing greater weight on the recent past while still placing a small weight on the distant past (see Nielsen, 2016: 588 for an example).

One practical reason to omit unnecessary lags is that some are likely to be missing. Analysts can impute these missing values, but it complicates matching (D'Agostino Jr and Rubin, 2000). If treatment assignment is not a function of these missing lags, then avoid the complication.

### ***Can Units Provide Multiple Observations?***

Considering each row of a 'long' TSCS data set as an independent observation dramatically overstates the amount of information the data contain. But transforming it to 'wide' format implicitly assumes that repeated observations are completely dependent, which is probably too conservative. There is often independent information in repeated observations of each unit that could be exploited.

This motivates some IR scholars to use a different unit of analysis – the country-block (see, for example, Simmons and Hopkins, 2005; Hollyer and Rosendorff, 2012; Nielsen and Simmons, 2015). The analyst selects a number of  $l$  lags which they consider to be sufficient for conditional ignorability on all variables, and a number of  $m$  post-treatment periods for measuring the outcome. Each treatment block is defined by the  $l$  time-period observations before treatment and the  $m$  time periods after. Control units are also divided into blocks of  $l+m$  consecutive observation periods. If the analyst wishes to match exactly on time, then time subscripts of treated and control blocks must match. If exactly matching time is unnecessary, then treated blocks can match control blocks with different time subscripts, greatly increasing the number of available controls. Each unit

that never receives treatment can potentially offer multiple control blocks, rather than one. Additional control blocks can come from the pre-treatment life histories of units that eventually get treatment. In some IR data sets, almost every unit eventually receives treatment, so drawing from the pre-treatment histories is the only source of control blocks.

Approximately 15% of the TSCS matching papers in IR have landed on this strategy, including the pioneering paper of Simmons and Hopkins (2005). Simmons and Hopkins use the following procedure: first, for each treated unit, they drop all lags except for the four years prior to treatment, the year of treatment, and the year after. They divide the control units into blocks of six consecutive observations, using both countries that never receive treatment and countries that receive treatment later. They then average the lagged covariates over the first four years of both treated and control blocks, and do a propensity score matching with these averages, reporting improvements in balance and, presumably, a reduction in bias.

### ***The Potential for Violations of SUTVA***

Many applications in international relations and comparative politics are likely to violate the stable unit treatment value assumption (SUTVA). This is not a problem induced by matching; matching merely illuminates a problem that standard TSCS regression techniques often overlook.

One obvious violation of SUTVA arises from the dependence between repeated observations of the same unit that I have just discussed; there may be 'interference' between the observations. Causal inference with regression requires the same SUTVA assumptions as causal inference with matching, so it is puzzling that IR scholars sometimes wring their hands about matching repeated observations of the same unit to each other but then blithely throw them all

into a pooled regression. If pooled matching makes the analyst uncomfortable, then pooled regression is inappropriate. Matching TSCS data in the ‘wide’ format avoids the problem of dependence within repeated observation of a single unit, but interactions between units also threaten to violate SUTVA. Unlike a medical study in which subjects can be isolated, it is not generally reasonable to assume that there is no interference between units in the international system. There is currently no widely accepted solution to this problem, though causal inference under networked interference is an active area of research (Aronow and Samii, 2017).

Hidden versions of treatment are another major source of SUTVA violations. Common TSCS practices for estimating the effects of ‘sticky’ treatments can inadvertently create hidden versions of treatment. For example, when estimating the effect of a binary democracy variable on an outcome like trade flows, researchers typically estimate a model that compares each observed year of democracy to each year of non-democracy. However, the first year of democracy after democratization may not be equivalent to a year of mature democracy many years after democratization. Conceptualizing the treatment variable as a *transition to treatment* and using countries, rather than country-years, as the unit of analysis avoids this problem.

SUTVA is a strong assumption that may not be plausible in many TSCS applications. If so, TSCS matching will still mitigate model specification dependence but the results should probably not be interpreted causally. There has been very little research exploring when and how violations of SUTVA are problematic and methods for proceeding without SUTVA are in their infancy (Tchetgen Tchetgen and Vanderweele, 2012). The standard practice for applied researchers facing possible SUTVA violations is to simply proceed as if they did not exist. Rather than ignoring SUTVA violations entirely, first order violations of SUTVA may be avoided by following the advice above.

## ***Estimation after Matching***

What should analysts do after creating a matched TSCS sample? Following Ho et al. (2007), analysts may be able to proceed with the model they would have used on unmatched data. The data may need to be transformed back into ‘long’ format for use with popular TSCS model software. However, analysts may realize in the course of matching that the pooled regression they initially wanted to estimate probably violates the assumptions above.

If so, a reasonable approach is to estimate treatment effects using the difference-in-differences estimator (Keele, Chapter 43, this *Handbook*). This estimator assumes that the units observed have parallel over-time trajectories prior to treatment. If so, differences in the differences of their outcome trajectories after treatment of some panels are the effect of treatment (hence the name). However, it is difficult to find settings where the parallel trends assumption is plausible. Heckman et al. (1997) have suggested that researchers use matching to select units with similar trends prior to difference-in-differences estimation. The TSCS matching methods outlined above and in Imai et al. (2020) offer a way to perform this matching.

## **MATCH OR MISMATCH?**

Will matching help me get better, more reliable answers to my research questions? This is a crucial question for any International Relations scholar considering using statistical matching in their work. With over a decade of matching under our belts, we can step back and evaluate its usefulness for IR. Potential criticism comes in two varieties: matching is generally problematic, and matching is especially problematic when applied to the TSCS data sets common in IR.

To review, matching is a method for selecting cases to use in a subsequent statistical analysis. A matched sample is fully characterized by a data matrix of cases and a set of

weights (generally derived from a matching algorithm) for each case. Observations with weights of zero are considered ‘pruned’ from the data set, resulting in a data set that is more ‘balanced’ than the original (meaning treated and control observations are more similar on a set of possible confounders represented by  $X$ ). Once a matched sample is in hand, a researcher can typically use any appropriate regression technique to analyze the data without much modification.

As Geddes (1990) reminds us, the cases we choose affect the results we get. Because matching is case selection based on  $X$ , calculations based on the matched sample are conditional on  $X$  whether the subsequent estimation is explicitly conditional or not. This means that matching ‘controls’ for  $X$  in ways similar to regression, with added flexibility for interactions and ensuring common support. It also means that statistical results from matched data will depend less on which specific regression model an analyst chooses than results from unmatched data (Ho et al., 2007).

Critics of matching warn that it can produce misleading results (Arceneaux et al., 2006) and facilitate false discovery through p-hacking (Miller, 2019). At seminars and conferences, I have seen critics scold matching advocates for overstating the benefits (and benefiting professionally from those overstatements!). It is fair to say that some proponents of matching (including myself) have at times been overly sanguine about the method, though the same could be said for virtually every statistical technique. Perceptions that researchers benefit professionally from applying matching in their research are also probably correct. Using the data set of IR articles I described above, I estimate that articles using matching have gotten ten more citations on average than comparable articles that did not use matching.<sup>9</sup> It is worth asking whether this additional attention is warranted.

The critics have a point. Matching is not a statistical truth serum to extract causal information from even the most recalcitrant data sets. There is no secret ‘causality’ sauce in

the inner workings of matching methods. Matching is for researchers who want to make causal inferences, but it won’t necessarily allow them to do so. Matching cannot transform your unruly data into a neat and tidy experimental study. Moreover, existing matching methods have been used in an off-the-shelf manner not appropriate for the TSCS structure of many IR data sets. And it is unlikely that matching alleviates the risk of fishing for desired results despite early optimism on this score. Now that a decade has passed, my sense is that the critics of matching have successfully tempered these overly-optimistic claims about what matching can do.

Matching is not magic, but it is not all hype either. The upside of matching is that it is likely to help you understand your data better and make clear to you and your readers what assumptions underlie your conclusions. Fitting a good regression model for causal inference can be very hard, and bad regression models abound. My experience is that matching makes the assumptions necessary for reliable causal inference more transparent to researchers. The intuition of matching is easier for many people than the intuition of regression, and understanding the intuition can help analysts avoid pitfalls. Matching has proven to be a reliably useful method for causal inference with messy, non-experimental data, precisely the sort that most of us in IR are used to dealing with. Although conditioning with regression can get the same result as conditioning with matching, I generally find that someone using matching is going to have a better sense for whether the counterfactuals implied by their model make any sense.

Yet, even if matching is useful for cross-sectional data analysis, it may be that the dependencies of time-series cross-sectional data are too challenging for existing matching methods to tackle. I acknowledge that the challenges are formidable. It is difficult to confidently assert that the stable unit treatment value assumption and conditional ignorability have been satisfied in any

cross-national comparison study. However, these assumptions are necessary for making credible causal inferences from regressions analysis without matching. Experiments are currently infeasible for many pressing IR questions and genuine natural experiments are rare. This leaves us with the necessity of extracting the most credible inferences we can from the observational data provided by history. Matching offers a transparent, useful framework for doing so while foregrounding the challenges.

So, where does this leave us? Matching is here to stay and rightfully belongs in the tool kit of IR scholars. It is no silver bullet. Like any other method, it can be misused, oversold, and misunderstood. It should not be, if we care about learning the truth about international relations.

## Notes

- 1 Department of Political Science, MIT. Eliza Riley provided research assistance. Luigi Curini, Elizabeth Dekeyser, Rob Franzese, Kosuke Imai, In Song Kim, Kacie Miura, and Eliza Riley generously gave advice.
- 2 Matching is also useful as a case selection strategy for some qualitative studies. See Nielsen (2016) for explanation and Weeks (2018) for an example. However, my focus in this chapter is on matching for statistical inference.
- 3 I consider IR data to include either an international predictor variable, an international outcome variable, or both. I use the TRIP article database (Teaching, Research, and International Policy Project, 2017; Maliniak et al, 2018) to identify IR articles in 12 journals: APSR, AJPS, BJPS, JOP, IO, IS, ISQ, WP, SS, JCR, JPR, and EJIR. Using several methods for searching, I find 124 articles that use matching. A full list is in the online supplemental information.
- 4 These papers are collected into one volume in Rubin (2006).
- 5 Some matching algorithms also give units non-integer weights, which can be thought of as ‘partial inclusion’ in the matched sample.
- 6 Mahalanobis distance is a generalization of Euclidean distance that is unit-less, scale-invariant, and accounts for correlated variables.
- 7 See the online supplemental information for a list with citations.

- 8 There are many complicated issues involved with making causal inferences about time-varying (dynamic) treatments and treatment regimes (Murphy et al., 2001). But most IR scholars using matching have worked with static treatments, so I focus on how to extend the standard matching apparatus for static treatments to TSCS data.
- 9 See the online Supplemental Information (Nielsen, 2019) at <https://doi.org/10.7910/DVN/HEFNHA>.

# Differences-in-Differences: Neither Natural nor an Experiment

Luke Keele

## INTRODUCTION

When analysts seek to estimate causal effects, one of the most commonly used tools is differences-in-differences (DID). Widespread use of DID is most likely a result of two factors. One is that there are many cases where the method can be used. That is, it can be used in any context where before and after data exist for treated and control groups. Moreover, estimation can be done with linear regression models and, as such, no special software or programming is necessary. Another reason DID is widely employed is that many investigators assume that if one can apply DID, then the analysis tends to be classified as a type of natural experiment. Evidence from natural experiments is now widely viewed as the best alternative to evidence from randomized trials. As such, social scientists are often urged to identify a natural experiment when randomization is not possible (Angrist and Pischke, 2010). Research that can be classified as a natural experiment

is often imbued with a sense of greater credibility. Given that DID is often classified as a type of a natural experiment, I would argue this has given the method wider popularity.

In this essay, I highlight several issues in the use of DID. I specifically focus on whether an application that uses DID should be classified as a natural experiment. I argue that use of DID does not imply that one is analyzing a natural experiment. DID can be applied to any application with the right data configuration, and that configuration of the data does not imply that the treatment assignment mechanism is as-if randomized, which is the hallmark of a natural experiment. While DID can be readily applied to settings that are natural experiments, it is often applied to contexts where nothing about the treatment assignment mechanism implies a natural experiment. Next, I demonstrate that while DID protects against a specific form of bias, there are also instances where the use of DID may increase the bias in treatment effect estimates compared with a more basic

treatment and control comparison. Turning to estimation, I describe a specific form of matching that can be used as an alternative to linear regression models. Finally, I present an empirical example to demonstrate concepts. In the example, I use data on the introduction of election day registration in the state of Wisconsin. This essay is not, however, a tutorial on DID for readers hoping to learn the method for the first time. Readers interested in basic introduction to DID should see Angrist and Pischke (2009: ch. 5). Readers interested in a complete review of estimation methods for DID should see Lechner (2011).

## NOTATION AND METHOD

Here, I outline notation for the basic DID framework following the notation in Abadie (2005). In this framework, we observe data at the individual level for at least two time periods. For each unit  $i$  at time  $t$ , we denote the outcome as  $Y(i, t)$ , where  $t = 0$  for the pre-treatment time period and  $t = 1$  for the post-treatment time period. Some fraction of the units are exposed to a treatment between  $t = 0$  and  $t = 1$ . We denote a unit as treated if  $D(i, 1) = 1$ , and units are controls if  $D(i, 0) = 0$ . Given that we stipulate treatment is only given after  $t = 0$ , we can simplify the notation for treatment to  $D(i)$ . Next, for each unit, we define the effect of the treatment in terms of potential outcomes. The potential outcome if unit  $i$  at time  $t$  is untreated is  $Y^0(i, t)$ . Similarly, the potential outcome under treatment for unit  $i$  and time  $t$  is  $Y^1(i, t)$ . The unit level causal effect of the treatment is  $Y^1(i, t) - Y^0(i, t)$ . The fundamental problem of causal inference is that we cannot observe both potential outcomes for each unit. Instead, we can only observe the realized outcome which is a function of treatment status and potential outcomes:  $Y(i, t) = Y^0(i, t)(1 - D(i)) + Y^1(i, t)D(i)$ . Hereafter, we drop  $i$  to simplify the notation.

While individual level treatment effects cannot be computed, researchers generally focus on some population average effect. In the DID context, that effect is usually defined as the average effect of the treatment on the treated:  $E[Y^1(1) - Y^0(1) | D = 1]$ . However, further assumptions are needed to identify the causal effect. Specifically, in a DID analysis, we assume:

$$\begin{aligned} E[Y^0(1) - Y^0(0) | D = 1] \\ = E[Y^0(1) - Y^0(0) | D = 0] \end{aligned}$$

In words, this assumption requires that, in the absence of treatment, the potential outcomes for treated and control units are following the same common time trend. That is, we assume that the treated and control units are evolving over time, and absent treatment the two groups would evolve the same way. The only factor that causes the treated units to deviate from this common time trend is exposure to the treatment. Typically, researchers make this assumption conditional on a set of covariates:

$$\begin{aligned} E[Y^0(1) - Y^0(0) | X, D = 1] \\ = E[Y^0(1) - Y^0(0) | X, D = 0] \end{aligned}$$

Now, we stipulate that the outcomes of treated and control units that look similar in terms of observed characteristics change at the same rate across time. Under either of these identifying assumptions, one can straightforwardly estimate the DID treatment effect.

Next, I change the notation to compactly refer to outcomes in each for the four treatment time periods. That is, we now denote the observed outcome as  $Y(t, d)$  where  $Y(1, 1)$  refers to treated outcomes in the post-treatment time period. The DID estimator for the treatment effect of  $D$  is

$$\begin{aligned} \tau = & (\mathbb{E}[Y(1, 1)] - \mathbb{E}[Y(0, 1)]) \\ & - (\mathbb{E}[Y(1, 0)] - \mathbb{E}[Y(0, 0)]), \end{aligned}$$

Close examination of the basic DID estimator reveals the logic behind the term ‘differences-in-differences’. The DID estimator is the difference between the treated outcome trend and the control outcome trend. That is, one takes the difference in the outcomes after removing the time trends for the treated and control groups. Moreover, investigators can use a linear regression model to estimate the DID effect as well, which also simplifies inference when the data are IID (Donald and Lang, 2007; Bertrand et al., 2004).

The simple form of the estimator also makes DID very flexible in terms of data requirements. That is, DID can be applied to data settings where the same units are observed over time, but it can also be applied to settings where different units are observed over time. For example, survey data may be collected before and after a treatment goes into effect. The survey data need not be collected from the same individuals before and after treatment. This has made DID highly applicable to studying the effect of policy changes. That is, so long as survey data can be collected before and after a new law or policy is implemented, then DID can be easily applied.

DID is considered useful since it removes two types of bias. The first bias is a uniform time trend, which we denote  $\lambda_t$ , and the second bias is a constant difference between treated and control groups, which we denote  $\lambda_d$ . If only these two biases are present, then  $Y(1,1) - \tau = Y(0,0) + \lambda_t + \lambda_d$  where  $\tau$  is a constant-additive treatment effect. The differences-in-differences contrast:  $(Y(1,1) - Y(0,1)) - (Y(1,0) - Y(0,0))$  removes the bias from  $\lambda_t$  and  $\lambda_d$ . As such, DID removes these two forms of additive bias even if they arise from observed and unobserved sources. Thus, the particular advantage of DID is that it provides some protection against unobserved confounding. However, as I outline below, this leverage over unobservables is fairly limited.

## HISTORY

The DID method is one of the oldest in social science data analysis. The first recorded

example of DID is in Jon Snow’s ground-breaking study showing that cholera was a waterborne disease (Snow, 1854). What is perhaps more striking is how another early application of DID is remarkably similar to how DID is currently employed. Obenauer et al. (1915) sought to estimate the effect of a minimum wage law in Oregon that led to higher wages in Portland but not the rest of the state. In their study, they used Salem – another city in Oregon that the authors thought was similar to Portland – as the control group. They then compared the overtime changes in employment in Portland to the overtime changes in employment in Salem. Other early studies are also typical of current DID usage: a change in state or local laws is the treatment of interest. Data are then collected in the pre and post-treatment time periods for a treated group, the place with the new policy, and a control group, some place without a change in policy (Lester, 1946; Rose, 1952). In political science, changes in state regulation of the voting registration process are routinely analyzed using DID (Leighley and Nagler, 2013; Hanmer, 2009). Again, one reason for widespread use of DID is that the data configuration that makes DID possible is common. Moreover, as I outlined above, DID does protect against a specific form of unobserved bias. In sum, the attraction of DID as a strategy for estimating treatment effects is fairly obvious. Next, I review several issues related to DID.

## ISSUES IN DID

### *Scale Dependence*

As I highlighted above, the strength of DID is that it can remove bias due to time-invariant confounders. That is, if there are unobserved differences in the treated and control groups that do not change over time, those differences are removed by applying DID to the data. That would appear to be a significant advantage, given that bias from unobserved confounders is the specific weakness of most attempts to

estimate causal effects with observational data. However, closer examination reveals that the bias reducing properties of DID are highly dependent on functional form assumptions. That is, for DID to be successful, the bias can only be additive. There is, however, no reason to assume the bias is additive. One way to understand how restrictive this assumption is is to note that the bias reduction properties of DID do not hold under logarithmic transformations.

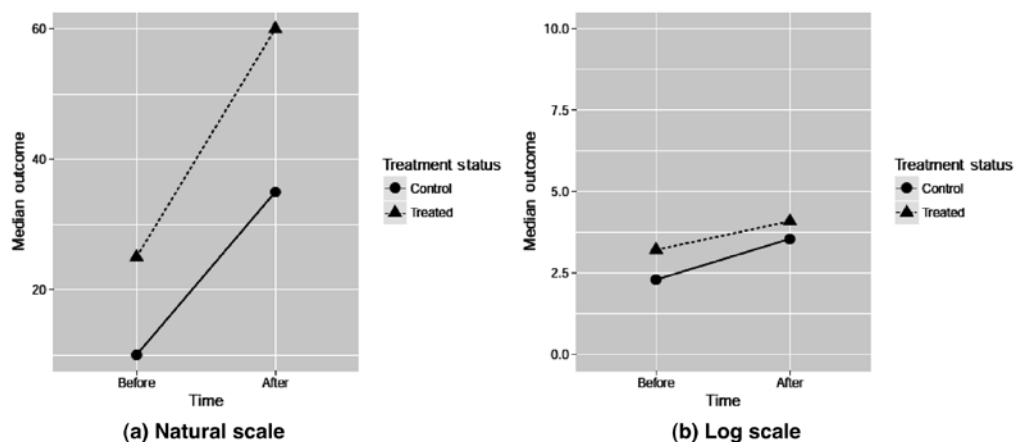

The left panel of Figure 43.1 contains the specific pattern in data for which DID is useful. By construction, both the treated and control groups increase over time by 25 units due to fixed over time changes in outcomes. The treated group outcome increases an additional 10 points due to exposure to the treatment. The pattern in the left panel of Figure 43.1 would appear to be the prototypical example of why one should use DID. However, let's say that an analyst decides to log transform this data, which is often done to decrease the variability in the outcome. The right panel of Figure 43.1 contains the same data after a log transformation of the outcome. Notice, however, that under the log transform, the treatment effect is mostly eliminated. This is due to the fact that the additive bias removed by DID may not hold for a strictly increasing transformation of the outcome. That is, when the bias takes any form that is more complex

than additive, DID offers little protection. There is, however, no reason to think that bias from unobservables takes such a simple form.

### Assignment Mechanism

One trend in empirical analysis over the last 15 years has been an increased use of natural experiments. Given that randomized experiments are often infeasible in many empirical settings, investigators attempt to find natural circumstances that assign treatments in a manner something like a randomized experiment. The hope is to reduce bias from confounding by exploiting circumstances where treatments are not purposely assigned. What is a natural experiment? Keele (2015) defines a natural experiment as a real-world situation that produces haphazard assignment to a treatment. See Dunning (2012) for a useful review of how to judge the quality of a natural experiment relative to actual randomization.

The DID method is closely identified with natural experiments. In fact, many authors often refer to any use of DID as a type of natural experiment. For example, Mayne et al. (2015) conducted a review of natural experiments in the study of obesity. Any study that applied differences-in-differences was classified as a natural

**Figure 43.1** Schematic representation of response in treated and control groups, before and after treatment, with and without transformation to log scale

experiment in their review. The close identification between DID and natural experiments is probably due to the fact that DID has been used to analyze several famous natural experiments including Jon Snow's cholera study. Another well-known example where DID was applied to natural experiment includes the study by Card (1990) which used the Mariel Boatlift from Cuba to estimate the effect of immigration on employment rates. Dynarski (1999) studied the treatment effect of the additional aid on the decision to attend college, using the Social Security Student Benefit Program, which awarded aid to high school seniors with deceased fathers of Social Security recipients. Referring to DID as a type of natural experiment tends to imbue the method with a level of credibility that is not deserved, since there is nothing about DID that implies the study is a natural experiment. One way to understand this limitation is by reviewing the concept of treatment assignment mechanisms.

In the literature on casual inference, treatment assignment mechanisms are often an area of emphasis (Rubin, 2008). For example, the power of randomized experiments largely stems from the fact that the treatment assignment mechanism follows a known probabilistic rule. An application can be categorized as a convincing natural experiment when the treatment assignment mechanism appears as-if random. For example, Lyall (2009) used artillery fire by Russian troops in Chechnya to understand whether indiscriminate violence increases insurgent attacks. More specifically, he exploited the fact that the shelling patterns of the Russian army appeared to be at worst indiscriminate and at best as-if random. That is, instead of firing on known military targets, the troops fired in what may have been random patterns. Research studies that utilize natural experiments are advised to use considerable qualitative knowledge to describe the process by which haphazard treatment occurs and to compare the results of haphazard assignment to what would have occurred under true random assignment (Dunning, 2012). That is,

when investigators claim to be exploiting a natural experiment, it requires considerable evidence to make a convincing case. Lyall (2009), for example, does find that the treatment, being shelled, appears to be uncorrelated with pre-treatment covariates as would be the case in a randomized experiment. Regression discontinuity designs are built on a series of falsification tests that compare haphazard assignment to random assignment (Cattaneo et al., 2018: ch. 5).

The critical point is that use of DID tells you nothing about the assignment mechanism. That is, DID can be applied to applications where treatments are assigned in a highly plausible, as-if random fashion. However, DID can also be applied to contexts where treatments are applied in a highly selective fashion. As an example, Mayne et al. (2015) classify studies that use DID to estimate the effect of built environment interventions on obesity as natural experiments. In a built environment intervention study, the investigator would be seek to estimate the effect of building a new playground on health outcomes in a community (Gustat et al., 2012). Like many policy changes, there is little that is haphazard about an intervention of this type. That is, without clear evidence to the contrary, it seems highly unlikely that a city would choose neighborhoods for playgrounds in an as-if random fashion. In all probability, the city government selects areas for new playgrounds in a highly purposive fashion. For example, the city may select neighborhoods where the local citizens are highly engaged and have strongly lobbied for a new playground. Such places are a likely to be different from other places in both observed and unobserved ways. The key point is that being able to apply DID to a specific application does not make it a natural experiment.

As I noted above, DID is widely used to evaluate the effect of changes in state or local laws. For example, DID might be used to evaluate a new voting regulation such as election day registration (EDR). In general, such changes in state policy are not natural experiments in that changes in such laws are typically highly purposeful. It is not an accident

that two upper Midwestern states – Minnesota and Wisconsin – with high levels of social capital enacted EDR years before any other state. The state legislatures in Minnesota and Wisconsin adopted these laws not by accident, but to maximize turnout in those states (Smolka, 1977). Moreover, the reason those two states adopted EDR is a function of most likely both observed and unobserved differences in the civic cultures of those states relative to other states.

In general, the DID framework should not be conflated with the concept of natural experiments. DID is essentially an estimation strategy that is applied to a particular data configuration in hopes that it removes a specific form of bias. Conflating DID with natural experiments gives it a status it does not deserve. Applications should be classified as natural experiments based on whether the assignment mechanism appears to approximate as-if random assignment. Widespread use of DID results from the fact that the necessary data configuration is common. That is, frequent use of DID is not unlike assuming that ‘one’s cancer is curable by a particular drug simply because one has an abundant supply of this specific drug’.<sup>1</sup>

### ***Bias Due to an Unobserved Time-Varying Confounder***

While the benefits of DID tend to be well understood, the general weakness of the method tends to be less well understood. Next, I use a simple numerical example to demonstrate how time-varying confounders can undermine estimates based on DID in a specific way. In this hypothetical example, the true outcome values for the four groups are as follows:

- $\mathbb{E}[Y(1,1)] = 75$ ,
- $\mathbb{E}[Y(0,1)] = 15$ ,
- $\mathbb{E}[Y(1,0)] = 25$ ,
- $\mathbb{E}[Y(0,0)] = 15$ .

The DID estimate of  $\tau$  is  $E[75 - 15] - E[25 - 15] = 50$ . Next, we define  $\gamma(t, d)$  as bias from a confounder that alters the average

outcomes in at least one or possibly more of the four groups. For example,  $\gamma(1, 0)$  is a bias that increases the average outcome in the control group when  $t = 1$ . First, we consider a bias of the form  $\gamma(1, 1) = \gamma(1, 0) = 10$ , where both treated and control outcomes increase when  $t = 1$  for reasons unrelated to treatment. If we apply the usual DID estimator, it is still the case that  $\hat{\tau} = 50$ . That is, when the bias takes this specific time-invariant form, DID works as advertised and removes that bias. Next, we consider a bias of the form  $\gamma(0, 0) = \gamma(1, 1) = 20$ . This type of bias increases outcomes in the control when  $t = 0$  and increases outcomes in the treated when  $t = 1$ . Here, the bias is no longer time invariant. Under a bias of this type, the DID estimate is now  $E[95 - 15] - E[25 - 35] = 90$ . A bias of this form distorts in a particular way such that DID is unable to offer any protection. Moreover, for this type of bias, if we did not apply DID and simply used the treated and control difference in the post-treatment time period, the estimate would be  $95 - 25 = 70$ . The key point is that under the right form of time-varying bias, one would be better off simply using a standard treated control difference instead of applying DID. This is due to the fact that under DID, one must assume that the bias only takes a specific time-invariant form.

One might reasonably ask whether a bias of this form is plausible? Perhaps a bias that changes outcomes in this specific way over time is hard to imagine and, thus, not something most investigators should worry about. Or perhaps not – let us return to the EDR example and assume we have two states: one adopts EDR and the other does not. It is well understood that during presidential elections, some states are considered battleground states due to the competitive nature of the election in that state. Voters in battleground states tend to be targeted for mobilization by the campaigns, while voters in non-battleground states may be subject to few, if any, mobilization efforts. Some states are perennial battleground states, and other

states become competitive in certain elections. Imagine that when  $t = 0$ , the presidential race is competitive in the control state, and that state is subject to national mobilization efforts, as it is designated a battleground state. However, after EDR goes into effect, the treated state becomes a battleground state while the control state is no longer competitive. As a result, the treated state experiences nationalized get-out-the-vote efforts in the post-treatment time period. A mechanism of this type is completely consistent with a bias of the form  $\gamma(0, 0) = \gamma(1, 1) = \delta$ . That is, it is not difficult to conceptualize a time varying bias of the type that biases differences-in-differences in a serious way.

### ***Bracketing Methods for DID***

DID, at the most basic level, requires longitudinal data. While one need not observe the exact same units over time, the investigator must at the very least observe grouped data over time. As such, in many cases, one alternative to DID is to condition on past outcomes directly. In the simplest form, this approach simply means including lagged outcomes on the right-hand side of a regression model designed to estimate the treatment effect of interest. Under this approach, the investigator is assuming that potential outcomes are independent of treatment once he or she conditions on observed covariates including lagged outcomes. Using the notation from above, the key identification assumption is

$$Y^1(i, t), Y^0(i, t) \perp D_i \mid \mathbf{X}, Y_{it-h}$$

where  $h$  is some unspecified lag length, such that  $h = 2$  would indicate conditioning on two past periods of the outcome. This assumption can be viewed as a variant of the common selection on observable assumption. Here, one assumes that potential outcomes are independent of treatment once one has conditioned on observables including measures of the outcome from time periods before the

treatment is in effect. What is gained by this identification strategy? First, unlike under DID, we need not assume treated and control observations had similar longitudinal trajectories. Here, we can directly control for the histories of each unit. Moreover, past outcomes are a function of both observed and unobserved factors; therefore, conditioning on past outcomes is an indirect way to condition on unobservables. Of course, given that DID can be implemented using regression models, in many cases, it would appear natural to combine the lagged outcome identification strategy with DID. However, OLS estimates are inconsistent in this case (Nickell, 1981). Solutions are possible, but they typically require exclusion restrictions that may be hard to justify. See Xu (2017) for an approach that combines past outcomes and fixed effects but relies on an exclusion restriction.

An alternative approach is to use a solution outlined in Angrist and Pischke (2009) and fully generalized in Ding and Li (2019). Ding and Li (2019) show that if the past outcomes identification strategy holds, but the analyst estimates the treatment effect using DID, the estimated treatment effect will be too large since the unestimated lag parameter will be additive with the treatment effect through the error term. Conversely, if the DID assumptions hold, and the analyst estimates a model that conditions on past outcomes, this will generate a correlation between the treatment and the lagged outcome which will bias the treatment effect downward. One can therefore view the estimates from these two methods as bounds for the causal effect of interest.

How might this work in practice? One key advantage of this approach is that it can be implemented quite simply. First, the investigator would estimate the treatment effect using DID methods. Next, the investigator would estimate the treatment effect controlling for lags of the outcome. In the simplest scenario, one would use linear models in both cases. The estimates from each approach then form bounds for the treatment effect of interest. Ideally, the sign of the two estimates

agree, which provides some evidence that the researcher has at least managed to identify the sign of the treatment effect of interest. See Keele et al. (2013) for an example of using this combined approach. However, in one recent comparative study, conditioning on past outcomes proved to be generally more robust than DID (O'Neill et al., 2016).

## DID ESTIMATION

Estimation in the DID framework typically relies on linear models. See Angrist and Pischke (2009) for a basic introduction and Lechner (2011) for a more detailed treatment of DID estimation. Instead of reviewing linear models for DID estimation, I present an alternative way to estimate treatment effects in the DID framework. Specifically, I present a matching framework outlined in Keele et al. (2018). Next, I then present an actual empirical example using this framework.

### *DID and Matching*

The key advantage to using matching over linear regression is that matching is more robust to a variety of data configurations (Imbens, 2015). Matching was first used for DID estimation in Heckman et al. (1998), but still remains under utilized. Here, I outline one matching plan that can be used to estimate the DID treatment effect in the basic setting with treated and control groups and one pre- and post-treatment time period. This form of DID matching is actually comprised of three different matches. These three matches balance units both with respect to treatment and control but also with respect to time periods. I motivate these matches using a familiar empirical application. Here, I apply this matching plan to estimate the DID treatment effect for EDR. Specifically, I estimate the EDR effect for Wisconsin. Wisconsin was one of the first states to adopt EDR, and

it is a state where the effect of EDR is widely understood to have contributed to an increase in turnout (Hanmer, 2009). The data I use are extracts from the 1972 and 1980 Current Population Survey (CPS) and are a subset of the data from Keele and Minozzi (2012). Wisconsin first used EDR in 1976, and I use turnout levels in the 1980 presidential election as the post-treatment period in case of any delay in the effect of EDR. I use voters from Illinois as controls, since it is adjacent to Wisconsin, and both states have large metropolitan areas with minority communities but have large rural populations as well.

The first match in the plan is to match treated and control units in the pre-treatment period. That is, in this application that requires matching Wisconsin voters to Illinois voters in 1972. The second match matches treated and control units in the post-treatment time period. In the EDR application, I match Wisconsin voters to Illinois voters in 1980. The final match pairs pre-treatment pairs to post-treatment pairs. Specifically, I would match the 1972 Wisconsin and Illinois pairs to the 1980 Wisconsin and Illinois pairs. This final match balances observed covariates with respect to time.

The first two matches are straightforward to implement and almost any form of matching can be used to form these two sets of matched pairs. In the results reported below, I used a matching method based on integer programming in the R package *designmatch* (Zubizarreta, 2012; Zubizarreta and Kilcioglu, 2016; Kilcioglu and Zubizarreta, 2017). The third match, which requires matching matched pairs to matched pairs, is not a standard matching problem. I can reduce this to a standard matching problem by creating a new dataset from the pre-treatment matched pairs and post-treatment matched pairs based on summary statistics. For example, in the EDR data, I calculate the within pair mean for covariates like age. This collapses the data for each set of pairs in each time period. With the collapsed data, standard pair matching techniques can be used to match pre-treatment pairs to post-treatment

pairs. For nominal covariates, exact matching can be applied to avoid having to apply summary statistics. For example, in the CPS data, income is recorded as categories. I use exact matching when forming the first two sets of pairs. Thus, when I collapse the matched pairs, no summary statistics are needed. The end result is matched quadruple comprised of two pre-treatment units and two post-treatment units. Estimation of the treatment effect can be accomplished by applying the usual DID formula. Testing can be done by applying paired tests to the over-time differences in outcomes. Moreover, the method of Rosenbaum bounds can also be applied so that sensitivity to hidden bias is also assessed. See Keele et al. (2018) for details.

When implementing a match of this type, the investigator must carefully select the covariates for matching. In general, one should only match on pre-treatment covariates to avoid bias from adjusting for a post-treatment covariate (Rosenbaum, 1984). The DID match, however, requires matching in the post-treatment period. Therefore, for all stages of the matching, analysts should be careful to match on covariates that are thought to be unaffected by the intervention but may affect the outcome. In the EDR example, education would appear to be a safe covariate to match on, since it is unlikely that a change in voter registration laws would affect levels of education. The reason we match across time is to remove bias due to group status that is thought to vary as a function of observed covariates (Keele et al., 2018).

## Empirical Results

Next, I present the results from the DID matching plan using the CPS data. I begin by matching Wisconsin residents to Illinois residents in 1972. I matched on age, an indicator if he or she is African-American, female, a categorical scale of education, a categorical scale of income and an interaction between education and income categories. In the match, I matched exactly on whether a resident was African-American, and I applied near-fine balance to education, income and the interaction between education and income categories. I allowed for a deviation of two categories on the near-fine balance in the match. After matching in 1972, we have 1,427 matched pairs. Table 43.1 contains the balance statistics for this first match.

I next implemented a match of the same form using the data from 1980. After matching in 1980, we have 1,718 matched pairs. Table 43.2 contains the balance statistics. In both of these matches, the largest discrepancy is for race as Illinois has a larger African-American population. However, after matching, all the standard differences are 0.05 or less.

Finally, I matched the pairs from 1972 to the pairs from 1980. For the pair-to-pair match, I used cardinality matching. After this final match, there are 938 matched pairs from 1972 matched to 938 matched pairs from 1980. Table 43.3 contains the balance statistics. It is worth noting that the imbalances are much larger across the two time periods than within each year. In particular, the standardized difference on income and the income education

**Table 43.1 Standardized differences and p-values for treated to control match in the pre-treatment period for the election day registration application**

	<i>Before matching</i>		<i>After matching</i>	
	<i>Std dif</i>	<i>P-val</i>	<i>Std dif</i>	<i>P-val</i>

	<i>Before matching</i>		<i>After matching</i>	
	<i>Std dif</i>	<i>P-val</i>	<i>Std dif</i>	<i>P-val</i>
Age	0.18	0.00	-0.05	0.29
African-American	-0.05	0.15	-0.07	0.12
Female	0.10	0.00	-0.02	0.67
Education	-0.27	0.00	0.05	0.28
Income	-1.27	0.00	-0.05	0.15
Education X income	-1.10	0.00	-0.05	0.18

interaction both exceed one. This implies fairly large differences in the composition of the samples across years. As is often the case, balance checking reveals what is mostly likely an important lack of overlap in the covariate distributions across the two time periods.

Next, I estimate the DID treatment effect of EDR. Here, I simply apply the usual DID formula to the quadruple outcomes. According to this estimate, the turnout rate increased 12.6 percentage points in Wisconsin as compared with Illinois. The DID estimate of the EDR treatment effect is also statistically significant ( $p < 0.001$ ). However, as noted in Keele et al. (2018), sensitivity analysis reveals that this result could easily be explained by an unobserved confounder.

In general, the EDR application is a case where DID is easily applied but the evidence is unconvincing. First, there is nothing as-if random about treatment assignment in this case. Presumably, lawmakers in Wisconsin selected this voter registration regime for a specific

reason. Thus, we have highly intentional self-selection into treatment. Moreover, we must assume that no other events beside the change in voter registration altered the temporal path of either the treated or control groups. Here, for example, no other events can occur in Wisconsin that might also boost turnout. In general, the key DID assumption is suspect in this case given that there are lots of ways that turnout might have changed overtime for reasons unrelated to EDR. Moreover, the covariates in the CPS data do not measure the temporal dynamics of turnout during this time period, since those tend to be driven by state specific campaign factors. As such, the use of DID does little to enhance the credibility of a study of this type.

## CONCLUSION

All in all, I have presented a fairly pessimistic take on differences-in-differences. My primary

objection is that investigators assume that since they can apply DID, then the design is necessarily a type of natural experiment. While it is true that DID can be applied to natural experiments, DID itself tells one little about whether a set of circumstances are indeed a natural experiment. Once this point is understood, justification of a DID identification strategy should proceed along lines that are similar to if one were assuming selection on observables. That is, a DID identification strategy requires careful explication of the key assumption and a detailed defense of why that assumption is plausible in a given context. One effective way to defend the DID identification strategy is through the use of falsification tests.

I conclude by reviewing one persuasive use of DID based on a falsification or placebo test. Gruber (1994) studied the labor market effects of mandates passed by 23 states between 1975 and 1979 that outlawed treating pregnancy differently from ‘comparable illnesses’, and mandated comprehensive coverage for childbirth in health insurance policies. Mandates of this type increase the costs of employing women of childbearing age and their husbands, under whose insurance these women might have been covered. Gruber employed DID to analyze whether the costs of these mandates were shifted to the wages of married women of childbearing age. Table 43.4 presents the results from a DID analysis. The results based on DID

indicate a decline in wages for married women of child-bearing age during this period  $(1.513 - 1.547) - (1.397 - 1.369) = 0.062$ . The evidence in Table 43.4 is far from conclusive given that a wide variety of other changes to the labor market might explain the decline in wages.

While key assumptions in observational studies are untestable, in many cases these assumptions can be tested indirectly via falsification. Angrist and Krueger (1999) refer to such tests as instances of ‘refutability’. Falsification tests arise from the fact that causal theories may do more than predict the presence of a causal effect; they may also predict an absence of causal effects (Rosenbaum, 2002; Lipsitch et al., 2010). One form of falsification test exploits the fact that treatment is known to be zero in some populations. Gruber (1994) noted that if larger trends in wages could explain the decline in wages observed in Table 43.4, that change in wages should also be present in single men aged between 20 and 40 and women over 40. However, if the decline in wages is due to childbirth mandates, no such treatment effect should be present in this population. Table 43.5 contains the results from the DID applied to women over 40 and single men aged 20–40. Indeed, we observe no significant change in wages for this group  $(1.748 - 1.759) - (1.627 - 1.630) = 0.008$ . That is, in the treated group, wages declined 6.2% while in the placebo test, the decline was an insignificant 0.8%.

**Table 43.4 Average log hourly wages, married women 20–40 years**

	<i>Before law change</i>	<i>After law change</i>
Treated states	1.547	1.513
Control states	1.369	1.397
DID estimate	6.2%	

**Table 43.5 Average log hourly wages, women over 40 and single men 20–40**

	<i>Before law change</i>	<i>After law change</i>

Control states	1.630	1.627
DID estimate	0.8%	

In general, research design elements of this type tend to be far more effective than when DID is used in isolation. In short, research designs are generally not persuasive just because DID was used. Instead, analysts should make the case for why they are analyzing a natural experiment and use of DID should be largely incidental.

# The Regression Discontinuity Design<sup>1</sup>

Matias D. Cattaneo, Rocío Titiunik, and  
Gonzalo Vazquez-Bare

## INTRODUCTION

The Regression Discontinuity (RD) design has emerged in recent decades as one of the most credible non-experimental research strategies to study causal treatment effects. The distinctive feature behind the RD design is that all units receive a score, and a treatment is offered to all units whose score exceeds a known cutoff, and it is withheld from all the units whose score is below the cutoff. Under the assumption that the units' characteristics do not change abruptly at the cutoff, the change in treatment status induced by the discontinuous treatment-assignment rule can be used to study different causal treatment effects on outcomes of interest.

The RD design was originally proposed by Thistlethwaite and Campbell (1960) in the context of an education policy, where an honorary certificate was given to students with test scores above a threshold. Over time, the design has become common in areas

beyond education and is now routinely used by scholars and policy-makers across the social, behavioral, and biomedical sciences. In particular, the RD design is now part of the standard quantitative toolkit of political science research, and it has been used to study the effect of many different interventions including party incumbency, foreign aid, and campaign persuasion.

In this chapter, we provide an overview of the basic RD framework, discussing the main assumptions required for identification, estimation, and inference. We first discuss the most common approach for RD analysis, the *continuity-based* framework, which relies on assumptions of continuity of the conditional expectations of potential outcomes given the score and defines the basic parameter of interest as an average treatment effect at the cutoff. We discuss how to estimate this effect using local polynomials, devoting special attention to the role of the bandwidth, which determines the

neighborhood around the cutoff where the analysis is implemented. We consider the bias-variance trade-off that is inherent in the most common bandwidth-selection method (which is based on mean-squared-error minimization) and how to make valid inferences within this bandwidth choice. We also discuss the local nature of the RD parameter, including recent developments in extrapolation methods that may enhance the external validity of RD-based results.

In the second part of the chapter, we overview an alternative framework for RD analysis that, instead of relying on continuity of the potential outcome-regression functions, makes the assumption that the treatment is as-if randomly assigned in a neighborhood around the cutoff. This interpretation was the intuition provided by Thistlethwaite and Campbell (1960) in their original contribution, though it now has become less common, due to the stronger nature of the assumptions it requires. We discuss situations in which this *local randomization* framework for RD analysis may be relevant, focusing on cases where the running variable has mass points, which occurs very frequently in applications.

To conclude, we discuss a battery of data-driven falsification tests that can provide empirical evidence about the validity of the design and the plausibility of its key identifying assumptions. These falsification tests are intuitive and easy to implement and thus should be included as part of any RD analysis in order to enhance its credibility and replicability.

Due to space limitations, we do not discuss variations and extensions of the canonical (sharp) RD designs such as fuzzy, kink, geographic, multi-cutoff, or multi-score RD designs. A practical introduction to those topics can be found in Cattaneo et al. (2019a, 2020a) and in the recent edited volume Cattaneo and Escanciano (2017) and the references therein. For a recent review on program evaluation methods see Abadie and Cattaneo (2018).

## GENERAL SETUP

We start by introducing the basic notation and framework. We consider a study where there are multiple units from a population of interest (such as politicians, parties, students, households, or firms), and each unit  $i$  has a *score* or *running variable*, denoted by  $X_i$ . This running variable could be, for example, a party's vote share in a congressional district, a student's score from a standardized test, a household's poverty index, or a firm's total revenue over a certain period of time. This running variable may be continuous, in which case no two units will have the same value of  $X_i$ , or not continuous, in which case the same value of  $X_i$  might be shared by multiple units. The latter case is usually called 'discrete', but in many empirical applications the score variable is actually both.

In the simplest RD design, each unit receives a binary treatment  $D_i$  when their score exceeds some fixed threshold  $c$  and does not receive the treatment otherwise. This type of RD design is commonly known as the *sharp RD design*, where the word *sharp* refers to the fact that the assignment of treatment coincides with the actual treatment taken – that is, compliance with treatment assignment is perfect. When treatment compliance is imperfect, the RD design becomes a *fuzzy RD design* and its analysis requires additional methods beyond the scope of this chapter. The methods described here for analyzing sharp RD designs can be applied directly in the context of fuzzy RD designs when the parameter of interest is the intention-to-treat effect.

The sharp RD treatment assignment rule can be formally written as

$$D_i = \mathbb{I}(X_i \geq c) = \begin{cases} 1 & \text{if } X_i \geq c \\ 0 & \text{if } X_i < c \end{cases} \quad (1)$$

where  $\mathbb{I}(\cdot)$  is the indicator function. For example,  $D_i$  could be a scholarship for college students that is assigned to those with a

score of seven or higher in an entry exam on a scale from 0 to 10. In this example,  $X_i$  is the exam score,  $c = 7$  is the cutoff used for treatment assignment, and  $D_i = \mathbb{I}(X_i \geq 7)$  is the binary variable that indicates receipt of the scholarship.

Our goal is to assess the effect of the binary treatment  $D_i$  on a certain outcome variable. For instance, in the previous scholarship example, we may be interested in analyzing whether the scholarship increases the academic performance during college or the probability of graduating. This problem can be formalized within the potential outcomes framework (Imbens and Rubin, 2015). In this framework, each unit  $i$  from the population of interest has two potential outcomes, denoted  $Y_i(1)$  and  $Y_i(0)$ , which measure the outcome that would be observed for unit  $i$  with and without treatment, respectively. For example, for a certain college student  $i$ ,  $Y_i(1)$  could be the student's GPA at a certain stage had she received the scholarship and  $Y_i(0)$  the student's GPA had she not received the scholarship. The individual-level treatment 'effect' for unit  $i$  is defined as the difference between the potential outcomes under treatment and control status,  $\tau_i = Y_i(1) - Y_i(0)$ .

Because the same unit can never be observed under both treated and control status (a student can either receive or not receive the scholarship, not both), one of the potential outcomes is always unobservable. The observed outcome, denoted  $Y_i$  equals  $Y_i(1)$  when  $i$  is treated and  $Y_i(0)$  if  $i$  is untreated, that is,

$$Y_i = Y_i(1)D_i + Y_i(0)(1 - D_i) \\ = \begin{cases} Y_i(1) & \text{if } D_i = 1 \\ Y_i(0) & \text{if } D_i = 0 \end{cases} \quad (2)$$

The observed outcome can never provide information on both potential outcomes. Hence, for each unit in the population, one of the potential outcomes is observed and the other one is a *counterfactual*. This problem is known as the *fundamental problem of causal inference* (Holland, 1986).

The RD design provides a way to address this problem by comparing treated units that are 'slightly above' the cutoff to control units that are 'slightly below' it. The rationale behind this comparison is that under appropriate assumptions, which will be made more precise in the upcoming sections, treated and control units in a small neighborhood or *window* around the cutoff are comparable in the sense of having similar observed and unobserved characteristics (with the only exception being treatment status). Thus, observing the outcomes of units just below the cutoff provides a valid measure of the average outcome that treated units just above the cutoff would have had if they had not received the treatment.

In the remainder of this chapter, we describe two alternative approaches for analyzing RD designs. The first one, which we call the *continuity-based framework*, assumes that the observed sample is a random draw from an infinite population of interest and invokes assumptions of continuity. In this framework, identification of the parameter of interest (defined precisely in the next section) relies on assuming that the average potential outcomes given the score are continuous as a function of the score. This assumption implies that the researcher can compare units marginally above the cutoff to units marginally below in order to identify (and estimate) the average treatment effect at the cutoff.

The second approach for RD analysis, which we call the *local randomization framework*, assumes that the treatment of interest is as-if randomly assigned in a small region around the cutoff. This approach formalizes the interpretation of RD designs as local experiments and allows researchers to use the standard tools from the classical analysis of experiments. In addition, if the researcher is willing to assume that potential outcomes are fixed (non-random) and that the  $n$  units observed in the sample form the finite population of interest, this approach also allows the researcher to use finite-sample exact randomization inference tools, which are especially

appealing in applications where the number of observations near the cutoff is small.

For both frameworks, we discuss the parameters of interest, estimation, inference, and bandwidth or window selection methods. We then compare the two approaches and provide a series of falsification methods that are commonly employed to assess the validity of the RD design. See also Cattaneo et al. (2017) for an overview and practical comparisons between these RD approaches.

## THE CONTINUITY-BASED FRAMEWORK

Under the continuity-based framework, the observed data  $\{Y_i(1), Y_i(0), X_i, D_i\}$ , for  $i = 1, 2, \dots, n$ , is a random sample from an infinite population of interest (or data-generating process). The main objects of interest under this framework are the conditional-expectation functions of the potential outcomes,

$$\begin{aligned} \mu_1(x) &= \mathbb{E}[Y_i(1)|X_i = x] \\ \text{and } \mu_0(x) &= \mathbb{E}[Y_i(0)|X_i = x] \end{aligned} \quad (3)$$

which capture the population average of the potential outcomes for each value of the score. In the sharp RD design, for each value of  $x$ , only one of these functions is observed:  $\mu_1(x)$  is observed for  $x$  at or above the cutoff and  $\mu_0(x)$  is observed for values of  $x$  below the cutoff.

The observed conditional expectation function is

$$\mu(x) = \mathbb{E}[Y_i|X_i = x] = \begin{cases} \mu_1(x) & \text{if } x \geq c \\ \mu_0(x) & \text{if } x < c \end{cases} \quad (4)$$

We start by defining the function  $\tau(x)$ , which gives the average treatment effect conditional on  $X_i = x$ :

$$\begin{aligned} \tau(x) &= \mathbb{E}[Y_i(1) - Y_i(0)|X_i = x] \\ &= \mu_1(x) - \mu_0(x) \end{aligned} \quad (5)$$

The first step is to establish conditions for identification, that is, conditions under which we can write the parameter of interest, which depends on unobservable quantities due to the fundamental problem of causal inference, in terms of observable (i.e., identifiable) and thus estimable quantities. In the continuity-based framework, the key assumption for identification is that  $\mu_1(x)$  and  $\mu_0(x)$  are continuous functions of the score at the cutoff point  $x = c$ . Intuitively and informally, this condition states that the observable and unobservable characteristics that determine the average potential outcomes do not jump abruptly at the cutoff. When this assumption holds, the only difference between units on opposite sides of the cutoff whose scores are ‘very close’ to the cutoff is their treatment status.

Intuitively, we may think that treated and control units with very different score values will generally be very different in terms of important observable and unobservable characteristics affecting the outcome of interest, but as their scores approach the cutoff and become similar in that dimension, the only remaining difference between them will be their treatment status, thus ensuring comparability between units just above and just below the cutoff, at least in terms of their potential outcome mean regression functions.

More formally, Hahn et al. (2001) showed that when conditional expectation functions are continuous in  $x$  at the cutoff level  $x = c$ ,

$$\tau(c) = \lim_{x \downarrow c} \mathbb{E}[Y_i|X_i = x] - \lim_{x \uparrow c} \mathbb{E}[Y_i|X_i = x] \quad (6)$$

that is, the difference between average observed outcomes for units just above and just below the cutoff is equal to the average treatment effect at the cutoff,  $\tau(c) = \mathbb{E}[Y_i(1) - Y_i(0)|X_i = c]$ . Note that this identification result expresses the estimand  $\tau(c)$ , which is unobservable, as a function of two limits that depend only on observable (i.e., identifiable) quantities that are estimable from the data.

As a consequence, in a sharp RD design, a natural parameter of interest is  $\tau(c)$ , the

average treatment effect at the cutoff. This parameter captures the average effect of the treatment on the outcome of interest, given that the value of the score is equal to the cutoff. It is useful to compare this parameter with the average treatment effect,  $ATE = \mathbb{E}[Y_i(1) - Y_i(0)]$ , which is the difference that we would see in average outcomes if all units were switched from control to treatment. In contrast to ATE, which is the average of  $\tau(x)$  over  $x$ ,  $ATE = \mathbb{E}[\tau(X_i)]$ ,  $\tau(c)$  is only the average effect of the treatment at a particular value of the score,  $x = c$ . For this reason, the RD parameter of interest  $\tau(c)$  is often referred to as a *local* average treatment effect, because it is only informative of the effect of the treatment for units whose value of the score is at (or, loosely speaking, in a local neighborhood of) the cutoff. This limits the external validity of the RD parameter  $\tau(c)$ . A recent and growing literature studies how to extrapolate treatment effects in RD designs (Angrist and Rokkanen, 2015; Dong and Lewbel, 2015; Cattaneo et al., 2016a; Bertanha and Imbens, 2019; Cattaneo et al., 2020c).

The main advantage of the identification result in equation (6) is that it relies on continuity conditions of  $\mu_1(x)$  and  $\mu_0(x)$  at  $x = c$ , which are nonparametric in nature and reasonable in a wide array of empirical applications. The fifth section describes several falsification strategies to provide indirect empirical evidence in order to assess the plausibility of this assumption. Assuming continuity holds, the estimation of the RD parameter  $\tau(c)$  can proceed without making parametric assumptions about the particular form of  $\mathbb{E}[Y_i|X_i = c]$ . Instead, estimation can proceed by using nonparametric methods to approximate the regression function  $\mathbb{E}[Y_i|X_i = x]$  separately for values of  $x$  above and below the cutoff.

However, estimation and inference via nonparametric local approximations near the cutoff is not without challenges. When the score is continuous, there are, in general, no units that have a value of the score exactly equal to the cutoff. Thus, estimation

of the limits of  $\mathbb{E}[Y_i|X_i = x]$  will necessarily require extrapolation as  $x$  tends to the cutoff from above or below. To this end, estimation in RD designs requires specifying a neighborhood or bandwidth around the cutoff in which to approximate the regression function  $\mathbb{E}[Y_i|X_i = x]$ , and then, based on that approximation, calculate the value that the function has exactly at  $x = c$ . In what follows, we describe different methods for estimation and bandwidth selection under the continuity-based framework.

### **Bandwidth Selection**

Selecting the bandwidth around the cutoff in which to estimate the effect is a crucial step in RD analysis, as the results and conclusions are typically sensitive to this choice. We now briefly outline some common methods for bandwidth selection in RD designs. See also Cattaneo and Vazquez-Bare (2016) for an overview of neighborhood selection methods in RD designs.

The approach for bandwidth selection used in early RD studies is what we call *ad hoc* bandwidth selection, in which the researcher chooses a bandwidth without a systematic data-driven criterion, perhaps relying on intuition or prior knowledge about the particular context. This approach is not recommended, since it lacks objectivity, does not have a rigorous justification, and, by leaving bandwidth selection to the discretion of the researcher, opens the door for specification searches. For these reasons, the ad hoc approach to bandwidth selection has been replaced by systematic, data-driven criteria.

In the RD continuity-based framework, the most widely used bandwidth selection criterion in empirical practice is the *mean squared error* (MSE) criterion (Imbens and Kalyanaraman, 2012; Calonico et al., 2014b; Arai and Ichimura, 2018; Calonico et al., 2019b), which relies on a tradeoff between the bias and variance of the RD point estimator.

The bandwidth determines the neighborhood of observations around the cutoff that will be used to approximate the unknown function  $\mathbb{E}[Y_i|X_i = x]$  above and below the cutoff. Intuitively, choosing a very small bandwidth around the cutoff will tend to reduce the misspecification error in the approximation, thus reducing bias. A very small bandwidth, however, requires discarding a large fraction of the observations and hence reduces the sample, leading to estimators with larger variance. Conversely, choosing a very large bandwidth allows the researcher to gain precision using more observations for estimation and inference, but it is at the expense of a larger misspecification error, since the function  $\mathbb{E}[Y_i|X_i = x]$  now has to be approximated over a larger range. The goal of bandwidth selection methods based on this tradeoff is therefore to find the bandwidth that optimally balances bias and variance.

We let  $\hat{\tau}$  denote a local polynomial estimator of the RD treatment effect  $\tau(c)$  – we explain how to construct this estimator in the next section. For a given bandwidth  $h$  and a total sample size  $n$ , the MSE of  $\hat{\tau}$  is

$$MSE(\hat{\tau}) = Bias^2(\hat{\tau}) + Variance(\hat{\tau}) \tag{7}$$

$$= B^2 + V,$$

which is the sum of the squared bias and the variance of the estimator. The MSE-optimal bandwidth,  $h_{MSE}$ , is the value of  $h$  that balances bias and variance by minimizing the MSE of  $\hat{\tau}$ ,

$$h_{MSE} \approx \arg \min_{h>0} MSE(\hat{\tau}) \tag{8}$$

The shape of the MSE depends on the specific estimator chosen. For example, when  $\hat{\tau}$  is obtained using local linear regression (LLR), which will be discussed in the next section, the MSE can be approximated by

$$MSE(\hat{\tau}) \approx h^4 B^2 + \frac{1}{nh} V$$

where  $B$  and  $V$  are constants that depend on the data-generating process and specific features of the estimator used. This expression clearly highlights how a smaller bandwidth reduces the bias term while increasing the variance and vice versa. In this case, the optimal bandwidth, simply obtained by setting the derivative of the above expression with respect to  $h$  equal to zero, is

$$h_{MSE}^{LLR} = C_{MSE} n^{-1/5}, \tag{9}$$

where the constant  $C_{MSE} = \left(\frac{V}{4B^2}\right)^{1/5}$  is unknown but estimable. This shows that the MSE-optimal bandwidth for a local linear estimator is proportional to  $n^{-1/5}$ .

While  $h_{MSE}$  is optimal for point estimation, it is generally not optimal for conducting inference. Calonico et al. (2018, 2019a, 2019b, 2020) show how to choose the bandwidth to obtain confidence intervals minimizing the coverage error probability (CER). More precisely, let  $CI(\hat{\tau})$  be an  $(1-\alpha)$ -level confidence interval for the RD parameter  $\tau(c)$ , based on the estimator  $\hat{\tau}$ . A CER-optimal bandwidth makes the coverage probability as close as possible to the desired level  $1 - \alpha$ :

$$h_{CER} \approx \arg \min_{h>0} \left| \mathbb{P}([\tau(c) \in CI(\hat{\tau})] - (1 - \alpha)) \right| \tag{10}$$

For the case of local linear regression, the CER-optimal  $h$  is

$$h_{CER}^{LLR} = C_{CER} n^{-1/4}$$

where, again, the constant  $C_{CER}$  is unknown, because it depends in part on the data-generating process, but it is estimable. Hence, the CER-optimal bandwidth is smaller than the MSE-optimal bandwidth, at least in large samples.

Based on the ideas above, several variations of optimal bandwidth selectors exist, including one-sided CER-optimal and MSE-optimal bandwidths with and without

accounting for covariate adjustment, clustering, or other specific features. In all cases, these bandwidth selectors are implemented in two steps: first, the constant (e.g.,  $C_{MSE}$  or  $C_{CER}$ ) is estimated, and then the bandwidth is chosen using that preliminary estimate and the appropriate rate formula (e.g.,  $n^{-1/5}$  or  $n^{-1/4}$ ).

### Estimation and Inference

Given a bandwidth  $h$ , continuity-based estimation in RD designs consists on estimating the outcome regression functions, given the score, separately for treated and control units whose scores are within the bandwidth. Recall from equation (6) that we need to estimate the limits of the conditional expectation function of the observed outcome from the right and from the left.

One possible approach would be to simply estimate the difference in average outcomes between treated and controls within  $h$ . This strategy is equivalent to fitting a regression that includes only an intercept at each side of the cutoff. However, since the goal is to estimate two boundary points, this local constant approach will have a bias that can be reduced by including a slope term in the regression. More generally, the most common approach for point estimation in the continuity-based RD framework is to employ *local polynomial* methods (Fan and Gijbels, 1996), which involve fitting a polynomial of order  $p$  separately on each side of the cutoff, only for observations inside the bandwidth. Local polynomial approximations usually include a weighting scheme that places more weight on observations that are closer to the cutoff; this weighting scheme is based on a *kernel function*, which we denote by  $K(\cdot)$ .

More formally, the treatment effect is estimated as:

$$\hat{\tau} = \hat{\alpha}_+ - \hat{\alpha}_-$$

where  $\hat{\alpha}_+$  is obtained as the intercept from the (possibly misspecified) regression model:

$$Y_i = \alpha_+ + \beta_{1+}(X_i - c) + \dots + \beta_{p+}(X_i - c)^p + u_i$$

on the treated observations using weights  $K((X_i - c)/h)$ , and similarly  $\hat{\alpha}_-$  is obtained as the intercept from an analogous regression fit employing only the control observations. Although theoretically a large value of  $p$  can capture more features of the unobserved regression functions,  $\mu_1(x)$  and  $\mu_0(x)$ , in practice, high-order polynomials can have erratic behavior, especially when estimating boundary points, a fact usually known as *Runge's phenomenon* (Calonico et al., 2015a: 1756–7). In addition, global polynomials can lead to counter-intuitive weighting schemes, as discussed by Gelman and Imbens (2019). Common choices for  $p$  are  $p = 1$  or  $p = 2$ .

As we can see, once the bandwidth has been appropriately chosen, the implementation of local polynomial regression reduces to simply fitting two linear or quadratic regressions via weighted least-squares – see Cattaneo et al. (2019a) for an extended discussion and practical introduction. Despite the implementation and algebraic similarities between ordinary least squares (OLS) methods and local polynomial methods, there is a crucial difference: OLS methods assume that the polynomial used for estimation is the true form of the function, while local polynomial methods see it as just an approximation to an unknown regression function. Thus, inherent in the use of local polynomial methods is the idea that the resulting estimate will contain a certain error of approximation or misspecification bias.

This difference between OLS and local polynomial methods turns out to be very consequential for inference purposes – that is, for testing statistical hypotheses and constructing confidence intervals. The conventional OLS inference procedure to test the null hypothesis of no treatment effect at the cutoff,  $H_0: \tau(c) = 0$ , relies on the assumption that the

distribution of the t-statistic is approximately standard normal in large samples:

$$\frac{\hat{\tau}}{\sqrt{\mathcal{V}}} \stackrel{a}{\sim} N(0,1) \quad (11)$$

where  $\mathcal{V}$  is the (conditional) variance of  $\hat{\tau}$ , that is, the square of the standard error.

However, this will only occur in cases where the misspecification bias or approximation error of the estimator  $\hat{\tau}$ , for  $\tau(c)$  becomes sufficiently small in large samples, so that the distribution of the t-statistic is correctly centered at zero. In general, this will not occur in RD analysis, where the local polynomials are used as a non-parametric approximation device and do not make any specific functional form assumptions about the regression functions  $\mu_1(x)$  and  $\mu_0(x)$ , which will generally be misspecified. The general approximation to the t-statistic in the presence of misspecification error is

$$\frac{\hat{\tau} - \mathcal{B}}{\sqrt{\mathcal{V}}} \stackrel{a}{\sim} N(0,1) \quad (12)$$

where  $\mathcal{B}$  is the (conditional) bias of  $\hat{\tau}$  for  $\tau(c)$ . This approximation will be equivalent to the one in equation (11) only when  $\mathcal{B} / \sqrt{\mathcal{V}}$  is small, at least in large samples.

More generally, it is crucial to account for the bias  $\mathcal{B}$  when conducting inference. The magnitude of the bias depends on the shape of the true regression functions and on the length of the bandwidth. As discussed before, the smaller the bandwidth, the smaller the bias. Although the conventional asymptotic approximation in equation (11) will be valid in some special cases, such as when the bandwidth is small enough, it is not valid in general. In particular, if the bandwidth chosen for implementation is the MSE-optimal bandwidth discussed in the prior section, the bias will remain even in large samples, making inferences based on equation (11) invalid. In other words, the

MSE-optimal bandwidth, which is optimal for point estimation, is too large when conducting inference, according to the usual OLS approximations.

Generally valid inferences thus require researchers to use the asymptotic approximation in equation (12), which contains the bias. In particular, Calonico et al. (2014b) propose a way to construct a t-statistic that corrects the bias of the estimator (thus making the approximation valid for more bandwidth choices, including the MSE-optimal choice) and simultaneously adjusts the standard errors to account for the variability that is introduced in the bias-correction step – this additional variability is introduced because the bias is unknown and thus must be estimated. This approach is known as *robust bias-corrected* inference.

Based on the approximation (12), Calonico et al. (2014b) propose robust bias-corrected confidence intervals

$$CI_{rbc} = \left[ \hat{\tau} - \hat{\mathcal{B}} \pm 1.96 \sqrt{\mathcal{V}_{bc}} \right], \quad (13)$$

where, in general,  $\mathcal{V}_{bc} > \mathcal{V}$  because  $\mathcal{V}_{bc}$  includes the variability of estimating  $\mathcal{B}$  with  $\hat{\mathcal{B}}$ . In terms of implementation, the infeasible variance  $\mathcal{V}_{bc}$  can be replaced by a consistent estimator  $\hat{\mathcal{V}}_{bc}$ , which can account for heteroskedasticity and clustering as appropriate.

Robust bias-correction methods for RD designs have been further developed in recent years. For example, see Calonico et al. (2019b) for robust bias-correction inference in the context of RD designs with covariate adjustments, clustered data, and other empirically relevant features. In addition, see Calonico et al. (2018, 2019a, 2019b, 2020) for theoretical results justifying some of features of robust bias-correction inference. Finally, see Ganong and Jäger (2018) and Hyytinen et al. (2018) for two recent applications and empirical comparisons of robust bias-correction methods.

### Continuity-based framework: summary

#### 1 Key assumptions:

- a) Random potential outcomes drawn from an infinite population
- b) The regression functions are continuous at the cutoff

#### 2 Bandwidth selection:

- a) Systematic, data-driven selection based on nonparametric methods
- b) Optimality criteria: MSE, coverage error

#### 3 Estimation:

- a) Nonparametric local polynomial regression within bandwidth
- b) Choice parameters: order of the polynomial, weighting method (kernel)

#### 4 Inference:

- a) Large-sample normal approximation
- b) Robust, bias corrected

## THE LOCAL RANDOMIZATION FRAMEWORK

The local randomization approach to RD analysis provides an alternative to the continuity-based framework. Instead of relying on assumptions about the continuity of regression functions and their approximation and extrapolation, this approach is based on the idea that close enough to the cutoff, the treatment can be interpreted to be ‘as good as randomly assigned’. The intuition is that if units either have no knowledge of the cutoff or have no ability to precisely manipulate their own score, units whose scores are close enough to the cutoff will have the same chance of being barely above the cutoff as barely below it. If this is true, then close enough to the cutoff, the RD design may create experimental-like variation in treatment assignment. The idea that RD designs create conditions that resemble an experiment near the cutoff has been present since the origins of the method (see Thistlethwaite and Campbell, 1960) and sometimes has been proposed as a heuristic interpretation of continuity-based RD results.

Cattaneo et al. (2015) used this local randomization idea to develop a formal framework and to derive alternative assumptions for the analysis of RD designs, which are stronger than the typical continuity conditions. The formal local randomization framework was further developed by Cattaneo et al. (2017). The central idea behind the local randomization approach is to assume the existence of a neighborhood or window around the cutoff where the assignment to above or below the cutoff behaves as it would have behaved in an experiment that assigned all units to treatment with equal (and known) probability.

The formalization of these assumptions requires a more general notation. In prior sections, we used  $Y_i(D_i)$  to denote the potential outcome under treatment  $D_i$ , which could be equal to one (treatment) or zero (control). Since  $D_i = \mathbb{I}(X_i \geq c)$ , this also allowed the score  $X_i$  to indirectly affect the potential outcomes; moreover, this notation did not prevent  $Y_i(\cdot)$  from being a function of  $X_i$ ; but this was not explicitly noted. We now generalize the notation to explicitly note that the potential outcomes may be a direct function of  $X_i$ , so we

write  $Y_i(D_i, X_i)$ . In addition, note that here and in all prior sections, we are implicitly assuming that potential outcomes only depend on unit  $i$ 's own treatment assignment and running variable, an assumption known as SUTVA (stable unit treatment value assumption). While some of the methods described in this section are robust to some violations of the SUTVA, we impose this assumption to ease exposition. See Cattaneo et al. (2017) for more discussion.

To formalize the local randomization RD approach, we assume that there exists a window  $W_0$  around the cutoff where the following two conditions hold:

- **Unconfounded assignment.** The distribution function of the score inside the window,  $F_{X_i | X_i \in W_0}(r)$ , does not depend on the potential outcomes, is the same for all units, and is known:

$$F_{X_i | X_i \in W_0}(x) = F_0(x), \quad (14)$$

where  $F_0(x)$  is a known distribution function.

- **Exclusion restriction.** The potential outcomes do not depend on the value of the running variable inside the window, except via the treatment assignment indicator

$$Y_i(d, x) = Y_i(d), \quad \forall i \quad (15)$$

*such that*  $X_i \in W_0$ .

This condition requires the potential outcomes to be unrelated to the score inside the window.

Importantly, these two assumptions would *not* be satisfied by randomly assigning the value of the score (and hence the treatment) inside  $W_0$ , because the random assignment of the score inside  $W_0$  does not by itself guarantee that the score and the potential outcomes are unrelated (the exclusion restriction). For example, imagine a RD design based on elections, where the treatment is the electoral victory of a political party, the score is the vote share, and the party wins the election if the vote share is above 50%. Even in

very close races, donors might still believe that districts where the party obtained a bare majority are more likely to support the party again, and thus they may donate more money to the races where the party's vote share was just above 50% than to races where the party was just below 50%. If donations are effective in boosting the party, this would induce a positive relationship near the cutoff between the running variable (vote share) and the outcome of interest (victory in the future election), even when the running variable is initially randomly assigned.

This illustrates why the unconfounded assignment assumption in equation (14) is not enough for a local randomization approach to RD analysis. In addition, we must explicitly assume that the score and the potential outcomes are unrelated inside  $W_0$ , which is not implied by equation (14). This issue is discussed in detail by Sekhon and Titiunik (2017), who use several examples to show that the exclusion restriction in equation 15 is implied neither by assuming statistical independence between the potential outcomes and the treatment in  $W_0$  nor by assuming that the running variable is randomly assigned in  $W_0$ . In addition, see Sekhon and Titiunik (2016) for a discussion of the status of RD designs among observational studies and Titiunik (2020) for a discussion of the connection between RD designs and natural experiments.

### ***Estimation and Inference within a Known Window***

The local randomization conditions (14) and (15) open new possibilities for RD estimation and inference. Of course, these conditions are strong and, just like the continuity conditions in the third section, they are not implied by the RD treatment assignment rule but rather must be assumed in addition to it (Sekhon and Titiunik, 2016). Because these assumptions are strong and are inherently untestable, it is

crucial for researchers to provide as much information as possible regarding their plausibility. We discuss this issue in the fifth section, where we present several strategies for empirical falsification of the RD assumptions.

The key assumption of the local randomization approach is that there exists a neighborhood around the cutoff in which equations (14) and (15) hold – implying that we can treat the RD design as a randomized experiment near the cutoff. We denote this neighborhood by  $W_0 = [c - w, c + w]$ , where  $c$  continues to be the RD cutoff, but we now use the notation  $w$  as opposed to  $h$  to emphasize that  $w$  will be chosen and interpreted differently from the previous section. Furthermore, to ease the exposition, we start by assuming that  $W_0$  is known and then discuss how to select  $W_0$  based on observable information. This data-driven window selection step will be crucial in applications, as in most empirical examples,  $W_0$  is fundamentally unknown, if it exists at all – but see Hyytinen et al. (2018) for an exception.

Given a window  $W_0$ , the local randomization framework summarized by assumptions (14) and (15) allows us to analyze the RD design employing the standard tools of the classical analysis of experiments. Depending on the available number of observations inside the window, the experimental analysis can follow two different approaches. In the Fisherian approach, also known as a randomization inference approach, potential outcomes are considered non-random, the assignment mechanism is assumed to be known, and this assignment is used to calculate the exact finite-sample distribution of a test statistic of interest under the null hypothesis that the treatment effect is zero for every unit. On the other hand, in the large-sample approach, the potential outcomes may be fixed or random, the assignment mechanism need not be known, and the finite-sample distribution of the test statistic is approximated under the assumption that the number of observations is large. Thus,

in contrast to the Fisherian approach, in the large-sample approach inferences are based on test statistics whose finite-sample properties are unknown but whose null distribution can be approximated by a normal distribution under the assumption that the sample size is large enough.

Next, we briefly review both Fisherian and large-sample methods for analysis of RD designs under a local randomization framework. Fisherian methods will be most useful when the number of observations near the cutoff is small, which may render large-sample methods invalid. In contrast, in applications with many observations, large-sample methods will be the most natural approach, and Fisherian methods can be used as a robustness check.

### *Fisherian Approach*

In the Fisherian framework, the potential outcomes are seen as fixed, non-random magnitudes from a finite population of  $n$  units. The information on the observed sample of units  $i = 1, \dots, n$  is not seen as a random draw from an infinite population but as the population of interest. This feature allows for the derivation of the finite-sample-exact distribution of test statistics without relying on approximations.

We follow the notation in Cattaneo et al. (2017), slightly adapting our previous notation. Let  $\mathbf{X} = (X_1, \dots, X_n)'$  denote the  $n \times 1$  column vector collecting the observed running variable of all units in the sample, and let  $\mathbf{D} = (D_1, \dots, D_n)'$  be the vector collecting treatment assignments. The non-random potential outcomes for each unit  $i$  are denoted by  $y_i(d, x)$  where  $d$  and  $x$  are possible values for  $D_i$  and  $X_i$ . All the potential outcomes are collected in the vector  $\mathbf{y} = (\mathbf{d}, \mathbf{x})$ . The vector of observed outcomes is simply the vector of potential outcomes, evaluated at the observed values of the treatment and running variable,  $\mathbf{Y} = \mathbf{y}(\mathbf{D}, \mathbf{X})$ .

Because potential outcomes are assumed non-random, all the randomness in the model

enters through the running variable vector  $\mathbf{X}$  and the treatment assignment  $\mathbf{D}$ , which is a function of it. In what follows, we let the subscript ‘0’ indicate the sub-vector inside the neighborhood  $W_0$ , so that  $\mathbf{X}_0$ ,  $\mathbf{D}_0$ , and  $\mathbf{Y}_0$  denote the vectors of running variables, treatment assignments, and observed outcomes inside  $W_0$ . Finally,  $N_0^+$  denotes the number of observations inside the neighborhood and above the cutoff (treated units inside  $W_0$ ) and  $N_0^-$  the number of units in the neighborhood below the cutoff (control units in  $W_0$ ), with  $N_0 = N_0^+ + N_0^-$ . Note that using the fixed-potential outcomes notation, the exclusion restriction becomes  $y_i(d, x) = y_i(d)$ ,  $\forall i \in W_0$  (see assumption 1(b) in Cattaneo et al., 2015).

In this Fisherian framework, a natural null hypothesis is the *sharp null of no effect*:

$$H_0^s: y_i(1) = y_i(0), \quad \forall i \in W_0.$$

This sharp null hypothesis states that switching treatment status does not affect potential outcomes, implying that the treatment does not have an effect on *any* unit inside the window. In this context, a hypothesis is *sharp* when it allows the researcher to impute all the missing potential outcomes. Thus,  $H_0^s$  is sharp because when there is no effect, all the missing potential outcomes are equal to the observed ones.

Under  $H_0^s$ , the researcher can impute all the missing potential outcomes and, since the assignment mechanism is assumed to be known, it is possible to calculate the distribution of any test statistic  $T(\mathbf{D}_0, \mathbf{Y}_0)$  to assess how far in the tails the observed statistic falls. This reasoning provides a way to calculate a p-value for  $H_0^s$  that is finite-sample exact and does not require any distributional approximation. This randomization inference p-value is obtained by calculating the value of  $T(\mathbf{D}_0, \mathbf{Y}_0)$  for all possible values of the treatment vector inside the window  $\mathbf{D}_0$  and calculating the probability of  $T(\mathbf{D}_0, \mathbf{Y}_0)$  being larger than

the observed value  $T_{obs}$ . See Cattaneo et al. (2015), Cattaneo et al. (2017) and Cattaneo et al. (2016b) for further details and implementation issues. See also Cattaneo et al. (2020a) for a practical introduction to local randomization methods.

In addition to testing the null hypothesis of no treatment effect, the researcher may be interested in obtaining a point estimate for the effect. When condition (15) holds, a difference in means between treated and controls inside the window,

$$\delta = \frac{1}{N_0^+} \sum_{i=1}^n Y_i D_i - \frac{1}{N_0^-} \sum_{i=1}^n Y_i (1 - D_i),$$

where the sum runs over all observations inside  $W_0$ , is unbiased for the sample average treatment effect in  $W_0$ ,

$$\tau_0 = \frac{1}{N_0} \sum_{i=1}^n (y_i(1) - y_i(0)).$$

However, it is important to emphasize that the randomization inference method described above cannot test hypotheses on  $\tau_0$ , because the null hypothesis that  $\tau_0 = 0$  is not sharp – that is, does not allow the researcher to unequivocally impute all the missing potential outcomes without further restrictive assumptions, which is a necessary condition to use Fisherian methods. Hence, under the assumptions imposed so far, hypothesis testing on  $\tau_0$  has to be based on asymptotic approximations, as described in the next section, on large-sample approaches.

The assumption that the potential outcomes do not depend on the running variable, stated in equation (15), can be relaxed by assuming a local parametric model for the relationship between  $\mathbf{Y}_0$  and  $\mathbf{X}_0$ . Specifically, Cattaneo et al. (2017) assume there exists a transformation  $\varphi(\cdot)$  such that the transformed outcomes do not depend on  $\mathbf{X}_0$ . This transformation could be, for instance, a linear adjustment that

removes the slope whenever the relationship between outcomes and the running variable is assumed to be linear. The case where potential outcomes do not depend on the running variable is a particular case in which  $\varphi(\cdot)$  is the identity function. Both inference and estimation can therefore be conducted using the transformed outcomes when the assumption that potential outcomes are unrelated is not reasonable or as a robustness check.

### *Large-Sample Approach*

In the most common large-sample approach, we treat potential outcomes as random variables and often see the units in the study as a random sample from a larger population (though in the Neyman large-sample approach, potential outcomes are fixed; see Imbens and Rubin (2015) for more discussion). In addition to the randomness of the potential outcomes, this approach differs from the Fisherian approach in its null hypothesis of interest. Given the randomness of the potential outcomes, the focus is no longer on the sharp null but rather typically on the hypothesis that the average treatment effect is zero. In our RD context, this null hypothesis can be written as

$$H_0^s : \mathbb{E}[Y_i(1)] = \mathbb{E}[Y_i(0)], \quad \forall_i \in W_0$$

Inference in this case is based on the usual large-sample methods for the analysis of experiments, relying on usual difference-in-means tests and normal-based confidence intervals. See Imbens and Rubin (2015) and Cattaneo et al. (2020a) for details.

### *Window Selection*

In practice, the window  $W_0$  in which the RD design can be seen as a randomized experiment is not known and needs to be estimated. Cattaneo et al. (2015) propose a window

selection mechanism based on the idea that in a randomized experiment, the distribution of observed covariates has to be equal between treated and controls. Thus, if the local assumption is plausible in any window, it should be in a window where we cannot reject the premise that the predetermined characteristics of treated and control units are, in distribution identical.

The idea of this procedure is to select a test statistic that summarizes differences in a vector of covariates between groups, such as the difference-in-means or the Kolmogorov–Smirnov statistic, and start with an initial ‘small’ window. Inside this initial window, the researcher conducts a test of the null hypothesis that covariates are balanced between treated and control groups. This can be done, for example, by assessing whether the minimum p-value from the tests of differences-in-means for each covariate is larger than some specified level or by conducting a joint test using, for instance, a Hotelling statistic. If the null hypothesis is not rejected, enlarge the window and repeat the process. The selected window will be the widest window in which the null hypothesis is not rejected. Common choices for the test statistic  $T(\mathbf{D}_0, \mathbf{Y}_0)$  are the difference-in-means between treated and controls, the two-sample Kolmogorov–Smirnov statistic, and the rank sum statistic. The minimum window to start the procedure should contain enough observations to ensure enough statistical power to reject the null hypothesis of covariate balance. The appropriate minimum number of observations will naturally depend on unknown, application-specific parameters, but based on standard power calculations, we suggest using no fewer than approximately 10 observations in each group.

See Cattaneo et al. (2015) and Cattaneo et al. (2017) for methodological details, Cattaneo, et al. (2020a) for a practical introduction, and Cattaneo et al. (2016b) for software implementation.

### Local randomization framework: summary

#### 1 Key assumptions:

- a) There exists a window  $W_0$  in which the treatment assignment mechanism satisfies two conditions:
- Probability of receiving a particular score value in  $W_0$  does not depend on the potential outcomes and is the same for all units
  - Exclusion restriction or parametric relationship between  $\mathbf{Y}$  and  $\mathbf{X}$  in  $W_0$

#### 2 Window selection:

- a) Goal: find a window where the key assumptions are plausible  
 b) Iterative procedure to balance observed covariates between groups  
 c) Choice parameters: test statistic, stopping rule

#### 3 Estimation:

- a) Difference in means between treated and controls within neighborhood, OR  
 b) Flexible parametric modeling to account for the effect of  $X_i$

#### 4 Inference:

- a) Fisherian randomization-based inference or large-sample inference  
 b) Conditional on sample and chosen window  
 c) Choice parameter: test statistic, randomization mechanism in Fisherian

## FALSIFICATION METHODS

Every time researchers use an RD design, they must rely on identification assumptions that are fundamentally untestable and that do not hold by construction. On one hand, if we employ a continuity-based approach, we must assume that the regression functions are smooth functions of the score at the cutoff. If, on the other hand, we employ a local randomization approach, we must assume that there exists a window where the treatment behaves as if it had been randomly assigned. These assumptions may be violated for many reasons. Thus, it is crucial for researchers to provide as much empirical evidence as possible about its validity.

Although testing the assumptions directly is not possible, there are several empirical regularities that we expect to hold in most cases where the assumptions are met. We discuss some of these tests below. Our discussion is brief, but we refer the reader to

Cattaneo et al. (2019a) for an extensive practical discussion of RD falsification methods and additional references.

- 1 **Covariate balance.** If either the continuity or local randomization assumptions hold, the treatment should not have an effect on any predetermined covariates, that is, on covariates whose values are realized before the treatment is assigned. Since the treatment effect on predetermined covariates is zero by construction, consistent evidence of non-zero effects on covariates that are likely to be confounders would raise questions about the validity of the RD assumptions. For implementation, researchers should analyze each covariate as if it were an outcome. In the continuity-based approach, this requires choosing a bandwidth and performing local polynomial estimation and inference within that bandwidth. Note that the optimal bandwidth is naturally different for each covariate. In the local randomization approach, the null hypothesis of no effect should be tested for each covariate using the same choices as used for the outcome. If the window is chosen

using the covariate-balance procedure discussed above, the selected window will automatically be a region where no treatment effects on covariates are found.

- 2 **Density of running variable.** Another common falsification test is to study the number of observations near the cutoff. If units cannot manipulate precisely the value of the score that they receive, we should expect as many observations just above the cutoff as just below it. In contrast, if units had the power to affect their score and they knew that the treatment were very beneficial, for example, we should expect more people just above the cutoff (where the treatment is received) than below it. In the continuity-based framework, the procedure is to test the null hypothesis that the density of the running variable is continuous at the cutoff (McCrary, 2008), which can be implemented in a more robust way via the novel density estimator proposed in Cattaneo et al. (2020b). In the local randomization framework, Cattaneo et al. (2017) propose a novel implementation via a finite-sample exact binomial test of the null hypothesis that the number of treated and control observations in the chosen window is compatible with a 50% probability of treatment assignment.
- 3 **Alternative cutoff values.** Another falsification test estimates the treatment effect on the outcome at a cutoff value different from the actual cutoff used for the RD treatment assignment, using the same procedures that were used to estimate the effect in the actual cutoff but only using observations that share the same treatment status (all treatment observations if the artificial cutoff is above the real one or all control observations if the artificial cutoff is below the real cutoff). The idea is that no treatment effect should be found at the artificial cutoff, since the treatment status is not changing.
- 4 **Alternative bandwidth and window choices.** Another approach is to study the robustness of the results to small changes in the size of the bandwidth or window. For implementation, the main analysis is typically repeated for values of the bandwidth or window that are slightly smaller and/or larger than the values used in the main analysis. If the effects completely change or disappear for small changes in the chosen neighborhood, researchers should be cautious in interpreting their results.

## EMPIRICAL ILLUSTRATION

To illustrate all the RD methods discussed so far, we partially reanalyze the study by Klašnja and Titiunik (2017). These authors study municipal mayor elections in Brazil between 1996 and 2012, examining the effect of a party's victory in the current election on the probability that the party wins a future election for mayor in the same municipality. The unit of analysis is the municipality, the score is the party's margin of victory at election  $t$  – defined as the party's vote share minus the vote share of the party's strongest opponent, and the treatment is the party's victory at  $t$ . Their original analysis focuses on the unconditional victory of the party at  $t + 1$  as the outcome of interest. In this illustration, our outcome of interest is instead the party's margin of victory at  $t + 1$ , which is only defined for those municipalities where the incumbent party runs for reelection at  $t + 1$ . We analyze this effect for the incumbent party (defined as the party that won election  $t - 1$ , whatever this party is) in the full sample. Klašnja and Titiunik (2017) discuss the interpretation and validity issues that arise when conditioning on the party's decision to rerun, but we ignore such issues here for the purposes of illustration.

In addition to the outcome and score variables used for the main empirical analysis, our covariate-adjusted local polynomial methods, window selection procedure, and falsification approaches employ seven covariates at the municipality level: per capita GDP, population, number of effective parties, and indicators for whether each of the four parties (the Democratas, PSDB, PT, and PMDB) had won the prior ( $t - 1$ ) election.

We implement the continuity-based analysis with the `rdrobust` software (Calonico et al., 2014a, 2015b; Calonico et al., 2017), the local randomization analysis using the `rdlocand` software (Cattaneo et al., 2016b), and the density test falsification using the `rddensity` software (Cattaneo et al., 2018).

The packages can be obtained for R and Stata from <https://sites.google.com/site/rdpackages/>. We do not present the code to conserve space, but the full code employed is available in the packages' website. Cattaneo et al. (2019a, 2020b) offer a detailed tutorial on how to use these packages, employing a different empirical illustration.

### Falsification Analysis

We start by presenting a falsification analysis. In order to falsify the continuity-based analysis, we analyze the density of the running variable and also the effect of the RD treatment on several predetermined covariates. We start by reporting the result of a continuity-based density test, using the local polynomial density estimator developed by Cattaneo et al. (2019b). The estimated difference in the density of the running variable at the cutoff is  $-0.0753$ , and the p-value associated with the test of the null hypothesis that this difference is zero is 0.94. This test is illustrated in Figure 44.1, which shows the local polynomial estimated density of the incumbent party's margin of victory at  $t$  at the cutoff, separately estimated from above and below the cutoff. These results indicate

**Figure 44.1.** Estimated density of running variable

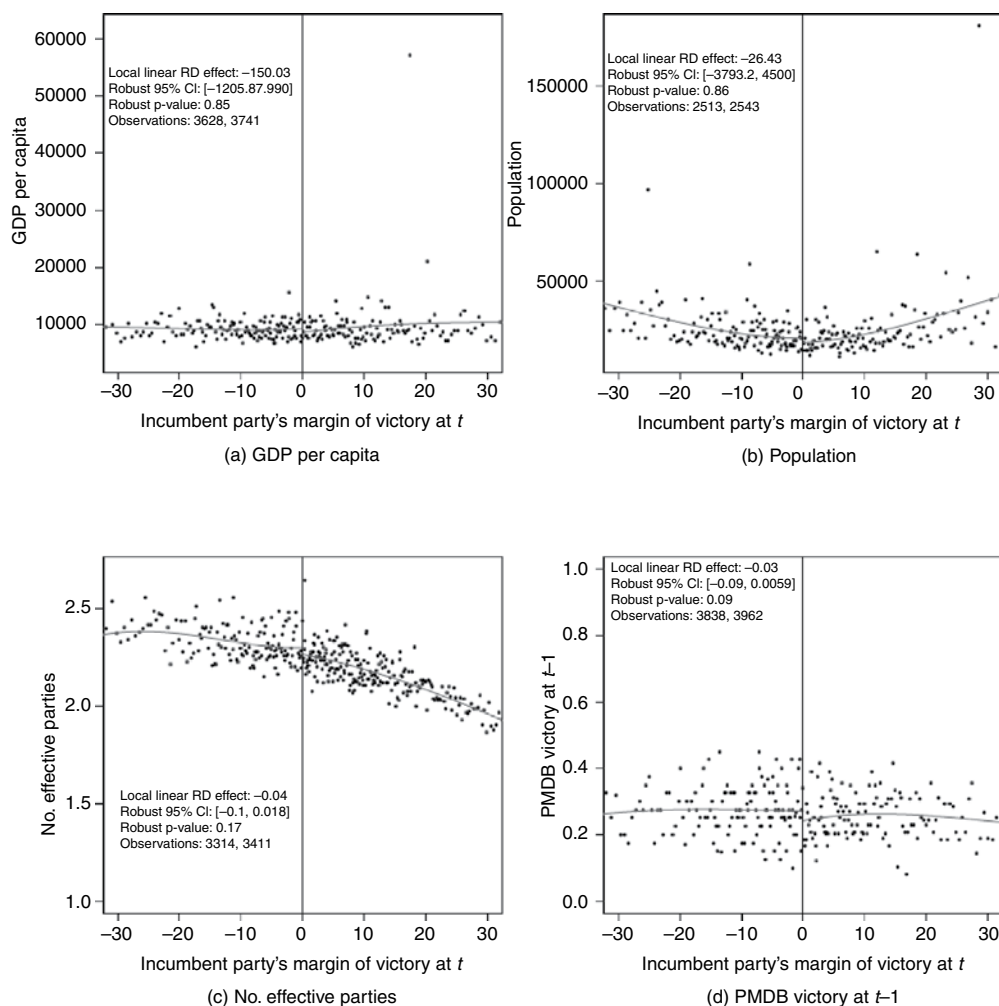

that the density of the running variable does not change abruptly at the cutoff and are thus consistent with the assumption that parties do not precisely manipulate their margin of victory to ensure a win in close races.

In addition, we also implemented the finite-sample exact binomial tests proposed in Cattaneo et al. (2017), which confirmed the empirical results obtained via local polynomial density methods. We do not report these numerical results, in order to conserve space, but they can be consulted using the accompanying replication files.

We also present local polynomial point estimates of the effect of the incumbent party's victory on each of the seven predetermined covariates mentioned above, and we perform robust local-polynomial inference to obtain confidence intervals and p-values for these effects. Since these covariates are all determined before the outcome of the election at  $t$  is known, the treatment effect on each of them is zero by construction. Our estimated effects and statistical inferences should therefore be consistent with these known null effects.

We present the results graphically in Figures 44.2 and 44.3 using typical RD plots (Calonico et al., 2015a), where binned means of the outcome within intervals of the score are plotted against the mid point of the score in each interval. A fourth-order polynomial, separately estimated above and below the cutoff, is superimposed to show the global shape of the regression functions. In these plots, we also report the formal local polynomial point estimate, 95% robust confidence interval, robust p-value, and number of observations within the bandwidth. The bandwidth (not reported) is chosen in each case to be MSE-optimal.

As we can see, the incumbent party's bare victory at  $t$  does not have an effect on any of the covariates. All 95% confidence intervals contain zero, most of these intervals are approximately symmetric around zero, and most point estimates are small. These results show that there are no obvious or notable

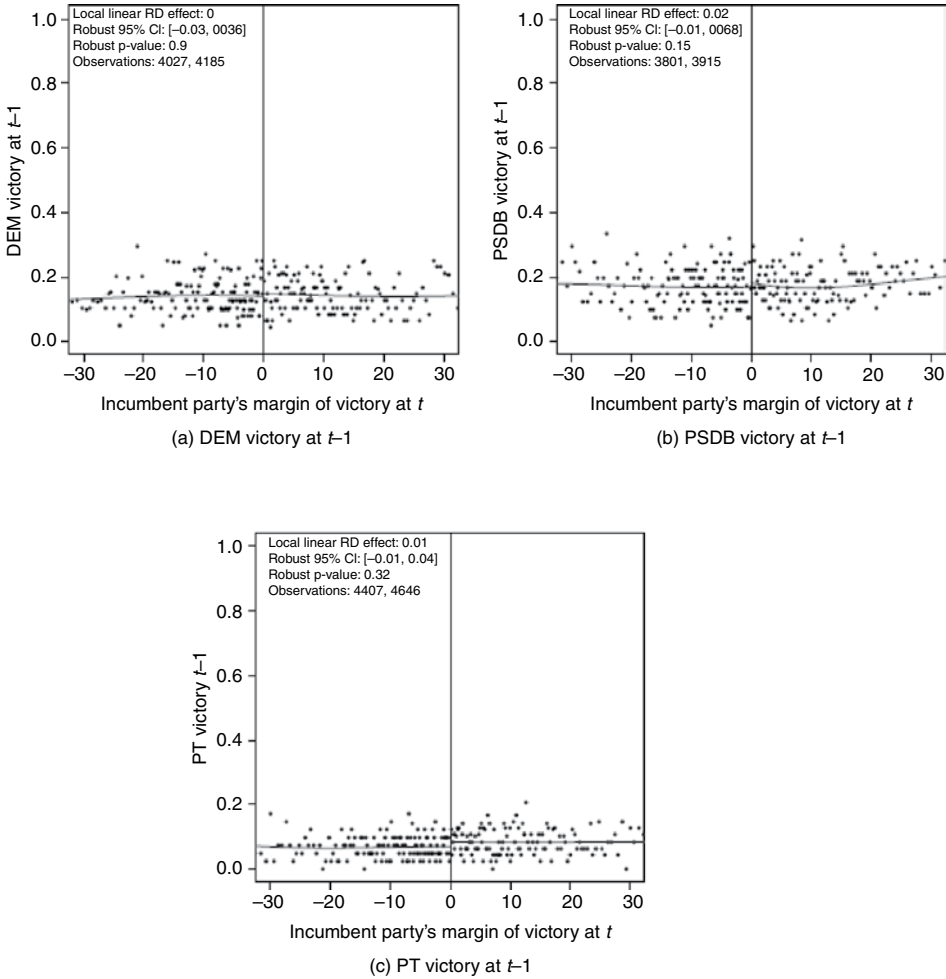

**Figure 44.2.** RD effects on predetermined covariates

covariate differences at the cutoff between municipalities where the incumbent party barely won at  $t$  and municipalities where the incumbent party barely lost at  $t$ .

### Outcome Analysis

Since the evidence from our falsification analysis is consistent with the validity of our RD design, we now proceed to analyze the treatment effect on the main outcome of

interest – the incumbent party’s margin of victory at  $t + 1$ . This effect is illustrated in Figure 44.4. A stark jump can be seen at the cutoff, where the margin of victory of the incumbent party at  $t + 1$  abruptly decreases as the score crosses the cutoff. This indicates that municipalities where the incumbent party barely wins at  $t$  obtain a lower margin of victory at election  $t + 1$  compared with municipalities where the incumbent party barely loses at  $t$ , one of the main substantive findings in Klačnjana and Titiunik (2017).

**Figure 44.3. RD effects on predetermined covariates**

We now analyze this effect formally. We first analyze RD effects using the continuity-based framework, employing local polynomial methods with  $p = 1$  and a MSE-optimal bandwidth. For inference, we use robust bias-corrected 95% confidence intervals. As we can see in Table 44.1, the MSE-optimal bandwidth is estimated to be around 15.3 percentage points, and within this bandwidth, the RD local-polynomial point estimate is about  $-6.3$ . This shows that at the cutoff, a victory at  $t$  reduces the incumbent party's vote margin at  $t + 1$  by about six percentage points

in those municipalities where the party seeks reelection. The 95% robust bias-corrected confidence interval ranges from  $-10.224$  to  $-2.945$ , rejecting the null hypothesis of no effect with a robust p-value of about 0.0004. Including covariates leads to very similar results: the MSE-optimal bandwidth changes to 14.45 and the point estimate moves from  $-6.28$  to  $-6.10$  – a very small change, as expected when the covariates are truly predetermined.

Second, we analyze the main outcome using a local randomization approach. For

**Figure 44.4.** Effect of victory at  $t$  on vote margin at  $t + 1$ . Incumbent party, Brazilian mayoral elections, 1996–2012

**Figure 44.5** Window selector based on covariates. Incumbent party, Brazilian mayoral elections, 1996–2012. The running variable is incumbent party’s margin of victory at  $t$

**Table 44.1** Continuity-based RD analysis: effect of victory at  $t$  on vote margin at  $t + 1$ . Incumbent party, Brazilian mayoral elections, 1996–2012

	RD effect ( $\hat{\tau}$ )	95% robust conf. int.	Robust p-value	$h$	$N_l$	$N_r$
Standard	-6.281	[-10.224, -2.945]	0.0004	15.294	1533	1740
Using covariates	-6.106	[-9.881, -2.656]	0.0007	14.453	1482	1672

this, we must choose the window around the cutoff where the assumption of local randomization appears plausible (if such a window exists). We implement our window selection procedure using the list of covariates mentioned above, an increment of 0.01 percentage points, and a cutoff p-value of 0.15. We use Fisherian randomization-based inference with the difference-in-means as the test statistic and assuming a fixed-margins randomization procedure using the actual number of treated and controls in each window. As shown in Table 44.2, starting at the [0.05, -0.05] window and considering all symmetric windows in 0.01 increments, we see that all windows between [0.05, -0.05] and [0.15, -0.15] have a minimum p-value above 0.15. The window [-0.16, 0.16] is the first window where the minimum p-value drops below 0.15; indeed, it drops all the way

down to 0.061. Thus, our selected window is [-0.15, 0.15], which has exactly 38 observations on each side of the cutoff.

In order to further illustrate the results in Table 44.2, Figure 44.5 shows the associated p-values for all symmetric windows in 0.01 increments between [0.05, -0.05] and [-2.00, 2.00].

In Table 44.3, we present our inference results in the chosen window [-0.15, 0.15], reporting both Fisherian inference (using the same choices as those used in the window selection procedure) and large-sample p-values. The treated-control difference-in-means is -9.992, with a Fisherian p-value of approximately 0.083 and a large-sample p-value of about 0.070, rejecting both the sharp null hypothesis and the hypothesis of no average effect at 10% level. The fact that the point estimate continues to be negative and that

the p-values are 8% and below suggests that the continuity-based results are broadly robust to a local randomization assumption, as both approaches lead to similar conclusions. The local randomization p-value is much larger than the p-value from the continuity-based local polynomial analysis, but this is likely due – at least in part – to the loss of observations, as the sample size goes from a total of 3,412 (1,740 + 1,672) observations to just 39 (19 + 20) (the discrepancy in the number of observations in [-0.15, 0.15] between the outcome analysis and the window-selector analysis stems from missing values in the outcome, as the margin of victory is undefined for races where the party does not run).

## CONCLUSION

We reviewed two alternative frameworks for analyzing sharp RD designs. First, the continuity-based approach, which is more common in empirical work, assumes that the unknown regression functions are continuous at the cutoff. Estimation is conducted non-parametrically using local polynomial methods, and bandwidth selection relies on minimizing a criterion such as the MSE or the coverage error probability. Inference under this framework relies on large sample distributional approximations and requires robust bias correction to account for misspecification errors local to the cutoff. Second, the local randomization approach

formalizes the intuition that RD designs can be interpreted as local experiments in a window around the cutoff. In this case, the window is chosen to ensure that treated and controls are comparable in terms of observed predetermined characteristics, as in a randomized experiment. Within this window, inference is conducted using randomization inference methods assuming that potential outcomes are non-random or other canonical analysis of experiments methods based on large-sample approximations.

These two approaches rely on different assumptions, each with its own advantages and disadvantages, and thus we see them as complementary. On the one hand, the continuity-based approach is agnostic about the data-generating process and does not require any modeling or distributional assumptions on the regression functions. This generality comes at the expense of basing inference on large-sample approximations, which may not be reliable when the sample size is small (a case that is common in RD designs, given their local nature). On the other hand, the Fisherian local randomization approach provides tools to conduct inference that is exact in finite samples and does not rely on distributional approximations. This type of inference is more reliable than large-sample-based inference when the sample size is small. And if the sample size near the cutoff is large, the analysis can also be conducted using standard large-sample methods for the analysis of experiments. However, the conclusions drawn under the local randomization approach (either Fisherian or large-sample) require stronger assumptions (unconfounded assignment, exclusion restriction) than the continuity-based approach, are conditional on a specific sample and window, and do not generalize to other samples or populations.

In sum, as in Cattaneo et al. (2017), we recommend the continuity-based approach as the default approach for analysis, since it does not require parametric modeling assumptions and automatically accounts for misspecification bias in the regression

functions when conducting estimation and inference. The local randomization approach can be used as a robustness check, especially when the sample size is small and the large-sample approximations may not be reliable.

There is one particular case, however, in which the continuity-based approach is not applicable: when the running variable exhibits only a few distinct values or mass points (even if the sample size is large because of repeated values). In this case, the nonparametric methods for estimation, inference, and bandwidth selection described above do not apply, since they are developed under the assumption of local approximations and continuity of the score variable, which are violated by construction when the running variable is discrete with a small number of mass points. Thus, in settings where the running variable has few mass points, local randomization methods – possibly employing only the closest observations to the cutoff – are a more natural approach for analysis. We refer the reader to Cattaneo et al. (2019a) for a more detailed discussion and practical illustration of this point.

## Note

- 1 We thank Rich Nielsen for his comments and suggestions on a previous version of this chapter.

# Network Analysis: Theory and Testing

Jennifer N. Victor and Elsa T. Khwaja

## INTRODUCTION

Although it is intuitive to conceptualize politics as a process that involves interactions, only within the last 20 years have political scientists had the theoretical and computational assets to fully engage an array of political questions using network-based theory and methods. Technological advances make computationally expensive network analysis more accessible to more scholars. This chapter proceeds by describing the major contributions that network analysis has made to the discipline of political science. The chapter continues with a discussion of the fundamental components of a network, which is tied to formal network theory. Then, a discussion follows of the basics of mathematical graph theory, as applicable to network analysis in politics. Next, the chapter gives practical advice about working with network data, including a section on how to visualize and represent relational data. Finally, the chapter closes with a discussion of properties of whole

networks and draws on political science examples, particularly the concepts of cohesion, reciprocity, transitivity, and centrality.

## THE ADDED VALUE OF NETWORKS IN POLITICAL SCIENCE

A diverse array of academic fields – anthropology, sociology, political science, and economics – have made fruitful applications of network theory and methods to important questions in public policy and international affairs. Social scientists from these intersecting fields have made significant contributions to the study of networks. As networks are omnipresent in social and political institutions, social network analysis is a multi-disciplinary methodology and paradigm, blending multiple methods and empirical applications that are evident in data collection and data analysis in both quantitative and qualitative techniques.

Network applications have made profound contributions to the study of US politics, from political discourse and voting, to legislative politics and political parties. Groundbreaking research from the so-called mid-20th-century Columbia school of political behavior focused attention on the relationship between mass communication and political behavior (Berelson, 1954; Lazarsfeld et al., 1948), which created the foundation on which the subfield of political behavior was built. The Michigan school developed the theoretical and empirical demonstrations of individual political behavior as being the psychological product of social context (Campbell et al., 1980; Putnam, 1966). Later, this thread of research became more explicitly relational and scholars expanded the understanding of individual political behavior by treating it as explicitly interdependent (Huckfeldt and Sprague, 1987a; Klofstad et al., 2013; McClurg, 2006; Mutz 2002; Sokhey and McClurg, 2012).

Researchers who specifically studied voting behavior then transformed a decades-long understanding of the individual motivation to vote, by applying network theory (Nickerson, 2008; Rolfe, 2013; Sinclair, 2012). In the legislative arena, scholars have long recognized the importance of social connections between lawmakers (Eulau, 1962; Patterson, 1959; Routt, 1938) but only recently had the computational power to study directly the patterns of relationships and their effect on legislative action by looking at co-sponsorship (Bratton and Rouse, 2011; Burkett and Skvoretz, 2001; Tam Cho and Fowler, 2010), committee assignments (Porter et al., 2005), campaign contributions (Kirkland, 2011; Koger and Victor, 2009; Victor and Koger, 2016), legislative staff (Montgomery and Nyhan, 2017; Ringe and Victor, 2013), and other subjects.

Beyond US politics, network methods and theories have been applied in many studies in the subfields of international relations, international development, human rights advocacy, and environmental studies, as well as to

the study of democratic peace, cooperation, and conflict. Hafner-Burton et al. (2009) write about network structure in international relations, specifically the power structures among international players. Analysis shows how state membership in international organizations creates positions of power that may sustain conflicts among states (Hafner-Burton and Montgomery, 2006). Further, Kinsella and Montgomery (2017) demonstrate the significance of networks of regional and global arms flows, lending critical observations on the study of arms supply and proliferation networks within the context of international security.

Network effects are also relevant in understanding major-party interventions on militarized interstate disputes, revealing that major parties influence other states' choices to join in conflicts (Corbetta and Dixon, 2005). Studies on terrorist or insurgency networks also contribute to critical observations about the significance of cohesion in networks. Staniland (2012) provides a qualitative account about the cohesion of insurgent groups in conflict-affected states, with a look into the dynamics of terrorist networks in Afghanistan, Kashmir, and Sri Lanka. In another study on terrorist networks, Horowitz and Potter (2013) write about how different terrorist organizations form intergroup alliances. They show how the organizations form preferential attachments with core-periphery network structures, which suggests the importance of a broader policy lens of addressing counterinsurgency tactics.

One common technique social scientists have used for identifying political networks between common citizens is the so-called 'name generator' approach, where survey respondents are asked to name their network contacts. While it is nearly impossible to identify the complete network of connections of a particular population through this method, it is highly useful for scholars who seek to engage in an 'egocentric' analysis. In such an approach, the scholar gathers information about the network of a particular

actor or set of actors and may draw inference about some outcome of interest based on the set of connections from these individualistic perspectives.

The approach was pioneered by sociologists in the 1980s (Burt, 1985) and adapted by political scientists (Huckfeldt and Sprague, 1987b). Its use has been critical to the study of social, political, and communication networks and has been adapted for application in the developing world – in particular to the spread of microfinance programs in India (Banerjee, 2012) and household level interactions in southern India (Shakya et al., 2017).

Recent policy networks studies have made significant contributions to an understanding of environmental sustainability and other topics critically related to environmental policy (Berardo and Lubell, 2016; Broadbent, 2017; Eilstrup-Sangiovanni, 2017). Broadbent's (2017) study examines a climate-change initiative that shows how differences among cases in the national policy-formation process are related to differences in their mitigation policies and carbon emissions. Additionally, with the use of policy networks, one can understand how bridging and bonding social capital are generated when governmental and non-governmental actors participate in forums on environment and climate change (Berardo and Lubell, 2016).

In part due to availability of data, scholars are benefiting from using human-generated data on social network platforms to study questions of political importance. An analysis of online blogs, social media including Facebook, Twitter, LinkedIn, and other online networks – as well as cyber-criminal networks – provide important insights on the online behavior of social media and how people engage with information. For example, a study of fake news and online engagement with misinformation is a relatively new area of research that attracts the interests of political networks analysts (Grinberg, 2018). Online networks intersect with a variety of topics from political discussion networks and engagement in political conversations on

social platforms, to social-media behaviors and cybercrimes (Klofstad et al., 2013; Lazer et al., 2015; Sokhey et al., 2015).

But even in a high-tech world with social media replacing traditional dialogue, many political scientists have increasingly incorporated fieldwork into their network-oriented research (Kapiszewski et al., 2015). One example is the application of Netmap, a tool used for understanding influence in a rural-development-program network, it uses participatory field-research methods that provide quantitative and qualitative data through low-cost, low-tech usage. (Schiffer and Hauck, 2010). It allows a low-tech, convenient way to conduct a social network analysis for a field study about all the stakeholders that can give a more sustainable solution for watershed management in the White Volta River Basin in northern Ghana. As a result, it generates a fuller understanding among stakeholders of their relationships and their level of influence (Schiffer and Hauck, 2010).

As the interdisciplinary nature of network analysis can be applied to diverse areas of study, network analysis can have great comparative value by demonstrating what types of networks matter over others (Razo, 2017; Vera and Schupp, 2006). Network analyses remain underutilized in comparative politics, where great insights are possible by blending network approaches with qualitative approaches. Some comparative politics scholars have noted the lack of network analysis and qualitative content analysis in the body of political-science literature (Fischer, 2011). Using both techniques, Fischer (2011) conducts an empirical study of Swiss political networks and compares 11 policy networks; he finds that the structure of the networks is the result of policy context, including the degree of Europeanization, federalism, intensity of the pre-parliamentary phase, and public attention.

Further, networks methods have been an increasingly relied upon tool to analyze global policy networks (Knoke and

Kostiuchenko, 2017). In recent decades, one emerging area in global public policy is the notion of ‘network governance’ (Eilstrup-Sangiovanni, 2017; Faul 2016). As the world becomes increasingly complex and interconnected, the toolbox of social scientific theories and methods to understand these complexities also expands.

One aspect of the trend is the growing literature about networks methods to analyze global and local human rights advocacy networks. The networks include local governance networks, civil-society organizations, also called CSOs, and transnational advocacy networks, or TANs (Keck and Sikkink, 1997; Murdie and Polizzi, 2017; Reinicke et al., 2000). For example, Murdie and Polizzi’s (2017) study examines how the human rights agenda, issues, and outcomes that receive international attention can be influenced by the nature of advocacy networks and their agendas.

While the studies mentioned herein are just a few examples of a much broader body of literature, they emphasize how network-based analyses give robust added value to the state of knowledge on important questions in politics, government, and policy.

## FUNDAMENTAL NETWORK COMPONENTS

The most consequential research-design choice in any network study is to identify the nodes and edges of the network. The *nodes* are the actors or units that take actions and have specific characteristics (Borgatti et al., 2018). A node typically has attributes – that is, features, characteristics, or traits. In a political network study of voting, the nodes might be individual voters, candidates, or parties. Their attributes may be age, political votes, or policy issues. A study of conflict between countries might use countries or treaty organizations as its nodes. When nodes are individual people, attributes may include demographic characteristics such as gender, age, marital status, or

profession. When nodes are institutions or coalitions, the attributes will describe characteristics of the institution or group.

*Edges* describe how they are related to one another. Edges might include a shared trait between two nodes (for example, both female, both members of the same group), or a shared action that two nodes take (for example, both nodes are parties to the same contract or both contributed to the same candidate). Defining the nodes and edges of a network study is akin to settling on the unit of analysis in a traditional statistical study. As with settling on a unit of analysis, defining the nodes and edges of the network give the study its boundaries as well as the objects through which the researcher can potentially draw inferences.

A network study usually has three potential units of analysis: node, edge, and network. When the researcher seeks to answer questions about individuals, it makes the most sense to perform analyses at the node level. If the researcher poses questions about the relationships between nodes, such as the conditions under which edges exist, the strength of relationships, or the properties of relationships, then the researcher will focus on edges as the key unit of analysis. It is relatively common in international relations to treat dyads, or pairs, as a unit of analysis. For example, in questions where a pair of countries is the defined critical unit of study, the focus becomes studying the edges of a network.

When conceptualizing relationships between nodes – factors to compare and contrast in a political analysis – there are generally five types of connections that can be described: similarities, relationships, cognition, events, and transactions. A similarity is any shared trait between two nodes, such as the same party, same state, same gender, or other. Relationship connections might describe those with familial connections, friendships, sexual partners, acquaintances, or something more hierarchical like teacher and student, boss and employee, conductor and musician. Cognitive relationships refer to connections between nodes that relate to

how they think about things, such as a shared attitude, common knowledge, a shared perception, trust or distrust. Edges can also be defined by events such as common participation in conflict, resolution, conference, convention, or other events. Edges can be described as transactions where one node transmits, sells, or communicates something to another node. In this way, networks can be used to describe the flow of information, money, or ideas across a group.

Notice that among the five types of relationships described above, they are not strictly social. For example, one may consider two members of Congress in a legislative caucus together to be connected by a common membership in a group, but this does not mean that the two legislators have a social connection to one another. Often, political scientists look at ties that are not social but either could be social or can be treated as a shared attribute for an analytical advantage, as demonstrated in the studies on campaign contributions (Koger and Victor, 2009; Victor and Koger, 2016). The downside to treating a non-social shared attribute as a relational edge in a network is that it may limit the inference one can draw on the edges. Challenges associated with causal inference and network studies are directly addressed in the next section.

Finally, scholars are frequently interested in properties found in the overall network or network component's relative positions to other components. Questions about the centrality of a political actor or set of political actors and the tendency to broker relationships between units can only be studied if one has information about the entire network. It has not been a standard approach for political scientists, but it is proving to be a form of study that brings thoughtful insights to questions of politics. Leveraging this level of analysis requires the researcher to think about their data and questions of study from a broader perspective than the one to which they are accustomed; however, as described below, many relevant politics can be studied at the level of whole networks.

## CAUSAL INFERENCE AND NETWORKS

It is important to define clearly the nodes and edges in a network analysis for the same reason it is important to define with clarity the unit of analysis in a traditional statistical analysis. Clear-cut definitions of units are the means to draw robust inferences. In other words, a claim of causal inference is constrained to the unit of study. Like traditional studies, network studies pose challenges in their pursuit of causal inference. Two particular challenges for causal inference in network research are 'homophily' and 'interference between units'.

*Homophily* refers to the extent to which characteristics in one unit are shared by connected units. A researcher who seeks to know if the presence of a characteristic is caused by a particular effect will have to wrestle with the fact that the presence of the characteristic is partially determined by the network effect. *Interference between units* refers to a spillover effect, where in an experimental setting, treatment effects spill over to adjacent, connected units because they are connected in a network. In a causal-inference framework, the researcher seeks to estimate the expected value of an observed outcome for units that have been randomly assigned a treatment.

In network studies, the assumption of random assignment might be violated due to *interference between units*, which is likely to lead to underestimating treatment effects (Rogowski and Sinclair, 2012, 2017). In general, the set of tools available to a scholar engaged in causal inference in a network study is no different than those available for a non-network study. Common approaches for identification include experiment, lagged variables, instrumental variables, and panel designs.

In observational studies of relational data, a researcher who seeks to draw inference about the effect of  $X$  on  $Y$  must be concerned about the possibility that variance in  $Y$  is determined by the dependent connection between units, rather than  $X$ . When similarities between actors cause connections

between actors, the connections themselves confound the observation of the independent and dependent variables. For example, in a study of voters, a researcher who seeks to know the effect of a particular message or campaign approach on a voter's probability of voting, or voting in a particular way, can randomize voters, administer treatment, and observe outcomes. However, if a voter changes conditions from non-voting to voting, the researcher cannot be certain whether the observed change is due to the treatment, whether it is due to the voter interacting with someone else who was treated, or because of some latent commonality between subjects. If it was due to the treatment, one would say the treatment caused the observed change. If it was due to the subject's interactions or other connections, one can say the observed difference is due to a 'peer effect', which might also be called 'contagion'. If it were due to the latent commonality, one would say that homophily explains the observed outcome. Discerning whether observations are due to peer effects, homophily, or some other treatment is a great challenge in network studies. The best practice under these conditions is to use sensitivity analysis.

A technique developed by VanderWeele (2011) allows a researcher to estimate the probability that an observed outcome is due to the presence of an unobserved factor, by estimating how sensitive outcomes are to varying levels of a latent factor. Demonstrating how sensitive a result is to an estimated bias factor reveals the extent to which observed differences are due to homophily, peer effects, or treatment. In an application of this technique to a well known study of peer effects on levels of obesity (Christakis and Fowler, 2007) and smoking cessation (Christakis and Fowler, 2008), VanderWeele (2011) finds evidence of contagion effects in obesity and smoking, which were 'reasonably' tolerant to latent factors for homophily and environmental confounders. The study also finds that the spread of happiness is not robust against such latent effects. Therefore, the conclusion

that happiness is contagious finds less support than claims of contagion effects for obesity and smoking when one uses sensitivity analysis (VanderWeele, 2011).

In experimental research designs, a network researcher's primary concern is the possibility of interference among units. That is, when units have received treatment and interacted with one another, the space of potential outcomes expands exponentially because each person in the study has had the potential to be exposed to treatment through every other person in the study. To address this problem, researchers need an understanding of the network structure among participants. When known, the pattern of connections among subjects can be used to constrain the outcome space. Individuals can be randomly assigned to treatment given a known network structure, as was done in the 61-million-person Facebook voting experiment (Bond et al., 2012). In the absence of a known network structure, a researcher can sometimes reasonably theorize and model such structure, using empirical estimates to evaluate the fit of the theorized structure (Bowers et al., 2013).

Now that the reader has a basic understanding of the levels of analysis and limits of inference in network studies, the chapter moves on to discuss the first principles behind network analysis, which come from mathematical graph theory and sociology.

## NETWORKS AND GRAPH THEORY

Graph theory is a subfield of mathematics that was developed in the 1940s. Mathematicians, such as Paul Erdos and Alfréd Rényi (1960), conceptualized nodes, edges, and graph properties by studying the distribution of edges in random graphs. Separately, sociologists began working on the 'small world problem', a phenomenon in which individual members of a large population are seemingly connected to everyone else by only a few steps. These two streams of work matured concurrently

without intersection for several decades. Mathematicians and sociologists appeared unaware of the parallel, related work advancing in other disciplines.

By the 1990s, physicists began applying graph theory to questions of particle physics. In 1999, Albert et al. published a paper on the size of the World Wide Web, drawing on the progress made in mathematics, sociology, and physics. Thus, it was just 20 years ago that scholars began to realize that networks are a natural phenomenon, present in nearly all aspects of life (Barabási, 2009; Barabási, 2014; Watts, 1999).

Today, one can use the known mathematical properties of networks to understand the relationships in everything from the human genome to the spread of disease, the distribution of oil fields across the globe, the distribution of insurance claims across beneficiaries, and participation in voting. One can use a common language to understand these phenomena because the same set of mathematical properties underlie the relationships between nodes, regardless of the identity of the nodes. In other words, when events, people, or units are relational, an observer or political scientist can analyze and understand how the relationships affect some outcomes of interest by studying the properties of the network such as its density, the distribution of dyadic and triadic connections, the number of components, its tendency to cluster, and so on.

Of course, the nature and context of connections matter in any specific instance – betweenness centrality in an arms-trade network does not imply the same phenomenon as betweenness centrality in a network that describes the spread of an infection. But some properties have consistent interpretations; for example, triadic closure (three nodes connected) is consistently associated with trust and cooperation (Borgatti et al., 2018).

The most common distribution of nodes and edges that one observes in all types of relational data is called a Pareto distribution, or a power-law distribution. Imagine a graph that describes the number of

connections – that is, edges – that each node holds in a particular population. If the nodes were independent individuals or events, one can expect the distribution to follow a ‘normal’ pattern, according to the principles of the mathematical central-limit theorem. However, a Pareto distribution is heavily skewed with a fat tail, describing that relatively few nodes have a high number of connections and many nodes have a very low number of connections. The relationship between nodes and edges is exponential.

In mathematics, a graph is an object that describes the nodes and edges of a network. For a mathematician, a network is simply a graph,  $G = \{V, E\}$ , where  $G$  stands for *graph*,  $V$  stands for *vertices*, also called nodes, and  $E$  stands for *edges*. Using the mathematical set-theory notation to describe when an object is an element of a set or group ( $\in$ ), one can describe that node  $i$  and node  $j$  are connected in graph  $G$ :  $(i, j) \in G$ . For the analysis, one can use specific terms to describe relationships within graphs using the following common language:

- When two nodes are connected, one says they are *adjacent* which means they share a tie.
- If node  $A$  and node  $B$  are connected and node  $A$  and node  $C$  are connected, one says the two edges are *incident* upon  $A$ .
- The number of edges incident on a node is its *degree*.
- A node not connected to any other nodes is an *isolate*.
- A sequence of adjacent nodes forms a *path*. Paths are unique; one cannot revisit a node more than once in a path. One might model the contagion of a virus as a path if death or immunity prevents nodes from being re-infected.
- A sequence that revisits nodes but not edges is a *trail*. One might graph the flow of gossip as a trail because gossip may come back around to the same person, or node, but from a different source, or edge.
- A sequence of adjacent nodes without restrictions on revisiting nodes or edges is a *walk*. One might graph the flow of a single dollar bill as a walk because it can travel to anyone and repeat its steps.

- The shortest path between two nodes is a *geodesic*.
- A set of nodes in which every node can reach every other node by some path is a *component*.
- An edge that connects two components that would otherwise be separated is a *bridge*.

The aforementioned terminology helps identify and describe relational data in precise ways. Doing so is a critical part of engaging in social scientific inference. If the political scientist and analyst can identify data as having dependencies but she or he does not attempt to identify and account for those dependencies in the analytical strategy, then the observers run the risk of drawing incorrect conclusions. Once a researcher determines that a set of data has network properties, or dependencies, the researcher must be deliberate about identifying the nodes and the connections between them. Many political networks contain multiple networks between nodes (referred to a *multiplex*). For example, where countries are nodes, they can be described as being connected through trade, conflict, treaty, economic investment, or any number of possible ties. It is helpful to think of each possible tie as its own network graph, so the properties of the graph can be studied; however, sometimes we seek to aggregate ties or explicitly model a multiplex.

## A SHORT PRACTICAL GUIDE TO NETWORK MATRICES

A traditional data structure is ‘rectangular’, where rows represent cases or observations, and columns represent variables or attributes of those cases. Network data is relational – it shows the relationships between nodes, observations, or cases – and is often described as ‘square’. A matrix that shows the relationships between students who take classes together, for example, might be presented as a square matrix ( $N \times N$ ), where the rows and columns are identical lists of the population

of students, and the cells represent how many classes each dyad of students have in common. The main diagonal of the matrix (where  $i = j$ ) can show the number of classes in which each individual student is enrolled. Most software for analyzing network data can read relational data in a variety of formats, so it may not be necessary for researchers to explicitly organize their data into square matrices; but much of the graph-theory mathematics that underlie network analyses assume that network data fit this basic shape.

Network data can generally be described as being ‘one-mode’ or ‘two-mode’. In *one-mode* data, the data are square; the data can be arranged as an  $N \times N$  adjacency matrix, with the same number of rows and columns. The rows and columns both refer to the same entities (nodes), and the entries in the cells describe the relationships between them. In *two-mode* data, the rows represent nodes (for example, cases, entities, individuals), and the columns represent some event, characteristic, or attribute of the nodes. A two-mode matrix, also called *bipartite*, is similar to a traditional rectangular data matrix, but the columns in a two-mode matrix refer to some common group.

For example, one might have a two-mode affiliation matrix of members of Congress (rows) and legislation (columns). The values in the cells might represent votes or bill co-sponsorship. One can convert the two-mode affiliation matrix to a one-mode adjacency matrix by multiplying a matrix by its transpose (switch the positions of the rows and columns). The following is a generic example of this procedure:

$$AA^T = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} a & c \\ b & d \end{bmatrix} \\ = \begin{bmatrix} aa + bb & ac + bd \\ ca + db & cc + dd \end{bmatrix}$$

These mathematical properties are highly convenient for working with relational or network data. For example, one can easily

calculate how many co-sponsored bills two members of congress have in common. Or, one can calculate how many co-sponsoring legislators have one or several bills in common. The summation feature of the matrix multiplication operation means that we can readily move between two-mode and one-mode data, all the while obtaining useful information about the pairs or dyads.

The following is an overly simplified example of the utility of the properties of matrix algebra for manipulating relational data. One can easily scale this for larger, more realistic data sets. Here, I have a matrix of legislators and bill co-sponsorships, called *A*.

Matrix *A*

	HR1	HR2	HR3
RYAN	1	0	1
MCCARTHY	1	0	0
PELOSI	0	1	1

The transpose of *A*, or *A*<sup>T</sup> looks like this:

	RYAN	MCCARTHY	PELOSI
HR1	1	1	0
HR2	0	0	1
HR3	1	1	1

If one multiplies *A* by *A*<sup>T</sup> one gets the *N* × *N* adjacency matrix of shared co-sponsorship by legislator. *A* × *A*<sup>T</sup> =

	RYAN	MCCARTHY	PELOSI
RYAN	2	2	1
MCCARTHY	2	2	1
PELOSI	1	1	2

If one multiplies *A*<sup>T</sup> by *A* one gets the *M* × *M* adjacency matrix of shared legislators by bill.

*A*<sup>T</sup> × *A* =

	HR1	HR2	HR3
HR1	2	0	2
HR2	0	1	1
HR3	2	1	3

In addition, it is important to distinguish between *directed* networks and *non-directed* networks. The network example above is non-directed because the pair McCarthy–Pelosi is the same as the pair Pelosi–McCarthy. Think of the matrix as being split along the main diagonal of the matrix, from top left to bottom right. In a non-directed network, the matrix is symmetrical, and thus, the top half and bottom half of the matrix – on either side of the main diagonal – are identical. However, sometimes one’s network data are directed. In directed networks, also called a digraph, the edge that connects A to B is characteristically different than the edge that connects B to A. Directed networks are sensible for data that include interactions, such as a sender and receiver or a buyer and seller. If a network is directed, then the top and bottom half of the network will not likely be symmetrical.

In directed networks that are in square or adjacency format, one is able to distinguish between the *indegree* and *outdegree* of a node. The *indegree* are the number of edges that connect or point toward the node, and the *outdegree* are the number of edges that point away from the node. One can envision *outdegree* as the number of nodes that a given node connects to and *indegree* as the number of nodes that are connected to a given node. In a square directed matrix, the rows represent the ‘senders’ and the columns represent the ‘receivers’. In adjacency format, an observer is able to calculate the indegree and outdegree of directed data by simply calculating the sum of the rows (outdegree) or columns (called indegree). In non-directed data, the degree of a node is the sum of its row or column; row sums and column sums will be equal in non-directed data.

**MEASUREMENT, SAMPLING, AND MISSINGNESS IN NETWORK DATA**

Scholars trained in traditional social science research-methods theory and techniques will be familiar with challenges related to

measurement theory. The social scientist is consistently concerned about the reliability and validity of their measures and seeks to avoid making so-called Type I and Type II errors in the inferences they draw from the analysis.

It is crucial that when using network methods to pursue social scientific questions, the researcher is particularly diligent about such concerns.

Recall that the *reliability* of a measure describes the extent to which it produces the same result upon repeated trials, while the *validity* of a measure refers to the correspondence between a measure and the concept it is meant to capture. If a measurement strategy is at risk for violating these principles, the researcher is more likely to produce false positives, known as a Type I error, or false negatives, which is called a Type II error. In network studies, one must consider the possibility of developing measures or using data collection strategies that result in false-positive nodes, false-negative nodes, false-positive edges, false-negative edges, falsely aggregated nodes, or falsely disaggregated nodes. Lack of careful attention to these details can result in incorrect inference or erroneous descriptions of a network.

A false-positive node may occur if one inadvertently includes a node in a network to which it does not belong. In such a case, one would underestimate the density of the data, which could pose a threat to validity of network measures.

A false-negative node may occur if one excludes a node from a network to which it belongs. If the researcher excludes an important node, measures of centrality and power will be negatively affected. However, if the excluded node is of low degree or importance, there may not be much consequence to the inference drawn from network properties.

A false-positive edge occurs when a network measure includes a connection that does not exist. This would lead a researcher to overestimate the density of the network, but it is unlikely to have too many other consequences.

Likewise, a false-negative edge would occur when the researcher fails to observe a connection between two nodes that *is* actually present. The omission can lead the researcher to underestimate density as well as other measures of centrality and importance. The severity of such an omission will vary depending on the importance of the omitted edge.

A falsely aggregated node would occur if, for example, you counted Senator Bill Nelson (a Democrat from Florida) and Senator Ben Nelson (a Democrat from Delaware) as the same node, because perhaps you only recorded the last name and party of each node. Such an error can lead a researcher to overestimate the degree distribution of the data and can lessen the sensitivity available in the data. Likewise, a falsely disaggregated node would occur if a researcher counted South Carolina Senator Timothy Eugen Scott and Senator Tim Scott, Republican legislator of South Carolina, as different nodes, when in fact they are the same person. If this occurs, a researcher will underestimate the degree distribution of their data.

Issues of aggregation and identification are critical in network studies because network analysis typically draws on the properties of a network and misidentifying the nodes and edges of network can impact one's observation of the properties. In a traditional study, misidentification of this type may lead to an error in the number of observations, perhaps one that is less critical.

It is imperative that the network scholar pays meticulous attention to detail in data collection for this reason.

Another significant difference between network analysis and traditional frequentist inference is the use of sampling. Many social scientists rely on a process of random sampling to produce a manageable data set on which to perform analyses. The quality of the sample is directly related to the quality of the inference the statistician can make about the population of interest. However, with network data, sampling is often not feasible. Many networks of interest are unbounded. One literally cannot define the limits of the

population of interest, so how can one reasonably sample from it?

Consider a researcher who seeks to study political discussion networks of a particular community. The researcher can take a random sample of members of that community to study, but if the community members talk about politics with people outside of their community (likely), then the sample will have omitted relevant nodes. The difference is that in traditional statistics, one seeks to draw inference about an individual or a group of individuals in an identified population, but in network studies the unit of interest is often the relationship itself. It may be unreasonable to define the population of possible connections that exist if nodes can reasonably be connected to nodes outside the primary population. In this way, it can be nearly impossible to sample from networks because the boundaries of the network are undefined.

In addition, if a network scholar seeks to know about relationships in a particular community and the scholar samples that community to study its relationships, it is not possible to discern all of the network properties without some significant statistical error. Unsampled nodes and edges is akin to missing data that can affect one's understanding of network density, centrality of nodes, or component structures. In short, missingness is a significantly more pernicious problem in network studies than it is in traditional statistical studies (Burt, 1987). Typically, when observations are interdependent, missingness is not randomly distributed. Missing data is therefore a much more serious threat to inference in network studies than it is in non-network analyses (Kossinets, 2006).

## NETWORK VISUALIZATION

One of the more attractive features of network data are the data-visualization possibilities that accompany an analysis. Almost by definition, most network data are complex.

If one is engaged in a relational analysis of data, one is attempting to convey or analyze complexities of data. If one can do this in a way that provides a compelling narrative, the analysis is more meaningful. Visualization of network data is a vital component of the enterprise of network analysis precisely because all data analysis is ultimately about storytelling. If a visualization can convey a story easily and compellingly, it is a useful visualization.

As described by Pfeffer (2017), there are three critical design elements in network data visualizations: substance, design, and algorithm. First, to create a compelling visualization, one must have a compelling story to tell, and that entails knowing the story before one tries to create the graph. Sometimes visualizations are a good means of exploring data, but if the exploration reveals something compelling, then the visualization will likely be part of the reporting stage as well. It is therefore critical to have a substantive narrative in the data that one seeks to convey through a visualization.

Second, the design allows for a meaningful arrangement of nodes and edges that reveal the substance and structure of the network. Careful attention to the details of the arrangements of nodes and edges can help to convey the story. Finally, the algorithm used to produce a layout of a graph is the most critical choice an analyst will make. Different algorithms produce different shapes, effects, and emphases. In these details, one finds the elements of the narrative.

In general, the criteria for a good layout of a graph include the following:

- Show the structure and shape of the network from a bird's-eye perspective.
- Optimize the distribution of details; do overlapping nodes simplify or misrepresent the data?
- Maximize the data-ink ratio and avoid added elements or details that convey no information to a graph.
- Optimize line lengths, since short lines imply connectedness.
- Minimize crossing lines because they create confusion.

- Maximize angles; acute angles lead to crossing lines and less space between lines.
- Optimize path distances; adjacent nodes should be drawn close together.
- Quantitative data is best represented in order by position, size, saturation, hue, and shape.
- Nominal data is best represented in order by position, hue, saturation, shape, and size.

Other considerations with visualization are similar to the type of choices one would make for non-network graphs. For example, when varying the size of nodes, size should reflect a meaningful quantitative metric; however, humans have a difficult time distinguishing one size from one another, especially when objects are not directly adjacent, so it is unwise to expect a reader to draw too much inference from a node's size.

In color selection, humans can readily distinguish red, blue, and green, but too many colors or insufficient contrast between colors will render the technique less effective. Varying saturation, such as light and dark intensity, can be an effective means of conveying the levels of ordinal data.

Typically, curved lines are more aesthetically pleasing than straight lines, particularly for sparse networks. When networks are very dense, it is best to bundle or aggregate edges or nodes in some meaningful way or prune the network using a logical threshold.

## USEFUL NETWORK PROPERTIES FOR POLITICAL SCIENTISTS

The overall shape of a network and the features of its structure have many significant implications for questions of interest by social scientists. This section reviews the network properties of cohesion, reciprocity, transitivity, and centrality, and it shows how these physical properties convey concepts of interest to political scientists. For example, cohesive networks have an easier time solving coordination and collective-action problems – the primary challenge of all questions of politics – than less

cohesive networks. Those with more reciprocal ties and greater transitivity engender greater trust among participants, and the network concept of centrality is akin to the political concept of power. Translating political concepts into network properties provides a researcher with analytical leverage.

Herein, when the chapter talks about the cohesiveness of a network, it generally looks to its density. Most simply, the density of a network is the proportion of ties that exist out of all possible ties. In a non-directed graph, the number of possible ties is  $\frac{n(n-1)}{2}$ , where  $n$  is the number of nodes in the network. Density is a descriptive statistic that does not have inferential interpretation. Whether a density of 0.41 is high or low depends on the context of the network or a network to which you seek comparison. If ties represent armed conflicts between nation-states, then 0.41 is very high, but if it is the communication network among a group of six friends, it seems low.

When interpreting density, it is also important to consider whether ties are positive, such as within friendships, or negative, such as conflict between or among adversaries. Typically, networks with positive ties have a higher density than those with negative ties. If one seeks to interpret the density of a network by making a comparison to some other network, it is best if the two networks have the same overall size or the same number of possible connections. A common denominator always makes things easier to compare.

Another common way to understand cohesion is to calculate the average degree of a network. This simply amounts to calculating the degree or number of ties for each node, such as row sums, and then taking the average across these values. The density of a network and its average degree are related in that average degree is density times one less than the number of nodes. Some scholars find average degree easier to interpret than density, but in skewed distributions, which is typical of networks, the average degree may not be a good

representation of the central tendency of the degree distribution.

Large networks often have multiple components in them. One way to gain a sense of the cohesiveness of a network is to look at the size of its main component – the larger the main components, the greater the cohesion of the network. There are two useful statistics that may be useful in this case. First, a component ratio is an inverse measure of cohesion because larger values indicate less cohesion. The component ratio will be equal to one if every node is an isolate and equal to zero if there is only one component in the network

$$\text{Component ratio} = \frac{(c-1)}{(n-1)},$$

where  $c$  is the number of components and  $n$  is the number of nodes. However, the component ratio is not particularly sensitive or intuitively descriptive.

An alternative method to calculate cohesion is to measure the extent of fragmentation in a graph and to infer the connectedness from its complement. David Krackhardt (1994) developed an elegant measure of fragmentation that describes the proportion of dyads that are *not* located in the same component. Fragmentation is equal to one minus connectedness:

$$F = 1 - \frac{\sum r_{i,j}}{n(n-1)} = 1 - \text{Connectedness},$$

where  $r_{i,j}$  are dyads in the same component ( $r$  stands for reachability).

One can also get at the idea of cohesion by simply calculating the average path length, known as the *geodesic distance*. This is a common measure that is often used to describe how efficiently things might flow through a graph or get from one point to another. If the graph has multiple components, however, this measure is less useful. To gather the same type of information in a graph with multiple components, one can measure the *compactness* of the graph. Compactness is a variant of the connectedness measure described above, except

the numerator is replaced by the inverse geodesic distance between each dyad. In this way, compactness allows for paths to be weighed inversely by their length, which provides a much more sensitive measure of cohesion than any of the others described here.

$$\text{Compactness} = \frac{\sum_{i \neq j} \left( \frac{1}{d_{i,j}} \right)}{n(n-1)}$$

Finally, one might think of cohesion as a form of robustness. Robustness describes what happens to the network when individual nodes are removed. If the number of components increases by removing only a few nodes, then the network is not robust. Scholars can experiment with the removal of individual nodes and observe changes in the number of components or level of compactness in a network to gain a sense of its overall robustness.

In short, there are many ways to measure the cohesiveness of a network, and cohesion is a useful concept in politics. Many questions in politics come down to understanding how a group of actors will decide or solve a problem and then identifying the conditions under which the actions occur. Cohesive groups have less conflict and can more easily solve problems than non-cohesive groups. Studying the cohesiveness of networks is a natural methodological tool in the study of political relationships.

In addition to these various measures of cohesion, in directed graphs, one often seeks to understand the degree of reciprocity. In a reciprocal tie, when A is connected to B, then B is connected to A. Reciprocity is a natural concept to convey in terms of politics. Many political interactions deal with exchanges between two entities. If the exchange is positive, then reciprocity demonstrates cooperation. The act of giving and receiving is naturally human and social; measuring it through rates of reciprocity can give a researcher a handle on the amount of generosity, gratitude, or willingness to engage one observes in a network. Of course, reciprocity is a dyad-level feature of a

network – meaning it occurs between two nodes – and our ability to draw inference from it is limited to this level.

Beyond reciprocity, one can observe the level of transitivity and clustering in a network to help one to gauge the amount of trust between the actors. In a transitive relationship, if A is connected to B, and B is connected to C, then A is also connected to C. A, B, and C form a triad. When networks have many triads, they tend to be clumpy, and a triad census can help the political observer and scientist discern the types of triads and their frequency in a network. Triadic relationships tend to breed trust, because they have built-in mechanisms of accountability and monitoring. To illustrate with a colorful example, if political actor A tells a lie to B and the truth to C, then B checks the information with C, A gets caught in the lie and may suffer social consequences. The triadic nature of the relationships encourages truthful and positive interactions. Studying the triads and the extent of triadic closure in a network is useful for political scientists who want to understand the nature of trusting relationships between actors.

The final set of structural considerations about a network to consider here is centrality. There are multiple forms of centrality that one can use to describe a network. In general, centrality is a useful characteristic of a network for a political scientist to study because it describes the position of a particular node relative to other nodes. Nodes that are identified as more central to a graph can be thought of as having more power or influence on the graph. However, being central in a graph is not necessarily a good thing. If the network you study, for example, explains the spread of some misinformation or disease, then being central is much less desirable.

The paragraphs that follow describe five types of centrality: degree, eigenvector, beta, betweenness, and closeness. *Degree centrality* is a straightforward measure based on each node's degree. The downside to degree centrality is that it does not consider each

node's position relative to other nodes. Some might argue that in this way, degree centrality is not a measure of 'centrality' because it does not account for the whole network's properties, but it measures only a degree of competition between individual nodes.

Similar to degree centrality, *eigenvector centrality* shows that each node is weighed by the centrality of the nodes adjacent to it. Eigenvector centrality reminds the observer that centrality cannot be calculated without information about the entire graph, yet the measure itself is node level. Depending on the context of the data, eigenvector centrality can be thought of as popularity or exposure. A downside of eigenvector centrality is that it will not count the members of smaller components, so a political scientist would not want to use an eigenvector centrality measure on a densely clumpy network of many disconnected clusters.

*Beta centrality* measures the total influence a node can have on all other nodes through direct and indirect influence. Mathematically, it is the weighted sum of the total number of walks between each pair of nodes. In a network with many long chains of connections, this measure may be a good choice to use; however, the user must select the weighting factor, which gives the measure a sense of arbitrariness. The centrality measure is sensitive to the weight selected so it is essential to have a theory about how much to weigh the indirect influence of long chains of interactions.

*Closeness centrality* is an inverse measure of the sum of geodesic distances from a node to all other nodes. Large values indicate a node that is highly peripheral, so a normalized version is more intuitive. This measure is not well adjusted for networks with low variance or for networks with many components.

Finally, the phrase *betweenness centrality* explains how often a given node falls along the shortest path between two other nodes. A node's betweenness is zero when it is never along the shortest path between any two other nodes. Betweenness centrality is typically interpreted in terms of its potential for controlling flows through a network. Nodes with

high betweenness are in a position to threaten network disruptions, for example, in the way that an airline hub going offline is highly disruptive, because hubs have high betweenness centrality.

## CONCLUSION

This chapter is a concise primer on network analysis for political scientists. It demonstrates a few ways that network theory and methods have made significant social science contributions to the understanding of US politics, public policy, public administration, international relations, and other sub-disciplines. The literature in political networks is flourishing, as scholars increasingly apply the logic and methods of network analysis to the relational questions in politics and the vast interconnectedness of human interactions as they govern and make decisions about and for one another (Victor et al., 2017).

The basic concepts explained in the chapter draw from sociology, mathematics, computer science, and political science to showcase the ease with which scholars can learn and incorporate them into their analysis and study of politics. Taking care to collect data with network methods in mind, organize and manage data for network analysis, and apply network methods is a matter of careful training and practice. While this chapter has been only an introduction on the topic, it conveys how accessible, useful, and applicable the ideas are for political science observers, analysts, and scholars.

# Network Modeling: Estimation, Inference, Comparison, and Selection

John P. Schoeneman and Bruce A. Desmarais

## INTRODUCTION

Which international trade relationships are most likely to break down over the next decade? What predicts the level of cross-party collaboration in a legislature? Do online political discussion networks constitute as echo chambers? What these questions have in common is that they address systems of political relationships (trade, lawmaking, political communication) – systems that can be represented as networks in which political actors constitute the nodes, and the relationships constitute the edges between the nodes. Inferential network analysis represents a methodological class that can be drawn upon to answer questions like these. Most statistical models used in the social sciences rely on the assumption that the observations in a dataset (or at least clusters of observations) are drawn independently from a common data generating process. However, when analyzing networks, it is often inappropriate to assume that observations are independent

(Hafner-Burton et al., 2009; Harris, 2013). Indeed, the network analyst is often interested in studying the ways in which observations depend upon each other (Ogburn, 2018) (e.g., do friends influence each others' choices to vote? (Bond et al., 2012); do legislators reciprocate support for legislation? (Kirkland and Williams, 2014)).

The network-scientific approach has proven fruitful across most subfields of political science. For example, many, perhaps even most, of the empirical phenomena of interest to scholars of international relations can be represented as international networks. Paired with the availability of accessible software implementations, the conceptual appropriateness of inferential network analysis in international relations has led to its widespread application over the last 10–15 years. Networks that have been studied through the use of inferential network analysis include, but are not limited to, trade (Ward and Hoff, 2007; Fagiolo and Mastrorillo, 2014; Chu-Shore, 2010; Chyzh, 2016), conflict

(Ward et al., 2007; Cranmer and Desmarais, 2011; Gallop, 2016; Dorff and Ward, 2013), alliances (Cranmer et al., 2012), transnational terrorism (Desmarais and Cranmer, 2013; Metternich et al., 2013; Bush and Bichler, 2015; Asal et al., 2016), sanctioning (Cranmer et al., 2014; Dorff and Minhas, 2017), international governmental organizations (Cao, 2012; Davis and Pratt, 2016; Lupu and Greenhill, 2017), and non-governmental organizations (Atouba and Shumate, 2015). This research has led to several innovative findings. For example, Kinne (2018) finds that defense cooperation agreements (DCAs) between states are self-exciting in that they become more attractive as more states sign on, leading to patterns of triadic closure (i.e., a friend of a friend is a friend) and preferential attachment (i.e., popular states gain more ties) in the formation of networks through DCAs. Duque (2018), in a study of international diplomatic networks, finds similar relational dynamics in that the diplomatic relations of a state with one partner state affects its relations with other partner states.

Methods for inferential network analysis come primarily in the form of probabilistic models for networks, which are fit to data using common estimation frameworks (e.g., maximum likelihood estimation, Bayesian inference). Inferential network analysis is now far too broad of a methodological area to effectively review all of the models in any detail in this chapter. For a general overview of inferential models, the book by Carrington et al. (2005) is a good place to start. Additionally, Luke (2015) provides an overview of the available models using R software packages, with tutorials on how to implement them. However, it should be noted that methodology in social network analysis is a rapidly developing field and therefore most book length projects will not include the most recent advancements. In this chapter, we will review three modeling approaches in detail. These include the latent space model (LSM) (Dorff et al., 2016), the exponential random graph model (ERGM) (Cranmer and

Desmarais, 2011), and the stochastic block model (SBM) (Latouche et al., 2011; Sweet, 2015). The first model, the LSM, is a class of models in which each node is attributed with a position in a latent space of features. The latent space of features is parameterized to represent the structure of the network. The second model, the ERGM is a model that can be customized to represent networks with any quantifiable characteristic (e.g., a high number of reciprocated ties, a strong degree of clustering). The third model we discuss in detail is the stochastic blockmodel (SBM), which is a model in which the ties among units (i.e., nodes) in the network are reduced to relationships between groups of nodes. We chose the first two models, the LSM and the ERGM, on the basis that they are commonly used in the political science literature and therefore relevant to readers of a political science handbook. The SBM, however, has seen little use in political science. We make the case that the SBM should be used more in political science as an alternative to ERGM and LSM due to its focus on community detection, which is often of interests to political scientists (Desmarais et al., 2015; Freelon et al., 2015; Majó-Vázquez et al., 2019). After presenting a review of these three models, we provide a brief overview of extensions of these models to deal with longitudinal and weighted edge data. Next, we replicate the analysis in Wojcik (2017), which was originally completed using ERGMs, and analyze the replication data using both the LSM and the SBM.

## MODEL DESCRIPTION

The three models we review in detail, the LSM, ERGM, and SBM, share a common starting point in the case of dichotomous ties/edges (i.e., the edge does or does not exist). Consider a research problem in which the researcher is interested in using covariates that can be measured on the directed pair of

nodes  $(i, j)$  – where  $i$  is the index of the potential sender of an edge, and  $j$  is the index of the potential receiver of the edge – to model whether the edge  $(i, j)$  exists. Denote the edge indicator  $y_{i,j} = 1$  if there is an edge from node  $i$  to node  $j$ , and 0 otherwise. Let  $x_{i,j}$  be a covariate that can be measured on the directed dyad (e.g., if the nodes are states, the distance between their capital cities) or mapped to the dyad (e.g.,  $x_{i,j}$  is the GDP of the sender state,  $i$ ). A standard approach to modeling the dyadic variable  $y$  as a function of  $x$  would be to estimate a logistic regression in which  $y$  is the dependent variable and  $x$  is the independent variable. The LSM, ERGM, and SBM all reduce to a standard logistic regression model in which edge indicators (or values) are regressed on covariates in the case where the network components do not contribute to the fit of the models (Lubbers and Snijders, 2007; Raftery et al., 2012; Sweet, 2015). As with common regression models, model fit can be assessed through information criteria, prediction experiments, and simulation of network structural quantities (e.g., the distribution of the number of ties to which nodes are incident, the number of triangles in the network). Stated succinctly, logistic regression is a special case of LSM, ERGM, and SBM when modeling a dichotomous tie (i.e., absent or present) network.

In the case of each model, network structure is layered on top of the regression model. The particular form of network structure added varies across the models. In the LSM, each node is represented by some number of continuous-valued features (e.g., coordinates in a Euclidean space), and the probability of a tie is given by some function of the features (e.g., the Euclidean distance between nodes). We refer to the network structure incorporated in the LSM framework as ‘selection’, since the function defined on the latent feature serves as a partner selection function for nodes in the network. The network component under ERGM is designed to capture the prevalence of subnetworks that are theoretically

interesting or otherwise distinct. Examples of these subnetworks include triangles (i.e., triples of nodes  $(i, j, k)$ , in which there is an edge connecting each pair of nodes) and mutual dyads (i.e., dyads, in which there is an edge from  $i$  to  $j$  and from  $j$  to  $i$ ). In the ERGM, subnetwork prevalence is controlled through the specification of dependence relationships among the edges. For example, if a network is modeled to have a relatively high number of mutual dyads, the formation of an edge from  $i$  to  $j$  increases the likelihood that an edge will form from  $j$  to  $i$ . Since the basic building blocks of the network component of the ERGM reflect different forms of dependence, we refer to the network structure in the ERGM as ‘dependence’. The network structure of the SBM is built on a common interest in identifying the communities, clusters, or groups that define the main blocks of ties in the networks. Under the SBM’s network structure, the blocks of which two nodes are members determines whether those two nodes will form an edge. Since the network component of the SBM is focused on segmenting the nodes into a set of groups, we refer to the network structure in the SBM as segmentation.

### ***Latent Space Modeling of Networks***

The notion of feature-based selection is deeply rooted in political science literature. For example, in the study of legislative networks, ties between legislators have been repeatedly found to be driven by ideology and the geographic proximity of districts (Bratton and Rouse, 2011; Clark and Caro, 2013; Osei and Malang, 2018). The probability of a tie between two legislators is a function of the features of the two legislators – primarily ideology and geography. The LSM reflects this very structure – the probability of a tie depending on a combination of functions of node (e.g., legislator) features – with exception being that the features inferred in

the LSM are latent (i.e., unmeasured). That is, given one or more functions according to which the latent features affect the probability of an edge, in the LSM, the nodes' feature values are inferred to be those that best explain the pattern of edges observed in the data.

Under the LSM,

$$Pr(y_{i,j} = 1) = \text{logit} \left[ \beta_0 + \sum_{p=1}^P \beta_p x_{i,j}^{(p)} + d(z_i, z_j) \right],$$

where  $\text{logit}(a) = 1/(1 + \exp(-a))$ ,  $\beta_0$  is an intercept that controls the overall density of the network,  $\sum_{p=1}^P \beta_p x_{i,j}^{(p)}$  models the effect of measured covariates on the probability of an edge forming,  $z_i$  and  $z_j$  are latent coordinates of nodes  $i$  and  $j$ , and  $d()$  is a distance function that maps the coordinates into a metric space. In the LSM, the  $z$  is inferred as parameters. They are latent attributes that capture the structure of the network but are not observed. Example functions that have been used for  $d()$  include the negated Euclidean distance (Mahmood and Sismeiro, 2017),

$$d(z_i, z_j) = -\sqrt{\sum_{k=1}^K (z_i^{(k)} - z_j^{(k)})^2},$$

and the bilinear metric (Vance et al., 2009),

$$d(z_i, z_j) = \sum_{k=1}^K z_i^{(k)} \times z_j^{(k)}.$$

The latent variables account for network structure, which is not modeled effectively using the observed covariates.

Selection of the particular distance function used can be based on a few different factors. First, the researcher may have a substantive reason to prefer one distance function over another. For example, the Euclidean function models the effect of latent variables such that the log-odds of a tie is inversely

proportional to the straight-line distance between two nodes in the latent space, whereas under the bilinear function, the log-odds of a tie is inversely proportional to the angle between the two coordinate vectors. In these two examples, the Euclidean distance relies solely on proximity as a fixed effect, where zero represents the highest likelihood of a tie, but the bilinear metric is a mean zero random effect, where two nodes being close to one another does not necessarily increase the likelihood of a tie since they need to be in the same direction to increase the likelihood of a tie (Dorff et al., 2016). The researcher may consider one distance function to be most substantively appropriate in their application based on this difference. Second, one function may fit the data most effectively. Based on information theoretic measures such as the Bayesian Information Criterion (BIC) (Wang, 2009) or visual assessments of model fit, the researcher may determine that one of the distance functions provides the best fit to the data. Third, if the network is very large, computational properties of estimation may make the use of one of the distance functions more feasible. If the Markov Chain Monte Carlo approach to Bayesian inference in the LSM converges much faster under one distance function than another, the researcher may choose to go with the model that converges faster.

### The Exponential Random Graph Model

Theories of dependence in political science have been developing rapidly in recent years. Example findings include a strong tendency towards rapid retaliation in the issuance of international economic sanctions (Cranmer et al., 2014), bilateral preferential trade agreement networks' formation of triads and/or four-cycles to share costs among larger partner groups (Milewicz et al., 2018), and that influence networks among policy actors are hierarchical – exhibiting a tendency towards

transitive tie formation (Christopoulos and Ingold, 2015). The ERGM opens up a new class of hypotheses that can be tested relative to regression models. In addition to studying how covariates effect the absence/presence of edges, the ERGM permits researchers to test hypotheses about how the edges affect each other (e.g., is the enemy of an enemy a friend?). The key components in using an ERGM are to develop hypotheses regarding the ways in which edges depend on each other and conceptualize these dependencies in terms of subnetwork structures such as dyads and triads.

Under the ERGM, the probability (likelihood function) of observing the entire network  $Y$  is

$$P(Y, \theta) = \frac{\exp\{\theta'Y\}}{\sum_{Y^* \in \mathcal{Y}} \exp\{\theta'Y^*\}}$$

where  $h(Y)$  is the vector of network statistics selected to specify the model,  $\theta$  is the vector of effects of the network statistics on the probability of observing a particular configuration of the network,  $\exp\{\theta'h(Y)\}$  is the positive weight associated with the respective network configuration,  $\mathcal{Y}$  is the set of all possible network configurations, and  $\sum_{Y^* \in \mathcal{Y}} \exp\{\theta'Y^*\}$  is the normalizing constant that assures that the probability distribution over networks sums to one. The ERGM is specified through the selection of  $h(Y)$  and is very flexible. This flexibility comes at two costs when it comes to application. First, since  $\mathcal{Y}$  is so large –  $2^{n*(n-1)}$  for a directed network with no self-ties, where  $n$  is the number of nodes in the network – the likelihood function cannot be computed exactly, which means estimation involves either approximation of the likelihood or method of moments criteria (Hummel et al., 2012; He and Zheng, 2016; Schmid and Desmarais, 2017). Second, the researcher may specify a model that cannot be effectively fit to the observed data, the consequence of which is model degeneracy. Model

degeneracy is a condition under which the model does not converge to a model that can effectively approximate even the number of edges in the network, the result of which is a model that places nearly all of the probability on either the completely full or completely empty network (Schweinberger, 2011). An active methodological literature has made substantial progress towards solving these two problems (DeMuse et al., 2018) and state-of-the-art open-source software implements many of these solutions (Hunter et al., 2008).

The ERGM has been used to study several different forms of dependence in political networks – structural patterns that go beyond the effects of covariates, of which the ERGM is uniquely capable of modeling. These dependence patterns concern the ways in which ties in the network are related to each other and are modeled through the specification of corresponding network statistics in  $h(Y)$ . Peng et al. (2016) apply the ERGM to study reciprocity in the online communication networks among members of the US Congress. Osei and Malang (2018) use the ERGM to analyze the degree to which political discussion is characterized by triadic closure (i.e., the friend of a friend is a friend) among members of the Ghanaian legislature. Gerber et al. (2013) use ERGMs to study the degree to which ties beget ties (i.e., tie formation is driven by popularity dynamics) in organizational collaboration networks surrounding local regional planning in California. Guerrero et al. (2015) analyze a multilevel collaboration network among organizations working on agricultural conservation in Australia. The levels include individual property owners, sub regional organizations (e.g., local governments) and supra-regional organizations (e.g., NGOs). They use the ERGM to study the prevalence of nodes that bridge multiple levels in the network. Dependence patterns such as the ones cited in this paragraph represent an exciting and important component of the function of

political systems, and a class of structural patterns that can only be studied through the use of inferential network analysis.

### The Stochastic Blockmodel

Concepts in political science related to group and system polarity (Baldassarri and Bearman, 2007; Cranmer et al., 2015) fall within the orbit of the SBM formulation. Under the SBM there is a finite number of node types or ‘blocks’, and each block is defined by the probabilities according to which nodes within the block form ties with each other and with nodes in other blocks. If there are  $n$  nodes in the network, the SBM reduces the complexity of interactions among those  $n$  nodes to interactions among and within a set of  $b$  blocks, where  $b$  is typically much smaller than  $n$ . The SBM with covariates, to our knowledge, has not been applied in the published political science literature. That is, perhaps, because it was only recently extended by Sweet (2015) to incorporate covariates – unlike the ERGM and the LSM, which were developed in part with the objective of modeling the effects of nodal and dyadic covariates. As such, unlike our review of the ERGM and the LSM, our presentation of the SBM represents an introduction of the model to the political science research methods literature.

Under the SBM, the probability of a tie from  $i$  to  $j$  is given by

$$Pr(y_{i,j} = 1) = \frac{1}{1 + \exp\left[-\left(\text{logit}\left(\pi_{B(i),B(j)}\right) + \sum_{p=1}^P \beta_p x_{i,j}^{(p)}\right)\right]}$$

where  $\pi_{B(i),B(j)}$  is the baseline probability with which a member of  $i$ 's block ( $B(i)$ ) sends a tie to a member of  $j$ 's block. The probability of a tie is also affected by a set of covariates. The blockmodel component of the SMB is defined by a  $k \times k$  matrix,  $\Pi$ , of probabilities,

where  $k$  is the number of blocks to which nodes are assigned, and the  $i, j$  element of  $\Pi$  gives the probability that a member of block  $i$  sends a tie to a member block  $j$ . If the network is undirected,  $\Pi$  is a symmetric matrix, and each element gives the probability of a tie between members of two blocks (or within the same block, if on the diagonal of  $\Pi$ ). Under the basic version of the SBM, the researcher sets the number of blocks, and each node is assigned to one block. The SBM, like the LSM, represents a latent variable approach to accounting for the network structure that cannot be modeled with the observed covariates. Also, like the LSM, the SBM cannot be used to model dependence effects and is most appropriate for applications in which the goal is to model the effects of covariates while accounting for network structure.

The specification of the SBM with covariates is, as is the specification in many modeling frameworks, driven by two factors – theoretical considerations and model fit. The selection of the number of blocks to which vertices are assigned is typically done using a measure of model fit such as the BIC (Robinson et al., 2015), or the Deviance Information Criterion (DIC) (Sohn and Park, 2017). In the application below, we select the model with the number of blocks that yields the lowest DIC. In terms of covariate specification, the SBM can model the effects of any covariates that one would include in a standard logistic regression, ERGM and/or LSM. As in logistic regression, and the standard versions of both the ERGM and the LSM, the coefficient associated with a covariate yields the change in the log odds of a tie due to a one unit increase in the covariate value.

### Additional Methods in Brief

The LSM, ERGM, and SBM reviewed above represent the basic forms of the most

commonly used models for statistical inference with networks. However, there is a substantial, decades-old, literature that expands upon these core model forms and has resulted in methods that are appropriate for studying networks characterized by ties that take on many different value types (e.g., continuous, count, textual) and are appropriate for time-stamped network data. In this section, we provide a brief review of the different extensions that have been built upon the foundations of the LSM, ERGM, and SBM, with a specific focus on networks with non-binary ties and those with temporal structure.

Any relationship that can be measured in a binary fashion can probably also be attributed with additional, and perhaps more theoretically interesting, quantitative information. For example, Cranmer and Desmarais (2011) and Baller (2017) use the ERGM to study cosponsorship networks between legislators by applying a threshold such that a tie between legislator  $i$  and  $j$  indicates that their cosponsorship relationship exceeded a set threshold. However, it may be more informative to study the network with weighted ties as a function of the number of times  $i$  cosponsored bills sponsored by  $j$  or the number of times two nodes cosponsored the same bills, as has been done in recent applications with cosponsorship networks (Kirkland, 2012; Signorelli and Wit, 2018). Both of the R packages commonly used for latent space modeling of networks – *amen* (Hoff et al., 2017) and *latentnet* (Krivitsky and Handcock, 2017) – include extensions of the binary LSM to allow modeling of continuous (*amen/latentnet*), count (*latentnet*), and ordinal (*amen*) edge weights. Krafft et al. (2012) developed a model for text-valued networks (e.g., e-mail text among a set of nodes) that integrates the LSM with topic modeling. The ERGM has been extended to model quantitatively valued and rank-ordered ties (Wyatt et al., 2009; Desmarais and Cranmer, 2012; Krivitsky, 2012; Krivitsky and Butts, 2017). The Weighted Stochastic Blockmodel,

introduced by Aicher et al. (2014), can be used to model edge values using any exponential family probability distribution. Though it is illustrative to consider each model in the case of simple binary ties, there are plenty of modeling options for working with ties that are attributed with more information.

Particularly in political science – where networks are often constructed from long-running historical records (e.g., international conflict (Li et al., 2017)), court/judicial processes (Box-Steffensmeier and Christenson, 2014), and legislative records (Ringe et al., 2013) – it is common for network data to be time-stamped and form long periods. The basic versions of the LSM, ERGM, and SBM presented above are appropriate for modeling single-time-point networks. However, each model has been extended to accommodate time series network data. There are two broad types of time-stamped data encountered in network analysis – relational state data and relational event data. Relational state data is network data in which the ties reflect durable relationship conditions (e.g., two states are or are not at war for sustained periods of time, two legislators are or are not serving on the same committee for sustained periods of time). Relational event data is network data in which relationships manifest as instantaneous (e.g., one government official sends an email to another) or very short-term (e.g., two political activists attend a rally together) interactions. Relational event data can be, and often is, converted to relational state data by indicating the existence of a tie between two nodes if the frequency and/or intensity of relational events within a given time period exceeds some threshold. For example, in the previous paragraph, we discussed ways in which researchers have measured cosponsorship networks, using them to indicate relational states over legislative session. Cosponsorship data is observed as relational events. Brandenberger (2018) analyzes time-stamped cosponsorship activity from the perspective of relational event network analysis. The LSM has been extended to model

relational state data (Sewell and Chen, 2015) but, to our knowledge, has not been developed for relational events. The ERGM has been extended for both relational state data (Hanneke et al., 2010) and relational events (Perry and Wolfe, 2013). The SBM has also been extended for both relational state data (Xu and Hero, 2014) and relational events (DuBois et al., 2013).

### **APPLICATION OF THE ERGM, LSM, AND SBM**

In this section we provide an example of using all three models of inferential network analysis covered in this chapter. This application is intended to demonstrate that the models produce comparable results with regard to covariate inferences, as they all have the same basic underlying regression framework, but also highlight how the different methods of approximating network structure shape differences in conclusions. The example also highlights differences such as the ability to include network structure in the ERGM and visually examine the latent space for the LSM and the block assignments in the SBM. For the application, we replicate a recent study of the factors that shape directed connections between legislators in Brazilian legislative networks (Wojcik, 2017). Wojcik argues that, despite high levels of personalism in Latin American politics, political parties are effective in shaping actor behavior, indicating that there are higher levels of party discipline than previously thought. By addressing this problem from a network framework, the author offers new evidence that the relationships between legislators exhibit complex forms of dependence.

We use the R software package *ergm* (Handcock et al., 2018) to replicate the ERGM models, *latentnet* (Krivitsky and Handcock, 2017) for the LSMs, and *CIDnetworks* (Adhikari et al., 2015) for the SBMs. The

ERGMs were replicated as originally specified and used the same random seed as the original paper. For the LSMs, we specify them the same way as the ERGMs, but without transitive ties, and run models with varying numbers of latent space dimensions and clusters, reporting the result from the models that had the lowest BIC. For the SBM, we fit models specified the same with two to five blocks, again reporting the model results that has the lowest DIC. In general, we find that results from all the models match the general conclusions of the paper. Below, we explain the data from the study, the model specifications, and the differences in results in more detail.

### **Data**

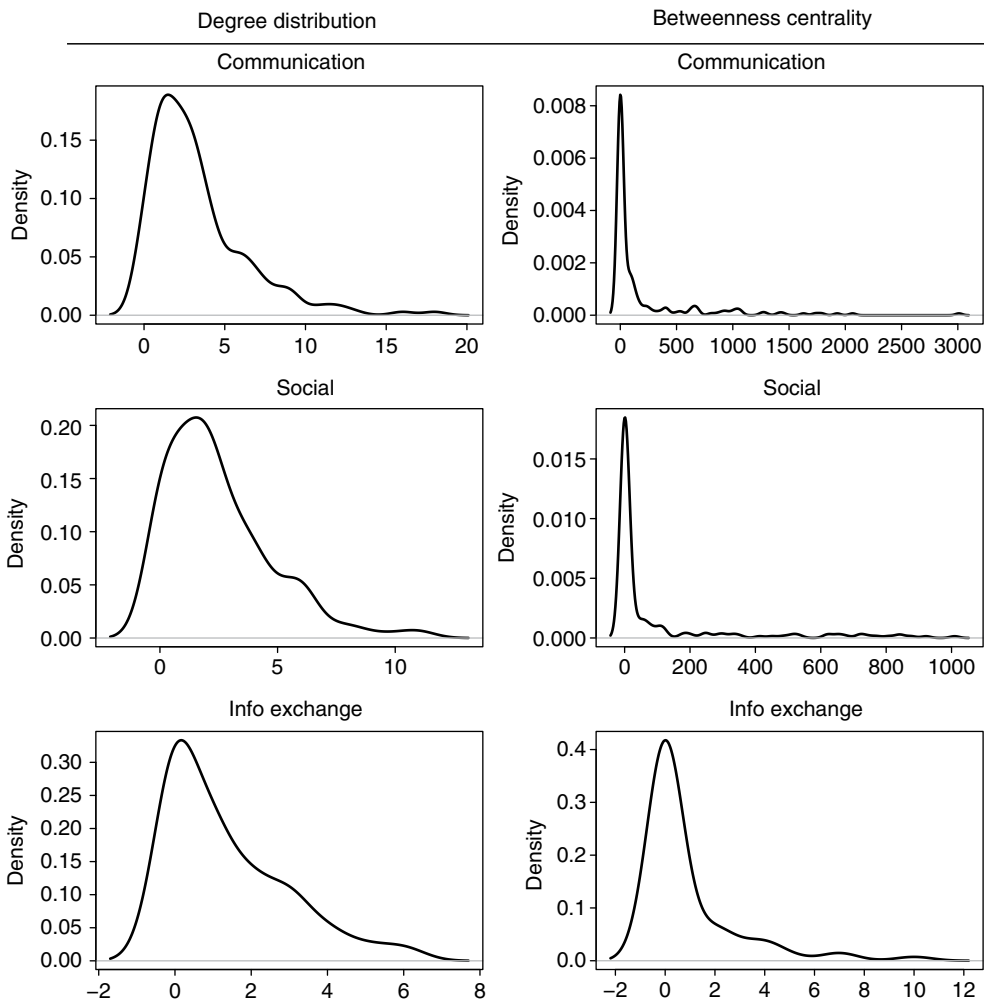

To collect the network data, Wojcik distributed an interactive digital survey to office managers from the offices of the lower chamber of the Brazilian national legislature. The three different types of connections surveyed were communication on legislative issues, socialization about non-legislative issues, and information gathering to resolve questions about legislative proposals and procedures. Wojcik also collected biographic information on those who completed the survey and compared traits of the sample to that of the entire Congress, finding no identifiable differences. The survey had a 25% response rate, and missing data was filled in using results from a pen-and-paper survey from 2013.<sup>1</sup>

Summary statistics of graph-level network measures for the three networks are presented in Table 46.1. All of the networks' edge densities – the proportion of possible ties that exist, with a range of zero to one – have fairly low values. This is interesting because, for this application, it indicates that legislative communications are sparse. This means that central actors are more important for assuring that information is spread throughout the network. Betweenness centrality of a node is the number of shortest paths between nodes

**Table 46.1 Summary statistics: networks**

Network	Measurement	Value
Communication	Edge density	0.008
Communication	Reciprocity	0.255
Communication	Transitivity	0.108
Social	Edge density	0.006
Social	Reciprocity	0.203
Social	Transitivity	0.119
Info exchange	Edge density	0.009
Info exchange	Reciprocity	0.157
Info exchange	Transitivity	0.135

in the network on which the node sits (Zhu and Watts, 2010) and is a common measure of how critical a node is to connect different parts of a network. Depicted in Figure 46.1, the long tails of the betweenness centrality distributions also indicate that there are only a handful of influentially positioned nodes. However, it should be noted that while the degree distributions – the distributions of the number of ties to which nodes are incident – are skewed right, the mean degree is high enough in the communication and social

**Figure 46.1 Density plots for degree distribution and betweenness centrality for all three networks**

networks to indicate that these networks are more spread out relative to the information exchange network. Additionally, the drop in reciprocity for the information exchange network, with an increase of transitivity, indicates that this network, relative to the others, mainly forms connections in one direction. Largely one-directional networks are interpreted as hierarchical (Liu et al., 2012). These substantial structural differences across networks drive home the usefulness of using inferential network analyses instead of models that assume independence, as they help explain the formation in ties beyond the exogenous covariates.

The independent variables, summarized in Table 46.2, have very similar values for all three networks. This is expected since they are drawn from the same population, but it does indicate that there are no major biases in the samples, despite the networks differing in size. We also see that most nodes have the same education level and that this lack of variation helps explain why education is not always a significant predictor of ties.

**Hypotheses**

The main hypothesis of the paper is that political parties actively work to form ties among members and thus counter the individualistic tendencies of politicians to increase their own electoral share/power at

the expense of the party. The network then creates trust and cohesion among the actors, while also facilitating monitoring. Wojcik expects that political party affiliation will be the stronger driver of tie formation, relative to individual traits.

The secondary hypotheses of the paper are based on the idea that politicians’ individual traits will significantly impact their likelihood to form a tie with one another, despite these effects being weaker than shared party membership. Wojcik includes five different individual traits with different combinations of assortative and disassortative hypotheses. The first is that when two politicians are both in leadership positions, they will need to interact more – but when neither are in leadership positions they will not need to interact with one another and can rely on party leaders. The second is that when politicians have similar ages, they will form connections based on shared experiences. The third is that when politicians are from the same state, they will form connections since there is a proportional voting system in Brazil, and that means that coordination among members in the same states is necessary to exchange information about local needs. The fourth is that politicians with the same education level are likely to have similar knowledge and social class, which increases the chance of network ties. The fifth is that when politicians work on the same floor this creates opportunity for interaction.

**Table 46.2 Summary statistics: independent variables**

Variable	Proportion		
	Communication	Social	Info exchange
Same education level	71%	70%	74%
Same floor	10%	10%	12%
Both leadership	6%	7%	6%
Both non-leadership	10%	10%	14%
Same state	10%	9%	12%
Same party	46%	50%	43%
	Average		
Δ Age	12	12	13

## Replication Design

The ERGMs are specified in the article to include an intercept term, the exogenous covariates, and a term for transitive ties. Transitive ties is a network statistic, specific to ERGM, and is defined as the number of ties from  $i$  to  $j$  for which there is at least one third node  $k$  such that there is a tie from  $i$  to  $k$  and a tie from  $j$  to  $k$ . The coefficient attached to the transitive ties term can be interpreted as the effect on the log odds of a tie from  $i$  to  $j$  of there being at least one indirect path of length two from  $i$  to  $j$  (i.e., some third node  $k$ , such that there is an edge from  $i$  to  $k$  and from  $k$  to  $j$ ).

For the LSM and the SBM, the specification is the same, except it does not include a transitive ties term. This is because the models do not have network statistics as an ERGM model does, but instead we specify the latent space that models higher order dependencies, including transitivity. For our extensions, we use the Euclidean distance model term that is equal to the negative Euclidean distance between actors in the unobserved social space. We estimated the term along two dimensions and across two or three clusters, depending on best model fit using the BIC. The SBMs do not include a constant term, as the block or group effect takes the place of the intercept term. It also does not have network terms like transitive ties as it accounts for dependencies using the block membership for the nodes.

## Results

The results regarding the direction and signs of the covariate effects are fairly consistent across models (Table 46.3). However, the coefficients in the LSMs, while signed the same, are mostly larger in magnitude. One exception is the node-match variables for leadership – a covariate that is equal to 1 if  $i$  and  $j$  have the same leadership status, and 0 otherwise. In Model 1, the effect size is

slightly larger, but in Model 3, the effect size is nearly one-third smaller. Moreover, the changes in magnitude are generally smaller for the leadership variables than the other variables. The latent space plots (Figure 46.2) show that the clusters are not distinct from one another, but rather there are inside groups that form clusters and each subsequent group of nodes are less central to the graph. Note, in the LSM, the clusters are post-hoc groupings of nodes, and do not play a significant role in the tie generation of the networks, unlike in the SBM.

The results from the SBM present a contrast to those of the LSM, as the coefficients for exogenous covariates, while signed the same, are mostly smaller in magnitude, indicating that block membership is capturing the impact of many of the variables. This is reasonable since we would expect block membership to be associated with variables such as party membership. Also, the coefficient estimates have smaller standard errors relative to the size of the estimate. In Figure 46.3, block likelihoods for each node assignment shows that for communication ties in Model 1, we see that the blocks are fairly evenly distributed but that membership is not distinct and that many of the nodes have spread out likelihoods for membership assignment. In Model 2, we see that this shared membership is even greater for the social networks. However, for the information network in Model 3, membership likelihood is sharply separated and concentrated in one block for each node.

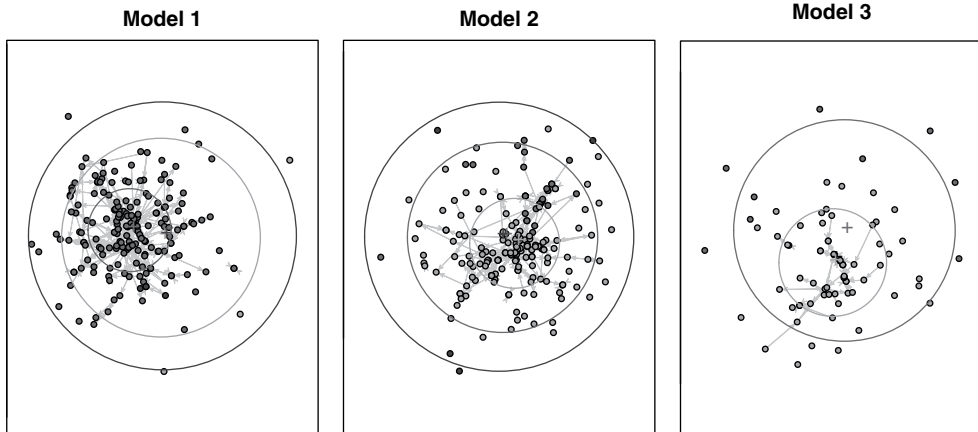

It is not immediately obvious which model performs best for this application, but, in general, there are a couple factors that influence which model is used for final analysis. The first is that theory should drive the decision of which model to use. All three models control for network dependence but differ in how they allow the researcher to explore the different forms. For example, the ERGM focuses on graph level dependence and if a scholar is interested in studying the presence and magnitude of a specific type of graph-level

**Table 46.3 Replication results**

**Table 46.4** Plots of latent space positions for the LSMs along two dimensions. The gray lines represent the directed edges between nodes. Each cluster has a unique grayscale shade that is used for the nodes and line that encloses the nodes in the cluster

network dependence, such as the transitive ties statistic in this application, the ERGM is the best suited model. If, however, a scholar is interested in understanding relationships between clusters of observations and the likelihood that an actor in one cluster will form ties with an actor in another cluster, the SBM is best suited for examining this. From the stochastic block matrices, researchers are also able to investigate network structure hypotheses such as the existence of overlapping or distinct communities, the rates of within-community tie formation, and how communities are connected to other communities (e.g. core-periphery). The LSM, on the other hand, is able to control for dependence, but does so in a way that embeds network structure in continuously valued attributes of nodes. Thus, it may work best for scholars that want to control for the dependence but are not interested in how network structure is driven by individual node attributes.

The second issue is practicality. Any scholar that has used ERGMs, has likely dealt with model degeneracy. For this reason, and if the scholar wants to account for network dependence, but does not want to work through specifying relevant dependence

terms, the LSM and SBMs are both viable options. As this replication has shown, the flexibility of each method often makes it possible that, if for nothing but robustness testing, scholars can implement more than one model type and gain insight through comparing model results. In the case of the current application, the central conclusion regarding party organization is very robust. The log odds of a tie is one to three units higher when two legislators are in the same party than when they are not in the same party, across networks and modeling approaches.

## DISCUSSION

Advances in methodology and software availability have allowed inferential network analysis to increasingly be used in political science. Inferential network analysis has opened the door to the empirical evaluation of new types of theoretical claims and improved the rigor with which political scientists approach dyadic data analysis. With the inherent relational structure of much data in political science, especially international

### Model 1

### Model 2

### Model 3

**Table 46.5 SBM block assignment plots. Each column represents one node and the rows are the block possibilities for each node. The blocks are shaded from white to black for the probability of block membership, with white representing a probability of approximately zero and black representing a likelihood of approximately one. The bottom right box is shaded according to the value of the block matrix value**

relations, inferential network analysis will continue to make an impact in political science methodology.

We hope that this chapter will help guide scholars in comparing and selecting available inferential network analysis tools, and understanding the methodology behind them, as well as their usefulness and their limitations. In this chapter, we have reviewed three of the most commonly used statistical network models, but it should be noted that the toolkit for inferential network analysis is broader than what we have reviewed and is constantly growing. As for the application, it provides a brief overview of network descriptive statistics and model specification options. There are many other useful network descriptive measures not included that scholars can employ, as well as other dependence terms to include in model specification, especially when using the ERGM. Furthermore, data-driven model selection across modeling frameworks presents an important and open methodological problem in political science. Lastly, regarding research software, R is the software of choice for inferential network analysis and contains a vast library of packages for static, time-dependent, and weighted networks. Other software packages for network analysis, albeit with limited functionality for inferential methods, include the Python library NetworkX (Hagberg et al., 2008), the Java-based program Gephi (Bastian et al., 2009), and user-friendly GUI-based software like PNet (Wang et al., 2009) and UCINET (Borgatti et al., 2014).

## Note

- 1 Network data, just like most types of data, are often found to be missing data. Dealing with this is an active and promising area of research. For example, for the ERGM model, researchers have had success using an ERGM-based imputation (Wang et al., 2016). Additionally, from the LSM and SBM, it is straightforward to estimate the probability of a tie from partial datasets, from which missing edge data can be imputed.

# Bayesian Methods in Political Science

Jong Hee Park and Sooahn Shin

## INTRODUCTION

Bayesian methods refer to a suite of statistical methods that consistently use Bayes' formula to update researchers' beliefs about statistical quantities of interest using observed data. The consistent use of Bayes' formula requires two major inputs – a prior distribution and a generative model of (observed and unobserved) data – and an efficient estimation method that can find statistical quantities of a new probability density (called a posterior distribution) from the product of multiple probability densities.

The beauty of Bayesian methods lies in the fact that if researchers have a theory of a real-world process that can be represented by a generative statistical model, Bayesian inference is the most consistent way to represent this belief using the theory of probability. This point is formally proved by Bruno de Finetti (1974). The re-discovery of Markov chain Monte Carlo (MCMC) methods in the 1970s and 1980s made it possible to

materialize de Finetti's theoretical conjecture in statistical inference.

Political scientists have been interested in the idea of Bayesian inference since the 1950s. At the time, political scientists applied Bayesian philosophy to decision problems following prominent work by Savage (1954). Bayesian inference as a data analytic methodology had to wait until the rediscovery of MCMC methods in the 1970s and 1980s, and the spread of personal computers in the 1990s. In the 1990s, Bayesian inference emerged as a vibrant research area in many different fields of science and the number of publications using Bayesian inference has exploded since then.

One distinct aspect of Bayesian inference in political science is that major developments have taken the form of 'model developments' accompanied by computational improvement. This parallel development in model development and computational improvement is due, in part, to the advent of powerful open-source software such as R (R Core Team, 2018), BUGS, python, and

STAN. This parallel development enhances the transparency of Bayesian methods, facilitates the wide usage of Bayesian methods in applied research, and helps methodologists develop a more sophisticated Bayesian method. During this progress, political methodologists find various Bayesian techniques such as data augmentation, parameter expansion, Gibbs sampling, Metropolis–Hasting sampling, and variational inference to be highly useful to address methodological challenges political scientists encounter. The most notable applications of the Bayesian technique in political science include roll-call data analysis, survey data analysis, discrete data analysis, time series cross sectional data analysis, network analysis, and text analysis.

Despite many impressive innovations, Bayesian inference in political science faces new challenges. The most critical challenge comes from big data and subsequent developments in machine learning/artificial intelligence methods. How does Bayesian inference adapt to the explosion of data size and model complexity while properly incorporating the uncertainty involved in model selection and parameter estimation? How does Bayesian computation satisfy the demand for scalability without sacrificing advantages of a fully probability inference? Although there is no question that Bayesian inference will continue to provide a consistent and complete answer to many problems political scientists face, a certain level of adaptation would be required to address these new inferential, as well as computational, challenges.

## WHAT IS A BAYESIAN INFERENCE?

A concise definition of Bayesian inference can be found in Gelman et al. (2012: 1): ‘Bayesian inference is the process of fitting a probability model to a set of data and summarizing the result by a probability distribution on the parameters of the model and on unobserved quantities such as predictions for

new observations’. A longer definition can be found in *Encyclopædia Britannica* (2016):

a method of statistical inference that allows one to combine prior information about a population parameter with evidence from information contained in a sample to guide the statistical inference process. A prior probability distribution for a parameter of interest is specified first. The evidence is then obtained and combined through an application of Bayes's theorem to provide a posterior probability distribution for the parameter. The posterior distribution provides the basis for statistical inferences concerning the parameter.

In both definitions, the central element of Bayesian inference lies in its consistent use of probability distribution in statistical inference.

The consistent nature of Bayesian inference arises from de Finetti's theorem. de Finetti shows the existence of a general representation form of Bayesian inference to any type of exchangeable observations. Let  $\theta$  be a parameter vector,  $y$  be a response vector,  $p(y_i|\theta)$  be a density of data  $i$  given  $\theta$ , and  $p(\theta)$  be a distribution on  $\theta$ . de Finetti's theorem says:

- de Finetti's Theorem: *For exchangeable random variables  $y_1, y_2, \dots, y_n$ ,*

$$p(y_1, y_2, \dots, y_n) = \int \prod_{i=1}^n p(y_i | \theta) p(\theta) d\theta.$$

de Finetti's theorem tells us that if we want to learn about data using parameters, we need to put some form of distribution on  $\theta$ . Thus, de Finetti's theorem justifies the hierarchical structure (i.e., parameters in the likelihood function first come from their own distributions and then follow the distribution of data) of Bayesian inference in its simplest form.

Bayesian inference uses Bayes theorem to learn parameter distributions after seeing data:

$$\underbrace{p(\theta | y, \mathcal{M})}_{\text{posterior distribution}} = \frac{\overbrace{p(y | \theta, \mathcal{M})}^{\text{likelihood}} \overbrace{p(\theta | \mathcal{M})}^{\text{prior}}}{\underbrace{p(y | \mathcal{M})}_{\text{marginal density of data}}}.$$

The above notation is different from a conventional Bayes theorem notation. We specifically denote the fact that all (model) parameters are dependent upon a certain data generative model ( $\mathcal{M}$ ). This expanded notation is highly useful when we think about what prior density, marginal density of data, and the probability of a model are.

First, prior density depends either directly or indirectly on the chosen data generative model ( $p(\theta|\mathcal{M})$ ). When prior density belongs to the same family of distribution with data density, the whole inference becomes straightforward, the property of which is called *conjugacy*. Second, the data density (or likelihood) is directly dependent upon the chosen parametric model ( $p(y|\theta, \mathcal{M})$ ). The density of data is read as the probability of observing data given a specific parametric form of a data generative model. Last, the marginal density of data is independent of the chosen parametric form but is not independent from a data generative model:  $p(y|\mathcal{M})$ . Thus, the marginal density of data should be read as the probability of observing data given a chosen data generative model. Since we want to know about  $\theta$  in most cases,  $p(y|\mathcal{M})$  is often ignored except when we assess model evidence given data ( $p(\mathcal{M}|y)$ ).

To summarize, Bayesian inference consists of the following probability distributions:

- $p(y|\theta, \mathcal{M})$  is a likelihood function or the density of data given parameters and a specific data generative model  $\mathcal{M}$ . This is a major concern of interest in model development.
- $p(\theta|\mathcal{M})$  is a prior distribution of parameters arising from a specific data generative model  $\mathcal{M}$ . We usually choose prior distributions of parameters in conjunction with  $p(y|\theta, \mathcal{M})$  in model development.
- $p(\theta|y, \mathcal{M})$  is a posterior distribution that represents our updated belief about the distribution of  $\theta$  given a specific data generative model  $\mathcal{M}$  and data  $y$ . This is the major quantity of interest in model fitting.
- $p(y|\mathcal{M})$  is a conditional density of data given a specific data generative model. It is also called

model evidence or marginal likelihood.  $p(y|\mathcal{M})$  approximates the probability of observing actually observed data over the entire prior distribution given a specific data generative model  $\mathcal{M}$ . Thus, without specifying a finite sample space for a prior probability distribution, it is difficult to define and interpret this quantity.  $p(y|\mathcal{M})$  is different from  $p(y)$ , which is an *unconditional* density of data and serves just as a normalizing constant in Bayesian model comparison.

- $p(\mathcal{M}|y)$  is a probability distribution of a specific data generative model. When we compare different models, this is the quantity we would like to compare different data generative models.

We can learn about all the above-mentioned quantities using the law of probability, a family of probability distributions, and data. For example, if researchers wish to know about predictive distributions of data  $p(y^{\text{pred}}|y)$ ,

$$\begin{aligned} p(y^{\text{pred}}|y, \mathcal{M}) &= \int p(y^{\text{pred}}, \theta|y, \mathcal{M}) d\theta \\ &= \int p(y^{\text{pred}} | \theta, y, \mathcal{M}) p(\theta | y, \mathcal{M}) d\theta \\ &= \int p(y^{\text{pred}} | \theta, \mathcal{M}) p(\theta | y, \mathcal{M}) d\theta. \end{aligned}$$

If we replace  $y^{\text{pred}}$  by  $y^{\text{missing}}$  and  $y$  by  $y^{\text{observed}}$ , the above formula is equivalent to a missing data imputation method.

If one wishes to assess the model probability of  $\mathcal{M}$ ,

$$p(\mathcal{M}|y) = \frac{p(y|\mathcal{M})p(\mathcal{M})}{p(y)} \propto p(y|\mathcal{M})p(\mathcal{M}).$$

The rightmost approximation indicates that  $p(y)$ , the unconditional data density, is just a normalizing constant and hence it can be ignored in the computation. Another interesting result from the above formula is that if we assume the constant probability for each  $\mathcal{M}$ , comparing  $p(y|\mathcal{M})$  is sufficient to check the model probability.

In many cases of political science research, a statistical model contains multiple parameters, and it is often difficult to sample directly from the joint posterior distribution. In such cases, there exists two general MCMC methods for approximating the posterior distribution: the *Metropolis–Hastings (MH) algorithm* and the *Gibbs sampler*. A probabilistic MCMC algorithm should satisfy the local reversibility condition (or the detailed balance) to make the chain converge to an invariant distribution:

$$p(\theta, \theta^*)f(\theta) = p(\theta^*, \theta)f(\theta^*).$$

The MH algorithm takes advantage of the idea that we can make irreversible transition kernels reversible by multiplying a proper acceptance rate. That is,

$$p(\theta, \theta^*)f(\theta)\alpha(\theta^*, \theta) = p(\theta^*, \theta)f(\theta^*).$$

Then, the acceptance rate is

$$\alpha(\theta^*, \theta) = \min \left[ \frac{p(\theta, \theta^*)f(\theta)}{p(\theta^*, \theta)f(\theta^*)}, 1 \right].$$

This idea can be applied to any posterior distribution. When we can directly sample from the full conditional distributions (i.e., the full conditional distributions have a known distributional form), the proposal distribution becomes the full conditional posterior distributions:

$$\alpha(\theta^*, \theta) = \min \left[ \frac{p(\theta^*)p(\theta)}{p(\theta)p(\theta^*)}, 1 \right] = 1.$$

The implementation of the Gibbs sampler is very similar to the MH algorithm except from the fact that the acceptance rate does not need to be computed because the full conditional distributions follow a known distributional form. Suppose a statistical model includes parameters  $\theta_1, \dots, \theta_k$  and let  $\theta$  denote the vector of length  $k$  that consists of all the model parameters. Here, we want to obtain  $n$  samples from the joint posterior distribution

$p(\theta|y)$ . The Gibbs sampler generates samples by following steps:

- 1 Initialize with  $\theta^{(0)} = (\theta_1^{(0)}, \dots, \theta_k^{(0)})$
- 2 For  $i = 1, \dots, n$  repeat: sample  $\theta_k^{(i)} \sim p(\theta_k | \theta_1^{(i)}, \dots, \theta_{k-1}^{(i-1)}, y)$

The samples generated by this algorithm constitute a dependent sequence of vectors  $\{\theta^{(0)}, \dots, \theta^{(n)}\}$ . Note that the probability of each vector depends only on the previous vector; that is, it is a Markov chain. Under some conditions, those samples approximate the joint posterior distribution.

Because of the computational simplicity, the Gibbs sampler is one of the most widely used MCMC methods. In particular, the Gibbs sampler becomes a major workhorse of Bayesian inference with the popularity of the data augmentation method that transforms an intractable conditional posterior distribution into a tractable one by augmenting latent parameters (Tanner and Wong, 1987; van Dyk and Meng, 2001).

Although the MH algorithm and the Gibbs sampler work well in most statistical models, they often show poor performance in high-dimensional models with many parameters. Many scholars have proposed various MCMC methods to improve the performance of existing MCMC methods. Examples include slice sampling, parallel tempering, particle filtering, and Hamiltonian Monte Carlo methods (see Gordon et al., 1993; Neal, 2003; Earl and Deem, 2005; Neal, 2011 for more details).

## A SHORT HISTORY OF BAYESIAN INFERENCE IN POLITICAL SCIENCE

In this section, we briefly review academic publications on Bayesian methods in political science with a focus on journal articles and open source software contributions. One caveat in this analysis is that we apply the

territorial principle, instead of the personal principle, in judging what constitutes ‘Bayesian inference in political science’. That is, we delimit our discussion to published work in political science journals, omitting a body of work published outside political science journals.

### **Journal Publications**

The word ‘Bayes formula’ appeared in political science publications as early as 1950 (Girshick and Lerner, 1950). However, between the 1950s and 1980s, Bayesian inference meant a decision theoretic analysis following the classical work of Savage (1954). The only exception is Achen (1978), who used the modern form of Bayesian inference to theoretically justify his measures.

The beginning of Bayesian analysis as a data analytical tool in political science was started by King and Gelman (1991). In this paper, King and Gelman show how Bayesian inference can be applied to estimate incumbency advantage in US Congressional elections. First, they showed why a probabilistic model should be preferred to deterministic methods. A probabilistic model is less susceptible to arbitrary decisions, allows our inference to be more realistic, and provides measures of uncertainty. Then, they built a Bayesian hierarchical model of district vote shares capturing variations across congressional districts and election years. In this way, the paper demonstrates how Bayesian inference can be used to quantify substantively important quantities of interest in political science such as partisan bias, electoral responsiveness, and incumbent advantages.

Since the publication of King and Gelman (1991), papers that use or develop Bayesian methods have increased dramatically in political science journals. For example, Jackman (1994) developed a Bayesian measurement model of electoral bias and responsiveness using summaries of posterior distributions.

Figure 47.1 shows the number of political science journal articles between 1991 and 2014 containing ‘Bayesian’ or ‘Bayes’ as a keyword. In this search, we excluded game theory papers. We also limited our search up to 2014 because the Jstor engine ([www.jstor.org](http://www.jstor.org)) does not have publication information for some journals after 2014. Figure 47.1 clearly demonstrates that the number of ‘Bayesian’ publications increased dramatically during the last two decades.

Table 47.1 summarizes the Bayesian publication between 1991 and 2014 by journals. *Political Analysis* is ranked at the top (137 articles), followed closely by the *American Journal of Political Science* (116 articles). *American Political Science Review*, the top flagship journal of political science, has as many as 51 publications during this period. Overall, the publication records clearly showed that Bayesian methods have been well established as a major data analytic paradigm during the last two decades.

Then, what types of topics have been covered by those publications? Table 47.2 summarizes the topics of Bayesian publications between 1991 and 2014. We fit a Latent Dirichlet Allocation model to a text dataset of journal abstracts for all the Bayesian publications between 1991 and 2014. Topic 1 represents Bayesian inference of voting behavior and electoral studies. Topic 2 covers political economy and public policy literature. Topic 3 concerns technical papers and time series analysis using Bayesian methods. Topic 4 corresponds to international politics applications of Bayesian inference. Topic 2 includes Bayesian inference of opinion poll analysis. Overall, the range of topics clearly shows that Bayesian methods have been widely applied to various sub fields in political science.

### **Software**

Another way to review a history of Bayesian inference in political science is to

**Figure 47.1** The number of journal articles containing Bayesian as a keyword excluding game theory papers. The search was done for journal articles between 1991 and 2014 using the JSTOR search engine

**Table 47.1** Summary by journals: the number of journal articles containing 'Bayesian' in the abstract excluding game theory-related articles

look at software developments. We focus on R packages contributed by political scientists to CRAN (2018). To identify Bayesian packages, we used the information in Bayesian Inference Task View (<https://cran.r-project.org/web/views/Bayesian.html>) and individual package descriptions and function contributions in package documents. Some packages cover a wide range of models and have multiple contributors.

As of September 2018, we identified 10 Bayesian packages contributed by political scientists to CRAN. The Bayesian software contributions in R do not closely match the increasing number of Bayesian publications in political science journals. One reason may be that political scientists prefer online version control platforms such as github for code sharing and repository instead of developing

**Table 47.2 Summary by topics: top 15 words sorted by the topic-word probability using text2vec package (Selivanov and Wang, 2018)**

<i>Topic 1</i>	<i>Topic 2</i>	<i>Topic 3</i>	<i>Topic 4</i>	<i>Topic 5</i>
Elections	Research	Statistical	Economic	Public

**Table 47.3 Bayesian R Packages: Bayesian packages hosted in CRAN**

<i>R package</i>	<i>Description</i>	<i>Author</i>
BaM	Companion of Bayesian methods: A social and behavioral sciences approach	Jonathan Homola, Danielle Korman, Jacob Metz, Miguel Pereira, Mauricio Vela, and Jeff Gill
EBMAforecast	Ensemble Bayesian model averaging model	Jacob M. Montgomery, Florian M. Hollenbach, Michael D. Ward
eco	Bayesian methods for ecological inference	Kosuke Imai, Ying Lu, and Aaron Strauss
MCMCpack	MCMC algorithms for a wide range of models	Andrew D. Martin, Kevin M. Quinn, Jong Hee Park
MNP	Bayesian multinomial probit model	Kosuke Imai and David van Dyk
NetworkChange	Bayesian changepoint analysis of network models	Jong Hee Park and Yunkyu Sohn
pscl	Bayesian analysis of IRT models	Simon Jackman
rstan	R interface to Stan	Jiqiang Guo, Jonah Gabry, Ben Goodrich
SimpleTable	Bayesian inference for causal effects from $2 \times 2$ tables K	Kevin M. Quinn
sparsereg	Sparse Bayesian models for regression, subgroup analysis, and panel data	Marc Ratkovic and Dustin Tingley.

a stand-alone package. Another reason is that more and more political scientists are interested in applied Bayesian research using existing software instead of developing their own models/algorithms and companion packages.

Beside journal publications and software development, we briefly mention books on

Bayesian methods published by political scientists. First, Gill's (2007) *Bayesian Methods: A Social and Behavioral Sciences Approach* is the first general social science introduction to Bayesian methods with a companion R package (BaM). Later, Jackman (2009) published *Bayesian Analysis for the Social*

*Sciences* as a general reference to Bayesian methods for social sciences. Gelman et al.'s (2012) *Bayesian Data Analysis* is the most comprehensive reference to Bayesian methods beyond political science and social science audience.

## MAJOR DEVELOPMENTS IN BAYESIAN INFERENCE IN POLITICAL SCIENCE

In this section, we briefly review major developments of Bayesian methods in political science in last two decades. Given the limitation of this review, we had to choose a small number of published work that could be classified by the categories of measurement models, hierarchical models, time series models, and new developments.

### *Measurement Models*

The measurement model refers to a statistical model that infers latent variables using observed data. Among several Bayesian approaches to the measurement problem, item-response theory (IRT) models have been widely used by political scientists. In this section, we briefly overview why Bayesian inference has been so successful in ideal point estimation (Jackman, 2001; Martin and Quinn, 2002; Clinton et al., 2004; Quinn, 2004; Bafumi et al., 2005; Barberá, 2015; Imai et al., 2016) and how this framework was transformed to measure different latent variables in political science (Treier and Jackman, 2008; Pemstein et al., 2010).

### *Measuring Ideal Points*

There is no doubt that ideal point estimation is one of the most successful applications of

Bayesian methods in political science. We will forward readers to Chapter 48 of this *Handbook* for the details of Bayesian ideal point estimation method. Instead, here, we highlight three factors that contributed to the success of Bayesian inference in ideal point estimation.

The first factor is the introduction of IRT models as a data generative model ( $\mathcal{M}$ ) of legislative voting. IRT was originally developed in psychometrics as a dimension-reduction technique of high-dimensional testing results. Poole and Rosenthal (1997) was the first important groundwork that connected a statistical model with a spatial voting model in the MLE framework. However, the IRT model was re-discovered by Bayesian statisticians (Albert, 1992) and political scientists as a better statistical framework for modeling legislative voting. The close connection between parameters of the (two-parameter) IRT model and a spatial voting model makes the IRT model a natural choice. Clinton et al., (2004) present a standard Bayesian implementation of the IRT model for ideal point estimation.

The second factor is the computational power of MCMC algorithms. Albert (1992) and Clinton et al., (2004) provide an efficient Gibbs sampling algorithm to update all the parameters of the (two-parameter) IRT model. The MCMC estimation of the IRT model can deal with large data and provide proper measures of estimation uncertainty. Easy to use Bayesian software such as *pscl*, *BUGS*, and *MCMCpack* allows users to fit Bayesian IRT models to their data without much programming skill.

The third, and most important, factor for the success of Bayesian inference in ideal point estimation is its modeling flexibility. Unlike other non-Bayesian frameworks, Bayesian IRT models prove to be highly flexible to incorporate additional layers of model complexity. For example, Martin and Quinn (2002) added a dynamic linear process of ideal points within a Bayesian IRT model to estimate US Supreme Court

justices' ideal point changes over their service time. Martin and Quinn's (2002) model

can be understood as a special type of

two-parameter IRT model with prior densities of subject-specific, first-order Markov processes:

$$z_{ijk} = \beta_i \theta_{j,t} - \alpha_i + \varepsilon_{ijt}, \quad \varepsilon_{ijt} \sim N(0,1) \quad [\text{Likelihood}]$$

$$\theta_{j,t} \sim N(\theta_{j,t-1}, \sigma_j^2) \quad \text{for } t > 1 \text{ and } j = 1, \dots, J \quad [\text{First-order Markov process}]$$

Quinn (2004) also developed a Bayesian measurement model for mixed multivariate responses. The model estimates latent factor components from ordinal and continuous response data. Recently, Barberá (2015) developed a simple model of network ideal point where the Twitter user  $i$ 's latent propensity to follow politician  $j$ 's Twitter is a decreasing function of the distance between ideal points of Twitter user  $i$  and politician  $j$ .

corresponds to the *item discrimination parameter* in the sense that it indicates how much the item  $j$  helps in distinguishing different levels of democracy. Pemstein et al., (2010) also proposed a Bayesian approach for measuring democracy. They assume that rating  $t_{ij}$  is generated by the following process:  $t_{ij} = z_i + e_{ij}$  where  $z_i$  is the latent level of democracy in country-year  $i$ .

Schnakenberg and Fariss (2014) presented a dynamic ordinal IRT (DO-IRT) model to measure temporal dependence in human rights levels using jags. They showed that a dynamic measurement of human rights levels using Bayesian methods outperforms a static measurement model.

### Measuring Democracy and Human Rights Levels

Based on the success of Bayesian IRT models in ideal point estimation, Treier and Jackman (2008) developed the ordinal IRT model to measure the level of democracy from the Polity indicators. Let  $i = 1, \dots, n$  index country-years,  $j = 1, \dots, m$  index the Polity indicators, and  $k = 1, \dots, K_j$  index the (ordered) response categories for item  $j$  – then the proposed model is

$$\begin{aligned} \Pr(y_{ij} = 1) &= F(\tau_{j1} - x_i \beta_j) && \vdots \\ &\vdots && \vdots \\ \Pr(y_{ij} = k) &= F(\tau_{jk} - x_i \beta_j) - F(\tau_{j,k-1} - x_i \beta_j) && \vdots \\ &\vdots && \vdots \\ \Pr(y_{ij} = K_j) &= 1 - F(\tau_{j,K_j-1} - x_i \beta_j) \end{aligned}$$

where  $x_i$  is the latent level of democracy in country-year  $i$ ,  $y_{ij}$  is the  $i$ th country-year's score on indicator  $j$ ,  $\tau_j$  is a vector of unobserved thresholds for item  $j$ , and  $F(\cdot)$  is here defined as the logistic CDF; that is,  $F(\tau_{jk} - z_i) = 1/(1 + \exp(-\tau_{jk} + z_i))$ . Note that  $\beta_j$

### Hierarchical Models

The idea of Bayesian inference as a scientific research method can be appealing in many different ways. What we have emphasized so far was the consistent use of probability distributions in the estimation, prediction, and diagnostics of a model. Moreover, we have mentioned that the de Finetti theorem tells us that Bayesian inference is a highly general framework to model any type of exchangeable data.

Another important appeal of Bayesian inference comes from the property of Bayesian estimates. The first important property is that the mean of the posterior distribution minimizes the mean square error (MSE). When we use a conjugate prior, the posterior mean can be decomposed into a weighted average of prior information and information from data.

Let  $y_i|\theta \sim N(\theta, \sigma^2)$  and  $\theta \sim N(\mu, \tau^2)$ . Then, the posterior mean is

$$E(\theta | y) = \bar{y} + \omega(\mu - \bar{y})$$

where  $\omega = \frac{\tau^{-2}}{n\sigma^{-2} + \tau^{-2}}$ .  $\omega$  is a shrinkage factor that pushes the posterior mean toward the prior mean as it approaches to 1.  $\omega$  approaches 1 as the sample variance of data ( $\sigma^2/n$ ) approaches to infinity. Then, we learn almost nothing from data and  $E(\theta|y)$  becomes the prior mean ( $\mu$ ). Instead, as the sample variance of data decreases,  $\omega$  approaches 0 and  $E(\theta|y)$  becomes  $\bar{y}$ .

The same can be said to a multilevel (or hierarchical) model. Let  $y_{ij}|\theta_j \sim N(\theta_j, \sigma^2)$  for  $i = 1, \dots, n_j$  and  $j = 1, \dots, J$ .  $i$  is an individual unit and  $j$  is a group indicator containing multiple individuals. We assume  $\theta_j \sim N(\mu, \tau^2)$ . Therefore, the posterior mean for group  $j$  is

$$E(\theta_j | y, \mu, \tau^2) = \bar{y}_j + \omega_j(\mu - \bar{y}_j)$$

where  $\bar{y}_j = \frac{1}{n_j} \sum_{i=1}^{n_j} y_{ij}$  and  $\omega_j = \frac{\tau^{-2}}{\sigma_j^{-2} + \tau^{-2}}$ . Again, the posterior mean is a weighted average of the prior mean and the sample mean of group  $j$ 's observations. Since we assume a known variance,  $\sigma_j^{-2} = \frac{\sigma^2}{n_j}$ . Then, as group  $j$ 's observations increase,  $\omega_j$  becomes smaller. In other words, the Bayesian mean estimate weighs prior mean and data mean based on the amount of information in each group.

This property of Bayesian estimates is known as a partial pooling or shrinkage estimation. As we have mentioned above, partial pooling or shrinkage estimates are the minimum MSE estimates in most cases and this property is particularly useful to make a statistical inference from complex data with multiple layers. For example, Western (1998) shows that Bayesian hierarchical models can be used to test a multiplicative hypothesis in social sciences as Bayesian hierarchical

models are a general version of a full interaction model. Gelman et al. (2007) use the idea of Bayesian partial pooling to illustrate the puzzle of switching signs of income and voting at the individual and state levels. Gelman et al. (2007) model individual vote choices to be affected by multi layered factors at the individual and state level. Then, they show that while individual income affects individual vote choices similarly across states, the association of average state income with state-level vote propensities varies significantly across states.

The method of partial pooling is particularly useful to aggregate multiple sources of polls into a national trend for election forecast and media bias estimation. For example, Jackman (2005) develops a hierarchical model of election polls where partially pooled estimates of pollster effects can be considered as pollster bias. Lock and Gelman (2010) also use Bayesian inference to forecast election outcomes using data collected from various sources (actual past election outcomes, pre-election polls, and model estimates).

Last, Hoff and Ward (2004) introduce a Bayesian hierarchical modeling approach to high-order network dependences. This hierarchical framework for network data significantly influences network analysis in international relations (Ward and Hoff, 2007, Minhas et al., 2016).

### ***Time-series Models***

Another important area in the development of Bayesian methods in political science is time series models. Although classical frequentist methods have dominated time series models for stationary processes in political science and economics for a long time, many scholars find Bayesian methods to be highly useful to model non-stationary stochastic processes in political science data. Martin and Quinn (2002) is the important early work that shows the power of Bayesian methods in

modeling temporal dynamics in a measurement model.

Bayesian time series developments in political science can be divided into three different areas. The first is change-point models (or discrete hidden Markov models) (Spirling, 2007; Park, 2010, 2011, 2012; Blackwell, 2018). The change-point problem can be stated as a problem to find break points of parameter heterogeneity in sequentially observed data. Let  $y = y_1, \dots, y_t$  be sequentially observed response data and  $x$  be a vector of covariates. Then,

$$y_t = \begin{cases} x'_t \beta_1 + \varepsilon_t, & \varepsilon_t \sim N(0, \sigma_1^2) & \text{for } t_0 \leq t < \tau_1 \\ \vdots & \vdots & \vdots \\ x'_t \beta_M + \varepsilon_t, & \varepsilon_t \sim N(0, \sigma_M^2) & \text{for } \tau_{M-1} \leq t < T. \end{cases}$$

The change-point problem is to find  $\tau = \{\tau_1, \dots, \tau_{M-1}\}$  for  $M$  changepoints and estimate regime-specific model parameters. Western and Kleykamp (2004) first showed the appeal of change-point analysis in political science research and provided a simple BUGS code to fit a single change-point model based on Carlin et al. (1992). Spirling (2007) further extended Carlin et al.'s (1992) single change-point model into discrete data cases. Based on these successful demonstrations of Bayesian change-point analysis, Park (2010) introduced a Poisson regression change-point model with multiple change-points based on Chib (1998) and Frühwirth-Schnatter and Wagner (2004). Park (2011) further developed a probit regression change-point model for binary and ordinal time series data. Recently, Blackwell (2018) presented change-point models for count data that allow infinitely many change-points through Dirichlet process prior.

The second area of time series modeling using Bayesian methods is the Bayesian implementation of vector autoregression (VAR) models (Brandt and Freeman, 2006, 2009; Brandt and Sandler, 2012). Brandt and Freeman (2006, 2009) introduced a Bayesian VAR model into political science and showed its utility to model macro political processes

with complex endogeneity and contemporaneous shocks. Brandt and Sandler (2012) further extended the Bayesian VAR into count data using a Poisson model.

The third important area of time series modeling using Bayesian methods is time-series cross sectional (TSCS) models. Pang (2010) developed a Bayesian generalized linear model for TSCS data with  $p$ th-order autoregressive error process. Pang (2014) further developed a Bayesian multilevel multifactor error structure model with a  $p$ th-order autoregressive process in linear, probit, and logistic specifications to account for complex cross-sectional dependence in TSCS data. While these models address unobserved time-varying shocks at the individual levels, another concern in TSCS analysis is regime-dependent shocks at the individual level or regime-dependent common shocks. To address these confounders, Park (2012) developed a hidden Markov fixed-effects model and a hidden Markov random-effects model.

## NEW DEVELOPMENTS AND DISCUSSIONS

Before we finalize our review, we would like to highlight a couple of important developments that use Bayesian models as a data generative model while using machine-learning techniques to estimate Bayesian models.

The first example is Bayesian models for text analysis. Grimmer (2010) presented a Bayesian hierarchical topic model for measuring expressed agenda from text data. In Grimmer's (2010) model, each US senator's expressed agenda is a random draw from a Senate-level multinomial distribution. Conditional upon the drawn agenda, a topic of each press release document is a random draw from document-level multinomial distribution. Then, word counts are normalized to have unit length and modeled to follow the von Mises–Fisher distribution. Due to the

complexity of the model, Grimmer (2010) employs variational Bayes methods.

The second example is a structural topic model (STM) (Roberts et al., 2014). Conventional LDA-based topic models use a Bayesian hierarchical structure to make inference about topic and word distributions. STM adds another layer to explain the path from exogenous covariates (or meta information) to topic and word distributions. STM significantly widens the scope of text data analysis in political science, as discussed in Roberts et al. (2014) and Lucas et al. (2015). Estimation of STM is based on variational expectation-maximization (EM).

The third example is a sparse Bayesian regression model (Ratkovic and Tingley, 2017). Ratkovic and Tingley (2017) proposed a Bayesian estimator of a sparse model by replacing the shape parameter of the global shrinkage parameter in Bayesian lasso by calibrated parameters. Ratkovic and Tingley (2017) show that the resulting sparse estimates are consistent and satisfy the Oracle Property and Oracle Inequality.

The last example is Imai et al. (2016). Imai et al. (2016) innovate the estimation method of various Bayesian item response theory models developed by political scientists using EM and variational Bayes methods while keeping the model structure intact. Imai et al. (2016) reported significant reductions in computation time compared to conventional MCMC-based estimation. Their estimation method is particularly useful when researchers analyze large-size data.

These three examples have commonality in using Bayesian models as a generative model for data generating process. However, they avoid conventional MCMC methods to improve computational performance and to account for a more sophisticated model structure.

There is no doubt that political scientists are witnessing an unprecedented inflow of data in the 21st century and these innovations

will serve as important resources to this new challenge. However, we would like to make some cautionary notes regarding this new trend.

First, computational improvements using EM or variational Bayes applies solely or mainly to point estimation at the *mode* of parameters. For example, EM algorithm finds maximum a posteriori (MAP) estimates of parameters, which tend to have a larger mean squared error (MSE) than posterior means (Kyung et al., 2010). When a model has multiple modes, as in mixture models, the MSE difference between MAP and posterior means could be sizable and leads to erroneous inference. Moreover, EM algorithm does not generate measures of uncertainty by itself. Thus, the estimation of uncertainty needs to be done separately after the MAP estimation. The case of Imai et al. (2016) is a good example. Although EM and variational Bayes-based algorithms significantly reduce the computing time to get point estimates of various IRT models, they need to re-run their models (i.e., bootstrap) to get standard errors after. These re-runs for standard error calculation are not just computationally expensive (maybe not that much compared to a full MCMC run) but also inferentially costly because we do not know how much information is lost in this two-step (point estimation and bootstrapping) process.

Generally speaking, most approximate Bayesian methods involve a fundamental shortcoming of understating parameter uncertainty. For example, Grimmer (2011) notes that ‘factorized approximations will always understate the variability in the posterior’ (Grimmer, 2011: 6). A troubling fact is that it is difficult to precisely gauge the level of understatement and the difficulty becomes more pronounced as model complexity increases.

‘Getting uncertainty right’ has been the most important vantage point of Bayesian methods and this is why MCMC methods

that provide proper Monte Carlo draws of a posterior distribution were hailed as a major breakthrough by many applied researchers. With this in mind, we should think carefully about the trade-off involved in recent computational innovations in Bayesian literature.

The second cautionary note is the lack of principled methods to check the model uncertainty in recent computational innovations. For example, EM and variational Bayes-based algorithms transform the Bayesian estimation from stochastic integration to numerical optimization through analytical reconstructions of the posterior distribution. In doing so, it becomes difficult to compute the posterior model probability ( $p(\mathcal{M}|y)$ ) using outputs of EM and variational Bayes-based algorithms. In the case of Grimmer (2010), researchers may want to learn the number of topics from data instead of assuming it to be known and fixed, as in Grimmer (2010). In the case of Imai et al. (2016), researchers may want to compare one data generative model for legislative voting with others to check different utility functions, different parametric forms, and different voting models. All of these questions require a proper evaluation of the posterior model probability ( $p(\mathcal{M}|y)$ ). It would be an interesting future research topic to develop a method to compute the posterior model probability ( $p(\mathcal{M}|y)$ ) using computationally efficient algorithms.

Bayesian inference in political science has contributed significantly to empirical research in political science through its representational consistency, computational power, and modeling flexibility. The advent of big data and innovative machine learning methods pose both opportunities and challenges to Bayesian methods. However, parameter and model uncertainty is essential information for social scientists in theory testing, variable selection, and model comparison. With that in mind, expanding the frontiers of Bayesian methods for

social scientists would be an exciting adventure of social science methodology in the 21st century.

# Bayesian Ideal Point Estimation

Shawn Treier

## INTRODUCTION

Ideology is a fundamental concept of politics, and this is especially true of legislatures. The popular understanding is that a politician makes policy decisions based on their discernible ideology, with relative comparisons of these politicians easily placed in common conversation. This is consistent with an academic conceptualization of ideology as a set of constrained belief systems, represented geometrically by low-dimensional ‘basic spaces’ where legislators’ ideal positions in this space determine their observed stances on the concrete policy proposals they regularly face in legislative session. This characterization, best enunciated by Poole (2005), implies that the secret to understanding how a legislature operates is through the configuration of these ideal points in the basic ideological space, demanding empirical measurement. This invitation was successfully answered with the ground-breaking NOMINATE-based

estimates, developed by Keith Poole and Howard Rosenthal (1985, 1991, 1997) and greatly facilitated by the presence of large amounts of recorded roll calls – and a lack of strict party discipline. The widespread distribution of these measures has advanced the study of Congress – and other legislatures and political institutions – immensely.<sup>1</sup>

The focus of this chapter is a survey of work that utilizes a new set of statistical tools to pursue the same measurement issues as well as address new questions. The increase in computing power by the 1990s made feasible the application of Bayesian approaches to the estimation of many types of models. Bayesian estimation of the ideal point model was first broadly promulgated by Clinton et al. (2004), who outline the advantages. These include the relatively simple simultaneous estimation of all parameters, a full characterization of uncertainty of the ideal points, and the immediate calculation of complex auxiliary quantities. These qualities also make

the models easily extendable, allowing for a straightforward incorporation of the ideal points into regression models that account for uncertainty or implementation of direct tests of theories based on the configuration of preferences.

This chapter will outline these developments and survey the many applications and extensions. First, the basics of the Clinton–Jackman–Rivers (CJR) IDEAL model (estimation, inference, identification, and model assessment) are presented, as well as comparisons to NOMINATE (including the Bayesian version). Next, many various extensions to the model are covered. Bayesian models are naturally modular through the specification of hierarchical structures, simplifying the inclusion of ideal points as dependent or independent variables in regression models. Many researchers also address the complicated identification issue of comparability over time and/or institutions. Some of these solutions are specifically Bayesian; most notably, the dynamic models behind the Martin Quinn Supreme Court ideal point estimates, which allow small movements over time in any direction. Others, such as identifying ‘bridge’ votes (e.g., votes on identical worded bills in the House and Senate) or other public positions (e.g., presidential proclamations), concern only the structure of the data but are easier to assess with Bayesian methods. Models have also been extended in order to include agenda information (tracking bill passages to identify status quo and bill parameters).

The inclusion of data other than roll calls will be a critical extension for the future estimating ideal points. Of all these potential data sources, the most important will be text data. Melding text data with roll calls may create greater distinctions between legislators, provide another basis for establishing comparability over time and institution, and characterize the ideological content of bills directly, with a Bayesian approach remaining the most feasible method, despite many challenges.

## SPATIAL MODEL OF VOTING AND RUM FRAMEWORK

Two methodological approaches familiar to most political scientists are the rational choice theory of spatial voting and the random utility model (RUM) framework applied to logit and probit regressions.

In the spatial model of voting, every vote  $j$  is a choice between two positions: ‘Nay’ (status quo,  $q_j$ ) and ‘Yea’ (bill proposal or amendment,  $p_j$ ). Every legislator’s preferences between these two options are determined by the relative ideological proximity of the individual’s ‘ideal’ point,  $x_i$  (i.e., proposal,  $p_j$ , is the most preferred proposal is closer to  $x_i$ , otherwise  $q_j$ ). Utility is defined for both options in the following one-dimensional representation:

$$U(q_j) = f(|x_i - q_j|) \tag{1}$$

$$U(p_j) = f(|x_i - p_j|) \tag{2}$$

with legislator  $i$ ’s vote on roll call  $j$  ( $y_{ij}$ ) represented as

$$y_{ij} = \begin{cases} \text{‘Yea’} & \text{if } U(p_j) > U(q_j) \\ \text{‘Nay’} & \text{if } U(q_j) > U(p_j) \end{cases} \tag{3}$$

and indifferent when  $U(p_j) = U(q_j)$  (but a probability zero event). The decision can be represented in terms of a threshold. Define the midpoint between  $q_j$  and  $p_j$  as  $c_j = \frac{q_j + p_j}{2}$ .

if  $p_j > q_j$ , legislator  $i$ ’s voting decision is

$$y_{ij} = \begin{cases} \text{‘Yea’} & \text{if } x_i > c_j \\ \text{‘Nay’} & \text{if } x_i < c_j \end{cases} \tag{4}$$

with  $>$  and  $<$  operators reversed if  $q_j > p_j$ .

An essential assumption in the spatial voting model is that only the distance between the ideal point and voting options are relevant. An almost universally applied assumption is that preferences are single-peaked, with utility  $U(p_j)$  [ $U(q_j)$ ] decreasing as  $|x_i - p_j|$  [ $|x_i - q_j|$ ] increases. Furthermore, these

preferences are assumed to be symmetric, regardless of the vote option being less than or greater than  $x_i$ .

The statistical model is characterized by specific parametric forms for  $f(\cdot)$  and the addition of random error in  $U(\cdot)$ . The Clinton et al. (2004) representation specifies  $f(\cdot)$  as the quadratic function, with the utility of each option including a linearly additive random error:

$$U(q_j) = -(x_i - q_j)^2 + \varepsilon_{i,q_j} \quad (5)$$

$$U(p_j) = -(x_i - p_j)^2 + \varepsilon_{i,p_j} \quad (6)$$

where both  $\varepsilon_{i,q_j} \sim N(0,0.5)$  and  $\varepsilon_{i,p_j} \sim N(0,0.5)$  are independent, thus implying  $\varepsilon_{i,p_j} - \varepsilon_{i,q_j} \sim N(0,1)$ , consistent with a traditional RUM specification for a probit model (conversely, each error term could follow a Type I error distribution in order to define a logistic model).

The difference of these utilities can be represented as

$$\begin{aligned} y_{ij}^* &= U_i(p_j) - U_i(q_j) \\ &= -(x_i - p_j)^2 + (x_i - q_j)^2 + (\varepsilon_{i,p_j} - \varepsilon_{i,q_j}) \\ &= -x_i^2 + 2p_jx_i + p_j^2 + x_i^2 \\ &\quad - 2q_jx_i + q_j^2 + (\varepsilon_{i,p_j} - \varepsilon_{i,q_j}) \\ &= 2(p_j - q_j)x_i - (p_j^2 - q_j^2) + (\varepsilon_{i,p_j} - \varepsilon_{i,q_j}) \\ &= \beta_jx_i - \alpha_j + \varepsilon_{ij}, \end{aligned}$$

where  $\beta_j = 2(p_j - q_j)$  and  $\alpha_j = p_j^2 - q_j^2$ . The model reduces to the latent-variable representation of a binary logit or probit, with the following complications: (1) the independent variable  $x_i$  is unobserved and (2) the intercept and slope coefficients  $\alpha_j$  and  $\beta_j$  vary by vote  $j$ . This model also corresponds to the binary item response theory (IRT) models from education and psychology, testing literatures with the following reparameterization:

$$\begin{aligned} y_{ij}^* &= \beta_jx_i - \alpha_j + \varepsilon_{ij} \\ &= \beta_j \left( x_i - \frac{\alpha_j}{\beta_j} \right) + \varepsilon_{ij} \\ &= \beta_j \left( x_i - \frac{p_j^2 - q_j^2}{2(p_j - q_j)} \right) + \varepsilon_{ij} \\ &= \beta_j \left( x_i - \frac{p_j + q_j}{2} \right) + \varepsilon_{ij} \\ &= \beta_j(x_i - \kappa_j) + \varepsilon_{ij} \end{aligned}$$

with  $\beta_j$  as the *discrimination* parameter and  $\kappa_j$  is the *difficulty* parameter. The difficulty parameter is identical to the cutpoint from the spatial voting model, so it can be recovered as  $\kappa_j = -\frac{\alpha_j}{\beta_j}$ , and is the value of  $x_i$  such

that  $\Pr(y_{ij} = 1) = 0.5$ . The discrimination parameter measures the extent to which the question separates higher- and lower-ability students in the testing literature, and – with respect to ideal point models – separates right and left (usually oriented as conservative and liberal) legislators; e.g., the higher the cutpoint, the more conservative the vote (relative to the status quo). If  $\beta_j = 0$ , it implies the vote is unrelated to the ideological positions of legislators.

The multidimensional representation of the CJR model is Euclidean, with equal weights for the dimensions. In two dimensions,

$$\begin{aligned} U(\mathbf{q}_j) &= -(x_{1i} - q_{1j})^2 - (x_{2i} - q_{2j})^2 + \varepsilon_{i,\mathbf{q}_j} \\ U(\mathbf{p}_j) &= -(x_{1i} - p_{1j})^2 - (x_{2i} - p_{2j})^2 + \varepsilon_{i,\mathbf{p}_j} \end{aligned}$$

with a reduced form of

$$y_{ij}^* = x_{1i}\beta_{1j} + x_{2i}\beta_{2j} - \alpha_j + \varepsilon_{ij}$$

More generally,

$$\begin{aligned} y_{ij}^* &= x_{1i}\beta_{1j} + x_{2i}\beta_{2j} + \dots + x_{ki}\beta_{kj} \\ &\quad - \alpha_j + \varepsilon_{ij} = \mathbf{x}\beta_j - \alpha_j + \varepsilon_{ij} \end{aligned}$$

is the reduced form for the difference in the following utilities:

$$\begin{aligned}
 U(\mathbf{q}_j) &= \sum_{k=1}^K -(x_{ki} - q_{kj})^2 + \varepsilon_{i,\mathbf{q}_j} \\
 &= -\|\mathbf{x}_i - \mathbf{q}_j\|^2 + \varepsilon_{i,\mathbf{q}_j} \\
 U(\mathbf{p}_j) &= \sum_{k=1}^K -(x_{ki} - p_{kj})^2 + \varepsilon_{i,\mathbf{p}_j} \\
 &= -\|\mathbf{x}_i - \mathbf{p}_j\|^2 + \varepsilon_{i,\mathbf{p}_j}
 \end{aligned}$$

where  $\beta_j = 2(\mathbf{p}_j - \mathbf{q}_j)$  and  $\alpha_j = \mathbf{p}'_j\mathbf{p}_j - \mathbf{q}'_j\mathbf{q}_j$ .

**ESTIMATION**

The probability that legislator  $i$  on roll call vote  $j$  votes ‘Yea’ is

$$\begin{aligned}
 \Pr(y_{ij} = 1) &= \Pr(y_{ij}^* > 0) \\
 &= \Pr(\varepsilon_{ij} < \beta_j \mathbf{x}_i - \alpha_j) = F(\beta_j \mathbf{x}_i - \alpha_j)
 \end{aligned}$$

and defines the likelihood of the model:

$$\begin{aligned}
 L(\mathbf{x}, \alpha, \beta | \mathbf{Y}) &\propto f(\mathbf{Y} | \mathbf{x}, \alpha, \beta) \\
 &= \prod_{i=1}^n \prod_{j=1}^J F(\beta_j \mathbf{x}_i - \alpha_j)^{y_{ij}} \\
 &\quad [1 - F(\beta_j \mathbf{x}_i - \alpha_j)]^{1-y_{ij}} \tag{7}
 \end{aligned}$$

Like all measurement models, this relies on the local independence assumption: conditional on  $\mathbf{x}_i$ , responses  $y_{ij}$ ,  $y_{ik}$  are independent; the only source of commonality is latent value  $x_i$ . So, not only are decisions by individuals independent (i.e.,  $y_{ij}$ ,  $y_{hj}$ ,  $i \neq h$ ), but each vote decision is distinct from the others. Violations could occur if the dimensionality is underestimated or if votes have a logical connection (such as a log-roll).

The estimation problem is particularly daunting; there are  $nJ$  observations with  $nK + J(K + 1)$  parameters and increases in either

$n$  or  $J$  present difficulties in the asymptotic properties of the model. Joint maximization of the full information likelihood is computationally difficult (and not necessarily consistent). Marginal maximum likelihood has been implemented in similar models of IRT, but a critical aspect of these models is that they *marginalize*  $\mathbf{x}_i$  – average over – from the likelihood, thus not estimating  $x_i$ . *Ex ante posteriori* approaches are used to recover the ideal points, but these employ the same prior distribution assumptions of the Bayesian model. In any case, direct marginalization is often quite difficult, so the E-M algorithm is deployed instead. Finally, the approach used with NOMINATE – alternating conditional maximum likelihood – estimates one set of parameters with the others fixed and repeats the process for the other parameter blocks, as discussed in detail below.

Proponents of a Bayesian approach argue that it provides a less problematic approach to estimation to all parameters. The fundamental difference between the two approaches appears superficial:

$$\begin{aligned}
 \text{Likelihood} : L(\mathbf{x}, \alpha, \beta | \mathbf{y}) &\propto f(\mathbf{y} | \mathbf{x}, \alpha, \beta) \\
 \text{Bayesian} : f(\mathbf{x}, \alpha, \beta | \mathbf{y}) &\propto f(\mathbf{y} | \mathbf{x}, \alpha, \beta) f(\mathbf{x}, \alpha, \beta)
 \end{aligned}$$

In the case of ideal point estimation, the prior distribution for each set of parameters are *a priori* independent —  $f(\mathbf{x}, \alpha, \beta) = f(\mathbf{x})f(\alpha)f(\beta)$  — with assumed distributions

$$\begin{aligned}
 x_i &\sim N(0, 1) \quad \forall i = 1, \dots, n \\
 \beta_j &\sim N(0, \sigma_\beta^2) \quad \forall j = 1, \dots, J \\
 \alpha_j &\sim N(0, \sigma_\alpha^2) \quad \forall j = 1, \dots, J
 \end{aligned}$$

Typically, the variance parameters are extremely diffuse, such as  $\sigma_\alpha^2 = \sigma_\beta^2 = 100$ . Both expressions condition the parameters on observed data  $\mathbf{y}$ , reflecting our focus on the parameters, but  $L(\mathbf{x}, \alpha, \beta | \mathbf{y})$  is not a proper joint probability distribution of the parameters. The addition of the prior completes the posterior distribution

$$f(\mathbf{x}, \boldsymbol{\alpha}, \boldsymbol{\beta} | \mathbf{y}) = \frac{f(\mathbf{x}, \boldsymbol{\alpha}, \boldsymbol{\beta}, \mathbf{y})}{f(\mathbf{y})}$$

$$= \frac{f(\mathbf{y} | \mathbf{x}, \boldsymbol{\alpha}, \boldsymbol{\beta}) f(\mathbf{x}, \boldsymbol{\alpha}, \boldsymbol{\beta})}{f(\mathbf{y})},$$

with

$$f(\mathbf{y}) = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} f(\mathbf{y} | \mathbf{x}, \boldsymbol{\alpha}, \boldsymbol{\beta}) f(\mathbf{x}, \boldsymbol{\alpha}, \boldsymbol{\beta}) d\mathbf{x} d\boldsymbol{\alpha} d\boldsymbol{\beta},$$

a complicated but unnecessary component (which, if calculable, is useful for model comparison) and thus the summary of the elements containing the parameters. The additional prior information does not contribute much influence to the posterior (other than set the scale) but does allow us to assign probabilistic interpretations to inferential statements. A second, more practical advantage is the relative ease of computation.

In general, there are three approaches to Bayesian estimation. First, for the simplest problems, the posterior distribution can be directly summarized from the data. When the joint posterior distribution does not define a standard distribution and cannot easily be sampled, there are two common approaches: one is to find the posterior mode and apply an approximation, similar to the maximization approach used for likelihood analysis. Since direct joint optimization in the ideal point model is impractical, the expectation-maximization algorithm can be applied, and such techniques have become more utilized as the size of vote matrices have exploded (see Imai et al., 2016, as an example). With an increased focus on text data, Bayesian variational approximation is another popular choice (Ormerod and Wand, 2010; Grimmer, 2011).<sup>2</sup>

The final approach, and the one most applicable to the Bayesian ideal point problem, is dependent sampling through Markov-chain Monte Carlo (MCMC) methods. The most general approach is Metropolis–Hastings sampling, where one samples from a ‘candidate’ distribution (usually a multivariate

normal or *t* distribution) and ‘adjusts’ the sample by comparing the target and candidate distributions at the sampled value. The algorithm always accepts draws sampled too infrequently from the candidate distribution and probabilistically rejects oversampled regions of the parameter space (and upon rejection, simply replicates another instance of the current value). Applying Metropolis–Hastings sampling to all parameters simultaneously is completely impractical, so Gibbs sampling can be employed instead. If each block of parameters, conditional on the other parameters, forms an easily sampled distribution (usually either an easily recognizable, standard distribution or one-dimensional), then samples are produced iteratively, conditional on other parameters, without rejection. There is also a hybrid approach, where parameter blocks that are less easily sampled employ Metropolis–Hastings sampling, while other parameters are sampled through Gibbs steps. The product is a sample of thousands of draws for the parameters from the posterior distribution. A summary of the distribution based on means, variances, and quantiles involves the simple calculation of summary statistics, as does the construction of summary measures for the posterior distribution of auxiliary quantities.

The multivariate binomial likelihood and normal distribution priors certainly do not combine to form semi-conjugate conditionals. One could apply Metropolis–Hastings sampling on each set of parameters (ideal points and discrimination and difficulty parameters), conditional on current iteration values of the other parameters (see, e.g., Patz and Junker, 1999b), but the simplest approach involves the probit specification of the utility error terms and the sampling approach of Albert (1992), which incorporates the latent utility differences  $y_{ij}^*$  as auxiliary parameters of the posterior. The steps are taken in the following order (following Jackman, 2009: 454–8): (1) sample  $\mathbf{Y}^{*(t)}$  from  $f(\mathbf{Y}^* | \mathbf{X}^{(t-1)}, \boldsymbol{\beta}^{(t-1)}, \boldsymbol{\alpha}^{(t-1)})$ ; (2) sample  $\boldsymbol{\Theta} = [\boldsymbol{\beta}^{(t)}, \boldsymbol{\alpha}^{(t)}]$  from  $f(\boldsymbol{\Theta} | \mathbf{Y}^{*(t)}, \mathbf{X}^{(t-1)})$ ; and (3) sample  $\mathbf{X}^{(t)}$  from

$f(\mathbf{X}|\mathbf{Y}^{*(t)}, \boldsymbol{\beta}^{(t)}, \boldsymbol{\alpha}^{(t)})$ . In one dimension, conditional on model parameters  $\mathbf{x}$ ,  $\boldsymbol{\alpha}$  and  $\boldsymbol{\beta}$ , each  $y_{ij}^*$  is distributed truncated normal:

$$f(y_{ij}^* | y_{ij}, \mathbf{x}_i, \boldsymbol{\beta}_j, \boldsymbol{\alpha}_j) = \begin{cases} N(\boldsymbol{\beta}_j x_i - \boldsymbol{\alpha}_j, 1)\mathbb{I}(-\infty, 0) & \text{if } y_{ij} = 0 \\ N(\boldsymbol{\beta}_j x_i - \boldsymbol{\alpha}_j, 1)\mathbb{I}(0, \infty) & \text{if } y_{ij} = 1 \end{cases}$$

with the implied threshold at 0, since  $y_{ij} = 1$  if  $U(p_j) - U(q_j) \equiv y_{ij}^* > 0$ , and less than 0 if  $y_{ij} = 0$ . Conditional on these latent values, the MCMC problem for  $\boldsymbol{\theta} = [\boldsymbol{\beta} \boldsymbol{\alpha}]$ , with ‘stacked’ prior  $N(\boldsymbol{\tau}_0, \mathbf{T}_0)$  and augmented  $\mathbf{X}^* = [-\mathbf{1} \ \mathbf{x}]$ , simply defines  $J$  Bayesian regressions of  $\mathbf{X}^*$  on  $\mathbf{Y}^*$ , which require draws from normal distributions:

$$f(\boldsymbol{\beta}_j, \boldsymbol{\alpha}_j | \mathbf{X}^*, \mathbf{y}_j^*) = N(\boldsymbol{\mu}_{\theta_j}, \mathbf{V}_{\theta_j})$$

where  $\boldsymbol{\mu}_{\theta_j} = (\mathbf{X}^{*\prime} \mathbf{X}^* + \mathbf{T}_0^{-1})^{-1} (\mathbf{X}^{*\prime} \mathbf{y}^* + \mathbf{T}_0^{-1} \boldsymbol{\tau}_0)$  and  $\mathbf{V}_{\theta_j} = (\mathbf{X}^{*\prime} \mathbf{X}^* + \mathbf{T}_0^{-1})^{-1}$ . Finally, conditional distributions for  $\mathbf{x}$  are defined by a ‘reverse regression’ relationship. Conditional on other parameters, we can rearrange

$$y_{ij}^* + \boldsymbol{\alpha}_j = x_i \boldsymbol{\beta}_j + \boldsymbol{\varepsilon}_{ij}$$

to form  $n$  regressions, each on  $J$  observations of the discrimination parameters  $\boldsymbol{\beta}$  regressed on artificial dependent variable  $w_{ij} = y_{ij}^* + \boldsymbol{\alpha}_j$ . Then,  $\mathbf{x}_i$  is sampled from

$$f(x_i | \mathbf{y}_i^*, \boldsymbol{\alpha}, \boldsymbol{\beta}) = N(\mu_{x_i}, \sigma_{x_i}^2)$$

where  $\mu_{x_i} = (\boldsymbol{\beta}' \boldsymbol{\beta} + 1)^{-1} \boldsymbol{\beta} \mathbf{w}_i$  and  $\sigma_{x_i}^2 = (\boldsymbol{\beta}' \boldsymbol{\beta} + 1)^{-1}$ . In multiple dimensions,  $\mathbf{X}^* = [-\mathbf{1} \ \mathbf{x}_1 \ \mathbf{x}_2 \ \dots \ \mathbf{x}_K]$  in steps 1 and 2, while step 3 involves  $\mathbf{x}'_i = \begin{bmatrix} x_{i1} & x_{i2} & \dots & x_{iK} \end{bmatrix}$  and identity matrix  $\mathbf{I}$  for the prior variance component in the variance.

An additional concern is missing data. Legislators will have missing roll calls due to absences or members not being considered during part of the Congress or Congresses. If the absences are unrelated to the vote, this

poses no particular problems. There are two approaches: the first uses the complete likelihood, where only members’ observed votes contribute to the likelihood. This is straightforward in the ideal point model, since each vote defines a separate probit model. In the Gibbs sampler,  $y_{ij}^*$  is sampled only for those  $j$  where legislator  $i$  votes ‘Yea’ or ‘Nay’. The sampler for  $x_i$  only conditions on  $y_{ij}^*$  and vote parameters  $\boldsymbol{\alpha}_j$  and  $\boldsymbol{\beta}_j$  for votes  $j$  that are observed; i.e., the reverse regression of dimension  $J_i$ . Finally, the sampler for  $\boldsymbol{\theta}_j$  is a normal Bayesian regression but with only  $n_j$  observations (the number of legislators who voted).

The second approach treats the missing votes as parameters to be estimated; at each iteration, a value for  $y_{ij}$  could be generated, then the algorithm proceeds normally (Patz and Junker, 1999a). In practice, the only additional step is in the generation of  $y_{ij}^*$ ; if  $y_{ij} = 1$ , one samples from a normal distribution truncated from below by zero, and if  $y_{ij} = 0$ , it is truncated from above by zero. If  $y_{ij}$  is missing, then the sample is generated from an untruncated normal distribution (Albert, 1992; Albert and Chib, 1993).

In general, considerations of missing data follow the same determinations of MCAR, MAR, and non-ignorability, with the approaches described so far being applicable to data that is MCAR or MAR. Missing data that is non-ignorable will require the specification of the missing-data process and will be problem specific (Mislevy, 2016). Rosas et al. (2015), for instance, posit a model of strategic abstention where actors decide to abstain when their own preferences conflict with those of a principal to whom they must answer (such as party leadership). They adjust the standard model to account for congruence or incongruity (incorporating identified positions of the principal on votes). Their Monte Carlo evidence indicates that this particular form of abstention is unproblematic – unless it occurs at high rates (e.g., certainly not in the US Congress, but it is characteristic of other legislatures and the UN General Assembly).<sup>3</sup>

To identify the model, one must set the *location*, *scale*, and *polarity*. In

$$y_{ij}^* = x_i \beta_j - \alpha_j + \varepsilon_{ij},$$

substituting  $x^* = \left(\frac{1}{c}\right)x_i$  and  $\beta_j^* = c\beta_j$  produces the same likelihood, as does  $x^* = x_i - c$  and  $\alpha_j^* = \alpha_j - \beta_j c$ . More generally,  $\mathbf{x}_i$  can be centered on any  $K$  length vector  $\mathbf{c}$  and/or transformed by any  $K \times K$  matrix  $\mathbf{C}$ , and corresponding shifts in  $\beta$  and  $\alpha$  will produce the same posterior. To identify the model, one could set the mean (location) and variance (scale) of the ideal points – although during estimation, this complicates the last Gibbs step. Furthermore, these restrictions do not address polarity; e.g., estimates where conservatives are located on the right or the left could be produced. This is discussed in CJR and Bafumi et al. (2005) and implemented in *ideal* (Jackman, 2015). Two alternatives exist: first, one could fix ideal points to constants. In one dimension, fix a ‘left’ legislator and a ‘right’ legislator (say, at  $-1$  and  $1$ ). In multiple dimensions,  $K(K + 1)$  linearly independent restrictions on ideal points are sufficient (and, if only considering constraints on the ideal points, necessary); e.g., for two dimensions, fixing three ideal points that form a triangle (Rivers 2003). While making such restrictions in one dimension is simple (pick two legislators who, by reputation, are far left and far right), in multiple dimensions these choices are more difficult. They need to be chosen carefully: if any of the positions are between two modes (say, in 1D, using a moderate as an anchor), selecting a high posterior mode is not guaranteed (Bafumi et al., 2005: 177–8). One may impose these constraints during estimation, applied to each iteration as they are sampled, or one can instead implement these restrictions after estimation through post-processing, since the likelihood does not need to be identified in order to sample from the posterior (de Jong et al., 2003). The convergence properties can also be improved as a result.

Second, a final approach to identification is the imposition of restrictions on the

reduced-form vote parameters  $\beta$ , similar to confirmatory factor analysis. To identify the model through the vote parameters, the items should be permutable into the following lower triangular structure.

$$\beta = \begin{bmatrix} 1 & 0 & 0 & \dots & 0 \\ \beta_{2,1} & 1 & 0 & \dots & 0 \\ \beta_{3,1} & \beta_{3,2} & 1 & \dots & 0 \\ \vdots & \vdots & \vdots & \dots & \vdots \\ \beta_{j,1} & \beta_{j,2} & \beta_{j,3} & \dots & 1 \\ \vdots & & & & \vdots \\ \beta_{J,1} & \beta_{J,2} & \beta_{J,3} & \dots & \beta_{J,K} \end{bmatrix}$$

Each dimension has a ‘reference’ item, with one item relating to only one dimension, and the upper triangle of zeros indicate that the reference items can only be related to a subset of issues (except for the  $K$ th dimension reference item). This is the *minimum* number of restrictions; in practice, most, if not all, of the reference items should load only on the reference dimension, and any reasonable exclusion restrictions on other votes should be implemented.

### NOMINATE

Without the ground-breaking work by Keith Poole and Howard Rosenthal, we might not be dissecting the topic of this chapter. They synthesized early political-science analysis of roll calls, rational-choice models of voting, psychological research on decision-making and measurement theory, and the cutting edge of scientific computing to produce one of the most consequential developments in political methodology. Their measures of ideal points revolutionized the study of Congress and have been applied to a myriad of legislatures outside the United States. Given the prominence and ubiquity of their techniques (NOMINATE, W-NOMINATE, and DW-NOMINATE), along with Poole’s additional contributions (Common Space

Scores, Optimal Classification), the IDEAL model of CJR and other variants inevitably must address the question ‘What advantage does the Bayesian model offer over the universally applied non-Bayesian approaches?’ These questions are considered in Clinton et al. (2004) and Bafumi et al. (2005), and they are debated extensively between Carroll et al. (2009) and Clinton and Jackman (2009).

For NOMINATE,  $f(\cdot)$  is the Gaussian function instead of a quadratic expression (Poole and Rosenthal, 1985):

$$U(q_j) = \beta e^{\left(\frac{1}{8}(x_i - q_j)^2\right)} + \varepsilon_{i,q_j}$$

$$U(p_j) = \beta e^{\left(\frac{1}{8}(x_i - p_j)^2\right)} + \varepsilon_{i,p_j}$$

where  $\beta$  is a ‘signal to noise ratio’, and the error terms follow Type I extreme value distributions (in NOMINATE and W-NOMINATE) or  $N(0, 0.5)$  distributions (for DW-NOMINATE).

The utility difference does not reduce, with the implemented model reparameterizing the ‘Yea’ and ‘Nay’ outcomes as  $z_{j,p_j} = z_{mj} + d_j$  and  $z_{j,q_j} = z_{mj} - d_j$  in the differences of utilities, estimating cutpoint  $z_{mj} = \frac{p_j + q_j}{2}$  and quantity  $d_j = \frac{p_j - q_j}{2}$ :

$$y_{ij}^* = \beta \left\{ \exp\left(\frac{1}{8}(x_i - z_{j,p_j})^2\right) - \exp\left(\frac{1}{8}(x_i - z_{i,q_j})^2\right) \right\} + \varepsilon_{ij}$$

To estimate ideal points and vote parameters, alternative conditional maximum likelihood is used:

- 1 Obtain start values for  $x_i$ .
- 2 Estimate roll call parameters, holding other parameters fixed (using normal steps in maximum likelihood estimation (MLE)).
- 3 Estimate ideal points, holding other parameters constant.
- 4 Estimate  $\beta$ , holding other parameters constant.
- 5 Repeat steps until convergence.

Each step employs regular MLE techniques for each set of parameters, at each iteration, until convergence. Final convergence occurs when parameters are correlated at 0.99 with previous estimates. The alternating nature of the algorithm does not guarantee the typical properties of MLE, and, in any case, the matrix of second derivatives is too large to be calculated. Clinton and Jackman (2009) provide an extended critique of estimation and inference from NOMINATE, while Carroll et al. (2009) question the sensitivity to prior information. Clinton and Jackman (2009) counter their characterization of the sensitivity of the model. The entire debate between the two camps is worth reading closely, but the primary differences between the NOMINATE and IDEAL models are (1) the functional form specified for utilities and (2) the mode of estimation and inference. While Carroll et al. (2013) demonstrate support for the Gaussian utility form, Carroll et al. (2009) find that the estimates of the ideal points and vote parameters are extremely similar; the choice is between Bayesian and non-Bayesian estimation. Clinton and Jackman (2009) argue that the Bayesian approach, regardless of model type, has advantages regarding (1) inference, (2) model assessment, and (3) model extensibility.

The advantages of (1) are most important and characterize nearly every article covered in this chapter. Means, medians, quantiles, and ranks of parameters – probability of events – and one- and two-dimensional probability interval calculations are all produced from simple summary statistic calculations on MCMC output. Simple calculations of complex quantities open up avenues for theory testing.

On the other hand, while most recognize (2) as being equally important, model assessment is deployed much too infrequently, with researchers rarely exploring item fit, observation outliers, dimensionality and local independence. Information criteria, especially the Deviance Information Criterion (Spiegelhalter et al., 2002), are frequently

used to compare separately estimated models, while Bayesian residual analysis (Albert and Chib, 1995) and posterior predictive model checks (Meng, 1994; Gelman et al., 1996) are underutilized. Sinharay (2016) provides an excellent summary of model assessment for IRT models. This chapter will present extensive examples of (3), which is the ease at which the standard Bayesian ideal point model can be adapted.

**COMPARABILITY**

**Over Time**

The difficulty with over-time comparisons is that *everything* is changing: potentially, both the bills being voted upon and the legislators’ positions change over time. If the agenda is changing, how do we know if legislators’ ideological positions have evolved if they are simply voting on more liberal (or conservative) policies? The restrictions to the agenda and/or the degree to which legislators’ ideal points change over time must be implemented.

The simplest approach is to assume constant preferences for the legislators, which appears in Poole’s Common Space Scores. DW-NOMINATE specifies the following model for ideal points, which parameterizes ideal points changing in terms of a polynomial time trend:

$$x_{it} = x_{i0} + x_{i1}\phi_{t1} + x_{i2}\phi_{t2} + x_{i3}\phi_{t3} + \dots + x_{iv}\phi_{tv}$$

where  $v = 0$  is a constant model ( $x_{it} = x_{i0}$ ) and  $v = 1$  is a linear model actually implemented. Consequently,

$$\begin{aligned} x_{it} &= x_{i0} + x_{i1}\phi_{t1} \\ &= x_{i0} + x_{i1} \left[ -1 + (t - 1) \left( \frac{2}{T_i - 1} \right) \right] \end{aligned}$$

The alternating conditional maximum likelihood procedure follows a slightly

different order for DW-NOMINATE than W-NOMINATE:  $\beta$  and weights  $w$ , roll call parameters, and then ideal points.  $x_{i0}$  lies in the unit sphere for identification. Conditional estimation also holds other dimensions constant and error terms are normal, not logistic.

In this specification, legislators can only change in one direction and by the same amount every year; only the start and end points are estimated, with all other points interpolated. This may not pose too many problems if one simply wants to control for shifts in the legislature over time beyond replacement, but it does render the estimates useless for testing responsiveness in particular elections, since regardless of how factors change from election to election, the member changes by *exactly* the same amount each election.<sup>4</sup> Higher-order polynomial approximations, such as quadratic and cubic specifications, are possible. Voeten (2004) implements a quadratic specification for sessions of the UN General Assembly between 1990 and 2001.

A more general and flexible approach was developed by Martin and Quinn (2002) applying the methods of Bayesian dynamic linear models (West and Harrison, 1997) to the latent-variable representation of the RUM. Their model is the same as CJR, except that the ideal points are also subscripted by time,  $t$ . The utility differences are

$$y_{ijt}^* = \beta_j x_{it} + \epsilon_{ijt}$$

Martin and Quinn (2002) apply this model to cases of the modern US Supreme Court since 1937. Ideal points for each justice across terms follow a random walk time series  $x_{it} = x_{i,t-1} + \delta_{it}$ , where  $\delta_{it} \sim N(0, \Delta_{it})$ . The justice’s first term is set through the prior  $x_{i0} \sim N(m_{i0}, C_{i0})$ . For most justices, this initial prior is  $N(0, 1)$ , with a select number of justices assigned less variable priors ( $C_{i0} = 0.1$ ) and liberal, moderate, or conservative prior ideal point positions (e.g., William Douglas at  $-3.0$ ; Clarence Thomas and Antonin Scalia at  $2.5$ ; William Rehnquist at  $2.0$ ). The evolutionary variance  $\Delta_{it}$  controls the amount

of year-to-year change in the ideal points;  $\Delta_{it} = 0$  implies constant preferences while  $\Delta_{it} \rightarrow \infty$  approaches a specification where the time series of ideal points is independent. The larger this variance, the more likely abrupt shifts in preferences are observed; smaller values result in much smoother trajectories. In Martin and Quinn's (2002) specification, this value is set to 0.1, except for William Douglas, whose value is set at 0.001 (for reasons of consistent ideological extremity and the substantial amount of missing votes near the end of his tenure).

The same Gibbs sampler can be applied to this dynamic model but with one important caveat. Because of the dynamic relation between ideal points, the samples for individual ideal point estimates will be highly correlated and thus mix slowly. Instead, Martin and Quinn (2002) implement the forward-filtering, backward sampling algorithm for dynamic linear models (West and Harrison, 1997: 569–71), which greatly improves convergence over standard Gibbs sampling (Frühwirth-Schnatter, 1994: 194–5). This approach ‘blocks’ the Gibbs sampler by drawing from a multivariate conditional distribution rather than individual conditional distributions. Drawing directly from a potentially large multivariate distribution (likely of unknown form), though, is impractical, so the multivariate distribution is defined by the product of its conditionals (with the structure defined by the random-walk process):

$$f(\mathbf{x}_i | D_T) = f(\mathbf{x}_{iT} | D_T) f(\mathbf{x}_{i,T-1} | \mathbf{x}_{iT}, D_{T-1}) \cdots f(\mathbf{x}_{i,1} | \mathbf{x}_{i,2}, D_1) f(\mathbf{x}_{i,0} | \mathbf{x}_{i,1}, D_0)$$

where  $D_t$  is the information up to time,  $t$  (latent utility differences, vote parameters, and hyperpriors). The functional form for each component distribution is determined through ‘forward-filtering’ (i.e., begin at period 0, combined with prior beliefs), deriving the distribution of each subsequent ideal point, conditional on previous information. These distributions (as depicted in Martin and Quinn, 2002: 142–5) are normal.

The actual sampling is ‘backwards’, beginning with  $x_{iT}$  and ultimately reaching  $x_{i0}$ . The model is implemented in `MCMCpack`, utilizing their own statistical library `Scythe` for computation (Martin et al., 2011; Pemstein et al., 2011).

Easily downloaded from <http://mqscores.lsa.umich.edu/> (accessed 24 November 2019), the Martin–Quinn scores have become as ubiquitous in the study of the Supreme Court as DW-NOMINATE scores are in the study of Congress, and they appear frequently in popular media (such as *The New York Times* and *The Economist*). Measures of uncertainty are available (posterior standard deviations and quantiles), although similar to DW-NOMINATE, are typically not used.

An alternative estimation approach is implemented in Bailey (2007), with the justices’ ideal points following a polynomial trend, where the degree varies (with the longest serving justices modeled with a polynomial of degree four and other justices modeled with quadratic, linear, or constant preferences). Even more critical is the incorporation of agenda information. For instance, justices in the 1960s might be estimated to be the most liberal over all periods, while some justices who served on later Courts might actually be more liberal. The difficulty is that with many liberal precedents settled in law, current liberal challenges are *extremely* liberal, so much so that justices will inadvertently appear more conservative than earlier justices when they vote against the more liberal position. For instance, the decision to support affirmative action in the 1970s is a more liberal position than simply desegregating schools, and the status quo position of no affirmative action is likely more liberal than *Brown v. Board of Education*, thus opposing such measures should not imply that justices would also support segregation.

Bailey (2007) examines cases related by precedent, coding whether later cases result in more liberal or conservative decisions, relative to earlier cases. Substantive knowledge

of decisions and their precedents is used to establish a relative ordering of the relevant cutpoints. A cutpoint that must be more conservative (greater than) or more liberal (less than) compared to another cutpoint is imposed through rejection sampling at each iteration (the model must be parameterized in terms of the cutpoint/difficulty parameter instead of a vote intercept). Justices' comments on earlier Court cases are coded into positions on the case, as if they were sitting judges at the time of decision.

The ordering of cutpoints can certainly be incorporated into the dynamic linear model approach of Martin and Quinn (2002), and Bailey (2013) does exactly that in order to compare these estimates to the Martin–Quinn scores.<sup>5</sup> The general trends appear, especially the liberal shift in the 1960s, but the Court – in Bailey's estimates – does not shift substantially right in the early 1970s (the more intuitive result, given the number of landmark liberal decisions decided by the Court) and is consistently moderately conservative from the 1980s to 2010 (without the surprising liberal shift in the 2000s). There is also no 'end period' issue from the dynamic estimates. There are some differences in estimates – a different prior for initial state, a standard Gibbs sampling routine for the ideal points, and a restriction of cases to those relating to social policy (i.e., crime, civil rights, free speech, religion, abortion, and privacy), while also incorporating non-spatial predictors into the decision model.

The arguments surrounding the estimation of justices' ideal points over time certainly apply to legislators. Bailey (2007) scales the Supreme Court justices jointly with the president and members of Congress, with those members' ideal points assumed to be constant over time (with the stated positions on specific court cases by members also included in the roll call data). Similarly, Bateman et al. (2017) examine a similar problem of comparability concerning civil-rights issues in Congress from 1877 to 2011. Standard estimates incredulously imply that

recent Congresses are as polarized on civil-rights issues as those just following the Civil War, while Bateman et al.'s (2017) estimates that incorporate ordering constraints demonstrate much less polarization between the contemporary parties.

Bateman et al. (2017) also assume that preferences of members of Congress are constant. The Martin and Quinn model for dynamic changes in ideal points has rarely been applied outside of judicial ideal point estimation. One example is Bailey et al. (2017), who estimate a dynamic model of UN states; it does not implement the forward-filtering, backward sampling approach though, and the number of votes, years, and countries are still much smaller than what one faces with congressional estimates. As highlighted by Martin and Quinn (2002), the sampling of ideal points can be *parallelized*; the ideal points for each justice are independent, so the joint distribution can be sampled using the forward-filtering, backward sampling algorithm for each justice or legislator, up to the number of cores available. Lewis and Tausanovitch (2018) implement the IDEAL model, parallelizing on machines using a NVIDIA graphics card or Amazon's EC2 service, and similar implementations are available for dynamic linear models following Gruber and West (2016).

Furthermore, all instances are unidimensional. Bailey and Voeten (2018) do estimate a multidimensional model but treat the ideal points as independent over time; comparability is established through ordering cutpoints, dimension by dimension, like Bailey (2007) and Bateman et al. (2017). A true multidimensional implementation of this model would be a definite advance, paralleling the specification in West and Harrison (1997: 582–6).

### ***Across Institutions***

One long-running dilemma is that DW-NOMINATE scores for the House and

Senate are not fitted to a comparable scale. To compare across chambers, Poole (1998) developed Common Space Scores (CSS), which place the president, House, and Senate on the same latent scale. Comparability is established by (1) assuming legislators have constant ideal points, even when (2) they switch from House to Senate, or to the president. The potential problem is that Senators represent different constituents to a narrower House district, and the president certainly responds to vastly different pressures than a Representative or Senator. Shor et al. (2010) expand the scope to consider state legislatures, using state legislators who became Representatives or Senators as the bridge.

Alternatively, one can focus on the comparability of votes. The House and Senate have separate agendas, but for a law to be enacted, it has to pass both chambers in identical forms. If these votes are recorded (which often fails for the Senate) one can impose the restrictions of  $\alpha_{j,H} = \alpha_{j,S}$  and  $\beta_{j,H} = \beta_{j,S}$  on each 'bridge' vote  $j$ . The implementation involves stacking the roll call matrices to align with the bridge votes (although this creates even larger roll call matrices with many empty cells – something that most implementations process inefficiently). This approach is utilized in Treier (2011) and appears frequently in educational testing (where an overlap of questions between groups of test-takers facilitates comparison). With additional assumptions, one can expand on this over time. Through cosponsorship, Asmussen and Jo (2016) identify positions on bills introduced in multiple Congresses to provide a common bridge.

An alternative (or additional) approach is to incorporate bridge actors who take positions on votes taken in Congress, such as the president, Supreme Court justices, bureaucrats, and interest groups. This occurs with DW-NOMINATE and CSS scores, with the president's 'roll call' record based on *Congressional Quarterly* positions included in the downloadable data from Voteview. It is also a critical component of Bailey and

Chang (2001) and Bailey (2007), who also code positions on court decisions for the president and members of Congress to create a set of bridge votes on issues before the court.<sup>6</sup> Treier (2010) evaluates the *CQ* positions and suggests supplementing these positions. Bertelli and Grose (2011) add cabinet-level secretaries into the estimation through coding their public positions and incorporating them into the roll call matrix. Treier (2011) utilizes the positions of interest groups rating members of Congress (the Americans for Democratic Action (ADA) and the American Conservative Union (ACU)) to supplement comparisons across chambers and time (assuming the groups have constant preferences). Bonica (2013, 2014) utilizes campaign donors as bridge agents, using their contribution decisions to presumably ideologically similar legislators to recover (non-Bayesian) ideal point estimates for candidates (incumbent and non-incumbent) and donors, while Bonica and Sen (2017) apply Bonica's approach to the legal profession.

Shor and McCarty (2011) supplement the approach by Shor et al. (2010) with responses of the National Political Awareness Test (NPAT) from Project Vote Smart, which survey state and national legislative candidates (incumbents and challengers). They scale the NPAT responses and estimate ideal points for each state and federal legislature separately using Bayesian item-response methods. The legislatures are then projected back to the NPAT space through ordinary least squares regression of the respective coordinates. The project is a common form of bridging, especially in connecting legislatures with other institutions or groups (e.g., voters). In particular, Epstein et al. (2007) map Martin–Quinn scores back to Congress (through a non-linear regression connecting the confirmed justices' first year estimated ideal points and the nominating president's CSS). Bonica (2018) also establishes mappings from the donor-based estimates to NOMINATE (Shor and McCarty, 2011: 533–4), and observes that, ideally, one would estimate these models

jointly, but the computational issues are simply too substantial.

Other applications address fundamental questions about the representative relationship, by placing the mass public and public officials on the same scale. Bridging occurs through surveys of both the public and legislators or surveys where some questions mimic important roll calls in Congress. Among the many analyses along these lines are Jessee (2009) and Bafumi and Herron (2010). The results of these studies are an interesting contrast, since they arrive at completely opposite conclusions: in Bafumi and Herron (2010), voters are more moderate than their representatives and senators, while in Jessee (2009), voters are more extreme. There are differences in surveys, bridging assumptions, and modeling (Jessee, 2009, includes an additional variance component for additional heterogeneity).

Jessee (2016) re-evaluates these examples (but using the 2008 CCES), providing some insight into the challenges of bridging observations. The most critical result is that the characterization of the latent dimension is primarily determined by the larger comparison group, leaving the estimates heavily dependent on assumptions that the mass public and legislators view issues the same way, and that this perspective is homogenous.

## IMPLEMENTATION

The most common implementations appear as model-specific R packages written by researchers (R Core Team, 2016). The IDEAL model is implemented with the `ideal` command in Simon Jackman's (2015) package `pscl`. The package includes extremely useful auxiliary functions for downloading and manipulating roll call data, defining a `rollcall` object that is also used by the Bayesian and classical implementations of NOMINATE in packages `anominat` and `wnominat` (Poole et al., 2011; Carroll et al., 2017).

Martin and Quinn implement the basic IDEAL model in their package `MCMCpack` with `MCMCirt1d` and `MCMCirtKd`, and the dynamic version with the command `MCMCdynamicIRT1d` (Martin et al., 2011). Thus, for the standard Bayesian ideal point model, using either quadratic or Gaussian utility functions, the researcher can simply estimate on their own roll call matrices.

Extending these approaches or including these estimates in a larger structural model (as an independent or dependent variable) is more difficult. `MCMCpack` includes a command that estimates simultaneously the ideal points and a regression model that predicts them with the command `MCMCirtHier1d`. One could also implement a two-stage approach, decoupling the idea-point model from the regression model but still allowing the uncertainty of the ideal point estimates to propagate through the regression (see, e.g., Treier and Jackman, 2008: 215).

More complicated extensions can be implemented in one of several general-purpose Bayesian software packages: `WinBUGS`, `OpenBUGS`, `JAGS`, and `Stan` (Lunn et al., 2000, 2009; Plummer, 2003; Stan Development Team, 2018). These programs expanded the reach of Bayesian methods in general, and their existence has made many of the extensions discussed in this chapter possible. Instead of the command-line-based systems with which many social scientists are most familiar (with `Stata` being the most prominent example), the BUGS approach involves a general model description, where the research simply specifies the likelihood, prior distributions, and conditional (hierarchical) distributions, with parameters and fixed data being either explicitly identified or inferred from the model specification. The original, `WinBUGS`, could piece together the models and step through criteria to apply sampling schemes from the most specific to the most general. It recognizes the canonical conjugate models and samples directly from the posterior and identifies instances where the conditional distribution of parameters

(univariate or multivariate) are conjugate and amendable to Gibbs sampling. For more challenging cases, the BUGS environments break down the posterior into one-dimensional blocks, from which *some* sampling scheme is always possible. The major advance is the implementation of derivative-free adaptive rejection sampling (dfARS) for Gibbs sampling.<sup>7</sup> Applicable to conditional distributions that are log-concave – a common condition in many of our specifications (which often utilize exponential families) – it samples from piecewise linear functions, the number of segments increasing with each rejection until it forms an extremely close approximation to the target Gibbs sampling distributions. For non-log-concave distributions, either slice sampling or one-dimensional random-walk Metropolis–Hastings sampling from a normal distribution occurs.<sup>8</sup>

These general approaches have made numerous innovations possible, e.g., the estimation of the agenda constrained models would be daunting without general modeling framework software. The utility functions do not reduce to the linear forms in standard IRT models, and the status quo and proposal parameters are complicated functions of the other parameters. Other models that adapt the standard model by altering the fundamental specification of utilities for the *Yea/Nay* positions and add non-spatial predictors or hierarchical elements are also easily specified.

An obvious trade-off that typically accompanies such generality is speed. These implementations can be extremely slow so are best reserved for moderate-sized data. The agenda-constrained models are a perfect example, where the focus has typically been on a small subset of roll calls on a specific policy or one with few legislators. A single legislature (or chamber) in a specific sitting is perfectly manageable but inappropriate for much larger or sparse data.

The user-packaged functions available in R implement the specific models

directly (e.g., Gibbs sampling for the IRT model with quadratic utility and roll call voting). The package `pscl` implements C code directly through the `.C` interface in R, while `MCMCpack` created their own statistical C++ library `Scythe` (Pemstein et al., 2011). The availability of the `Rcpp` package has greatly simplified working with C++ functions (Eddelbuettel and Francois, 2011; Eddelbuettel, 2013). Most usefully, one can write and use isolated functions to which R objects can be passed (rather than implementing full C++ programs with `main()` functions). `Rcpp` also links to the powerful scientific computing library `Armadillo` through the `RcppArmadillo` package (Eddelbuettel and Sanderson, 2014; Sanderson and Curtin, 2016).

A compromise between these options involves the `Stan` program, implemented in standalone versions as well as within programs such as R and `Stata` or languages such as Python. `Stan`'s interface follows the BUGS model of general model specification, with the syntax sharing recognizable similarities. `Stan`, however, compiles the model though in C++, providing substantial improvements in speed. Furthermore, it implements the model using a completely different MCMC algorithm. Instead of breaking the posterior into one-dimensional pieces, `Stan` implements a Metropolis–Hastings multivariate sampler, generating proposals using Hamiltonian Monte Carlo (HMC) methods instead of random-walk steps. It calculates a gradient of the posterior and an auxiliary distribution using numerical differentiation, from which a trajectory is generated through a discretized process ('leapfrog integrator'), which must be parameterized through program options or adapted automatically. A standard Metropolis step is taken to reject or accept the draws. The more complex a posterior distribution, the greater the number of steps that may be taken, and both the tuning of the algorithm and the convergence of the approximation must be monitored.

## AGENDA

The ideal point model is estimated based on the reduced-form vote parameters. Working directly with the status quo and proposal parameters  $p_j$  and  $q_j$  is elusive: in one dimension, these parameters are barely identified; in two or more dimensions, the parameters are completely unidentified, and all that is recoverable are the cutlines or cut planes. With NOMINATE, these positions are identified but only due to functional form.

In many applications, researchers are not concerned with these parameters; the specification is a means to the end goal of recovering ideal points. Even if one is only interested in the estimate of legislator ideal points, recovery of the vote positions may define a more accurate and interpretable ideological space. Clinton and Meiowitz (2001) prove that ideal point estimates that exclude such relational restrictions will underestimate the dimensionality. Pope and Treier, e.g., do not analyze the positions directly but still incorporate information on the agenda at the Constitutional Convention in order to determine the dimensionality of delegation positions (Pope and Treier, 2012) and provide a better understanding of the ideological dimensions (Pope and Treier, 2015).

Recall, the utilities in terms of the proposal and status quo policies are

$$\begin{aligned} U(\mathbf{q}_j) &= \sum_{k=1}^K -(x_{ki} - q_{kj})^2 + \varepsilon_{i,\mathbf{q}_j} \\ &= -\|\mathbf{x}_i - \mathbf{q}_j\|^2 + \varepsilon_{i,\mathbf{q}_j} \\ U(\mathbf{p}_j) &= \sum_{k=1}^K -(x_{ki} - p_{kj})^2 + \varepsilon_{i,\mathbf{p}_j} \\ &= -\|\mathbf{x}_i - \mathbf{p}_j\|^2 + \varepsilon_{i,\mathbf{p}_j} \end{aligned}$$

Clinton and Meiowitz (2001, 2003, 2004) estimate the status quo policies by incorporating changes (or lack of changes) in the

status quo directly into the estimation. First, if proposal  $\mathbf{p}_j$  passes, then the new status quo point equals this proposal:  $\mathbf{q}_{j+1} = \mathbf{p}_j$ . If  $\mathbf{p}_j$  fails, then the status quo remains unchanged:  $\mathbf{q}_{j+1} = \mathbf{q}_j$ . Second, if a proposal does not concern dimension  $d$ , then even if  $\mathbf{p}_j$  passes, the coordinates of the status quo for irrelevant dimensions will remain unchanged:  $q_{j+1,d} = q_{j,d}$ . By imposing these constraints, one can directly estimate the status quo points and proposals and effectively see the unfolding agenda. The parameters  $\mathbf{q}_j$  and  $\mathbf{p}_j$  are represented as  $\boldsymbol{\theta}$ , indexed by  $y(j)$  and  $n(j)$ , where  $\mathbf{q}_j = \boldsymbol{\theta}_{n(j)}$  and  $\mathbf{p}_j = \boldsymbol{\theta}_{y(j)}$ .

The estimated model, in utility differences, is

$$y_{ij}^* = \|\mathbf{x}_i - \boldsymbol{\theta}_{n(j)}\|^2 - \|\mathbf{x}_i - \boldsymbol{\theta}_{y(j)}\|^2 + \varepsilon_{ij} \quad (8)$$

which does not simplify into a reduced-form structural model; consequently, a hybrid Gibbs approach is implemented, where each conditional step follows a Metropolis–Hastings approach, with a normal distribution centered at the previous estimate and a variance that has been tuned.

Clinton and Meiowitz (2004) apply this approach to the question of the famous ‘Dinner Party Bargain’, where reportedly the details of a log-roll were worked out at a party hosted by Thomas Jefferson, regarding the location of the national capital and the federal assumption of state debt during the first Congress. Before the dinner-party agreement, every vote loads only on one dimension, and afterwards, votes load on both dimensions. The model is identified by fixing the status quo position to (0, 0), fixing proposals on each issue and Madison to constants, as well as identical proposals before and after the supposed bargaining. Clinton and Meiowitz (2004) hypothesize that once a deal had been perceived, one would expect the unconstrained passage of the bill on capital location to represent a shift both towards a Southern capital and greater assumption of debt; their estimates, however, illustrate the critical vote clearly only involves the capital.

Further, continual movements of the status quo after this vote contradict the possibility of a settled deal. Their analysis depicts perfectly the greatest strengths of the Bayesian approach. First, extending the basic model to include agenda information – which leaves the utility in its most general structural form but includes enhanced indexing of the data – is simply estimated by an application of the general Metropolis–Hastings algorithm. Second, summarizing uncertainty – graphically, with two-dimensional 95% posterior intervals, and by calculating the probability that any two positions will be distinct (e.g., assumption dimension of proposal 2 is greater than proposal 1 and the location dimension is lesser) – is a simple calculation from the MCMC samples.

Similar to Clinton and Meirowitz, Pope and Treier (2011) map the agenda for the Constitutional Convention (a quasi-legislative body), defining the initial status quo as the Articles of Confederation, with changes being considered section by section in the Virginia plan and subsequent action through the Great Compromise. In contrast to the Dinner Bargain example though, the 92 votes are defined on more general dimensions (i.e., representation and scope of Government) rather than specific issues. Model checks are conducted through test statistics created by sampling from the posterior predictive distribution (Sinharay et al., 2006). Another advantage of the Bayesian approach is the straightforward extensibility of the model. Complicating the roll call analysis are split-state delegations resulting in divided votes. The model is extended by treating division as the result of ‘thick indifference’, when the cutpoint or cutline is close to the ideal point, incorporating the model of Sanders (1998, 2001).

These historical examples are perfect for this approach, as proposed changes in the agenda are focused and easily categorized. In modern legislatures, however, one is faced with juggling many agendas with bills thousands of pages long and complex amendments

and agenda maneuvers. In contemporary legislatures, this approach works best in single-policy areas, focusing on the most important proposals in the agenda. Clinton (2012) follows this approach with the Fair Labor Standards Act, tracing proposed and successful changes to the legislation from 1971 to 2000 (primarily in the 1970s and 1990s) for 114 votes with 112 vote parameters. Members are assumed to have constant preferences (unless they switched party or chamber), with 16 members (nine representatives, seven senators) appearing throughout the period.

Gyung-Ho Jeong has applied this model to a myriad of modern applications: considering the creation of the Federal Reserve System (Jeong, 2008; Jeong et al., 2009); joining the League of Nations (Jeong, 2017); civil-rights legislation (Jeong et al., 2009); immigration (Jeong et al., 2011; Jeong, 2012); and energy policy (Jeong et al., 2014). Each of these applications consider very specific policy issues that have a small set of important votes with a discernible agenda structure. In these applications, Jeong relies on modern procedure (e.g., rules specifying ‘perfecting’ amendments that change a dimension at a time followed by substitution amendments typically combining earlier proposals on each dimension) to substantially reduce the number of parameters considered. Most impressive of the analyses and illustrative of the simplicity of Bayesian analysis, are the complex calculations (with uncertainty bounds) of the uncovered set, using the estimated ideal points with the algorithm of Bianco et al. (2004), overlaid with the status quo and proposal locations.

## HIERARCHICAL ESTIMATION

One of the most obvious advantages to the Bayesian framework is its natural inclusion of hierarchical structures, especially those concentrated around multilevel data. The basic ideal point model can be extended by

incorporating covariates as predictors for  $x_i$  in a hierarchical specification:

$$x_i = \mathbf{z}\boldsymbol{\gamma} + v_i$$

Without covariates  $\mathbf{z}$ , the model reduces to the standard ideal point model with  $x_i = v_i$ , in one dimension. Rotational invariance of the model can be imposed by restricting the coefficient of a well selected covariate to be positive; the location and scale of the model can be identified by standardizing the ideal points and applying the appropriate transformations to the other parameters of the model. Bafumi et al. (2005) illustrate this setup with the ideal points of Supreme Court justices, partly determined by the party of the nominating president. Zucco Jr. and Lauderdale (2011) institute a unique design by estimating a two-dimensional IDEAL model where each dimension is centered on a party mean, with the first (ideological) dimension informed through legislator responses to a survey (where they place themselves and other parties) and a standard normal hyperprior for the party mean on the second dimension. They recover two dimensions that clearly reflect an ideological motivation for legislators and a government–opposition dynamic on the second dimension. Imai et al. (2016) formulate a very general hierarchical model specification, then estimate a special case of the model: an IDEAL model over time with the same polynomial specification as DW-NOMINATE.

More generally, the IRT model can be extended through regression relations for the discrimination and difficulty parameters: Bafumi et al. (2005: 178) formulate this as

$$x_i \sim N(\mathbf{Z}\boldsymbol{\gamma}, \sigma_x) \quad \forall i = 1, \dots, n$$

$$\beta_j \sim N(\mathbf{W}\boldsymbol{\alpha}, \sigma_\beta^2) \quad \forall j = 1, \dots, J$$

$$\kappa_j \sim N(\mathbf{K}\boldsymbol{\lambda}, \sigma_\alpha^2) \quad \forall j = 1, \dots, J$$

with respect to the specification  $y^* = \beta_j(x_i - \kappa_j) + \varepsilon_{ij}$ . There are no general considerations of this model but there are considerations in educational testing and

psychometric literatures (in particular, see Fox, 2010: ch. 6). The primary concern for ideal point estimation is how the hierarchical or multilevel model relate to the utility model. A change in the cutpoint parameterization will alter the interpretation of the item parameters, and a hierarchical prior on the discrimination parameter will alter the considerations between status quo and proposal.

While hierarchical models for the ideal points are more common, there are a few examples of other hierarchical structures. Bailey and Maltzman (2008) specify a standard ideal point model for case votes on the Supreme Court but include non-spatial factors that directly impact the probability of voting for the plaintiff:  $U(y_{ij} = \text{'Yea'}) = -(x_i - p_j)^2 + \delta_i \text{Law}_j + \eta_{ij}$ . Note, the additional factors define an intercept shift not related to the spatial model (the three case variables and judge-specific coefficients relate to issues of precedent, deference, and speech).

## OTHER DATA

Ideal points have been estimated almost exclusively from roll call data. One obvious reason is the widespread availability of such data, the high participation of and separation between legislators, and the clear position taking motivations for legislators. But roll calls can present some difficult limitations. Strict agenda control can result in the roll calls taken only reflecting parts of the basic-issue space, as other measures are simply blocked (Clinton 2007). A further complication is the presence in many legislatures of strict party discipline. Systems where partisans never or almost never deviate from the position of their party leadership produce roll call records that are unable to differentiate between members of the same party (even when there are clear perceptions of different ideological positions) and merely separate out the governing party from the opposition (Spirling and McLean 2007; Dewan and Spirling 2011).

Consequently, alternative sources of data have been considered as supplements or replacements to roll calls. An alternative is cosponsorships. These are an obvious form of public position taking on measures that have little to no party whip activity, and while many bills will be excluded from the agenda, legislators are still able to take positions on proposals which likely span the entire basic-issue space.

While cosponsoring indicates clear support, the effect of not cosponsoring is ambiguous. Some researchers do treat the cosponsorship data exactly like roll call data, with non-sponsorship being equivalent to opposition and standard implementations of W-NOMINATE or IDEAL being applied. Asmussen and Jo (2016) more conservatively only consider cosponsorship, while treating non-sponsorship as missing. Kellerman (2012), using early day motions to estimate positions from the UK House of Commons, treats the data as regular roll call data but adds an additional legislator intercept to the utility of signing an EDM to reflect the professional *cost* of stating a public position. Desposato et al. (2011) derive a variant of the roll call model that treats the utility of the implied proposal or status quo the same but incorporates the probability of whether or not one *considers* the cosponsoring.

Desposato et al. (2011) consider different specifications, including a constant factor and a ‘neighbor’ model that reflects the distance between a legislator and the original sponsor of the bill. Ultimately, though, they only test their implementation on simulated data (cosponsoring data is much larger than roll call data).

Cosponsorship defined as a complete social network is common, but the ideological element has not factored substantially. Fowler (2006), using a massive dataset covering 1973 to 2004, relies on network summary statistics, while Alemán et al.’s (2009) calculation of cosponsorship ideal points relies exclusively on the decomposition of a network agreement matrix.

An actual ideological model is applied to a different sort of network data: Twitter followers. Barberá (2015) specifies a *latent space* network model, following Hoff et al. (2002). This model considers Twitter user  $i$  deciding whether or not to follow politician  $j$  as

$$\text{logit}\left(\Pr(y_{ij} = 1 \mid \theta)\right) = \alpha_j + \beta_i - \gamma \|x_i - x_j\|^2$$

i.e., it is determined by the spatial distance between potential follower and elite (note that this also holds for elites following other elites), the general popularity of elite  $j$  and level of political engagement for user  $i$ . Six countries are analyzed (separately), with the general Twitter sample of users ranging from approximately 50,000 to 300,000 and between 118 and 318 political actors. The estimation is in two stages: a `Stan` model of the political actors alone (i.e., the basic-issue space will be first defined by their mutual affinity) and then a second model for general Twitter users’ decisions to follow elites. The estimates for members of Congress match DW-NOMINATE scores well, with the placements of other prominent elites appearing as expected. The latent-space model also seems quite appropriate for the application, where similarity (or *homophily*) is the overwhelming motivation for following.<sup>9</sup>

## IDEAL POINTS AND TEXT DATA

As we saw in the previous section, the ideal point model has been intrinsically linked with roll call voting, but a variety of behaviors could be related to ideology. A natural candidate, infeasible until very recently, is incorporating speech data. Differentiation through speech patterns allows greater intraparty distinction, even in the presence of strict party discipline (Schwarz et al., 2017). Furthermore, since the language of policy remains similar

through the period of analysis, this text-data approach can connect legislatures over time. Supplementing observed votes with speeches that occur in assembly is one of the latest methodological frontiers.

The first notable latent-trait model using text data was the non-Bayesian WORDFISH (Slapin and Proksch, 2008). This approach, applied to party manifestos, was a direct response to the supervised Wordscores approach (Laver et al., 2003). Wordscores provided estimates of location through comparison to two reference documents. The ideological positions of the reference documents were fixed, with all other party manifestos assigned a position based on their similarity to the references documents. The resulting score was a convex combination of the reference positions, based on the similarity between documents. Of course, a major limitation of this approach was that these estimates were guaranteed to take more moderate positions than the reference documents, and all attempts to alleviate the problem were merely unjustified rescalings. Wordfish, on the other hand, is based on a latent-trait approach for the counts of each word  $j$  for unit  $i$ ,  $y_{ij}^*$ , which is distributed Poisson with mean  $y_{ij}^*$ , the individual's latent word 'emphasis'. The parameterization is inspired by the IRT model,

$$y_{ij}^* = \gamma_i + \alpha_j + \beta_j x_i$$

with  $x_i$ , the ideological position and intercepts for unit and word, related to verbosity and aptness. This reduced form is borrowed directly from statistical and psychometric literature, without a structural representation of the ideal point model.

Kim et al. (2018) provide such a derivation from the spatial model for word choice by legislators in speeches and connect to the RUM over voting. This work is the most promising approach to combining votes and speeches into comparable measures of ideology. The roll call voting model is standard

Euclidean, with differential weights  $a_d$  for dimension  $d$ . These weights also appear in the word-choice model, where they represent the utility for emphasis  $y_{iw}^*$  for legislator  $i$  over word  $w$  (distinguishing from vote  $j$ ) varying proportionally with spatial and non-spatial terms, along with a penalty for word overuse and random error:

$$U_{iw}(y_{iw}^*) = y_{iw}^* \left( s_w + v_i - \frac{1}{2} y_{iw}^* - \frac{1}{2} \sum_{d=1}^D a_d (x_{id} - g_{wd})^2 + \varepsilon_{iw} \right)$$

Optimizing this utility in terms of  $y_{iw}^*$  results in a choice of

$$\begin{aligned} y_{iw}^* &= v_i + s_w \\ &- \frac{1}{2} \sum_{d=1}^D a_d (x_{id}^2 - 2x_{id}g_{wd} + g_{wd}^2) + \varepsilon_{iw} \\ &= \left( v_i - \frac{1}{2} \sum_{d=1}^D a_d x_{id}^2 \right) + \left( s_w - \frac{1}{2} \sum_{d=1}^D a_d g_{wd}^2 \right) \\ &+ \sum_{d=1}^D a_d g_{wd} x_{id} + \varepsilon_{iw} \\ &= c_i + b_w + \sum_{d=1}^D a_d g_{wd} x_{id} + \varepsilon_{iw} \end{aligned}$$

which corresponds to the Wordfish representation.<sup>10</sup> Instead of assuming a Poisson distribution, the word counts are connected to the latent emphases through an ordered probit model, where

$$\Pr(y_{iw} = k) = \Phi(\tau_{k-1} < y_{iw}^* < \tau_k)$$

with the thresholds being constant across words and individuals and estimated semi-parametrically from the empirical cumulative distributions of the words. The approach accounts for the large number of zero counts in the data, guaranteeing that the probability of no usage matches the observed frequencies.

Kim et al. (2018) also include the standard roll call model on votes, with one major extension: while the random errors in the utilities remain normal distributions with equal variances, the mean of each error differs. The specification is linear additive, with  $E(\varepsilon_{ij}^y) = \pi_i^y + \psi_j^y$  and  $E(\varepsilon_{ij}^n) = \pi_i^n + \psi_j^n$ , for individual random effects  $\pi_i = \pi_i^y - \pi_i^n$  and bill random effects  $\varphi = \varphi_j^y - \varphi_j^n$ . The translation from structural to reduced form is<sup>11</sup>

$$\begin{aligned} & U_{ij}(\text{'Yea'}) - U_{ij}(\text{'Nay'}) \\ &= -\frac{1}{2} \sum_{d=1}^D a_d (x_{id} - p_{jd})^2 \\ &\quad + \frac{1}{2} \sum_{d=1}^D a_d (x_{id} - q_{jd})^2 + (\varepsilon_{ij}^y - \varepsilon_{ij}^n) \\ &= (\pi_i^y - \pi_i^n) \\ &\quad + \left( (\varphi_j^y - \varphi_j^n) + \frac{1}{2} \sum_{d=1}^D a_d (q_{jd}^2 - p_{jd}^2) \right) \\ &\quad + \sum_{d=1}^D a_d (p_j - q_j) x_{id} + \tilde{\varepsilon}_{ij} \\ &= c_i^y + b_j^y + \sum_{d=1}^D a_d g_j^y x_{id} + \tilde{\varepsilon}_{ij} \end{aligned}$$

Again, there is a slight disconnect, with  $a_d$  also appearing in the intercepts, and the motivation for legislator random effects is partially suspect;<sup>12</sup> but Kim et al. (2018) present an impressive model that combines both individual speeches and roll call votes. All of the parameters, except for the term emphasis, cutpoints and the dimension weights are Gibbs sampled, with the semi-parametric approach to the cutpoints implemented through Hamiltonian methods. The conditional distribution of the dimensional weights  $a_d$  are recovered through a hierarchical Gibbs sampler for the Bayesian Lasso (Park and Casella, 2008); the shrinkage in these coefficients towards zero determines

the dimension from the model. The number of dimensions is determined within the model and is highly sensitive to whether text or votes dominate, so a weighting parameter  $\alpha$  between the two components is specified *a priori*.<sup>13</sup> This arbitrariness of dimensionality might suggest more substantive constraints on dimensions, where the core dimensions are defined *a priori*, associated with particular votes, with residual dimensions sorted out in the analysis.

Another promising aspect is that it can be applied to legislatures with strong party discipline. These are cases where standard approaches using roll call votes fail, since party members will have identical voting patterns, outside of absences and the occasional free vote. In their model, one might use only roll call data from the party leadership<sup>14</sup> and the speech text of all individuals, which dominates in the estimation.

A few alternative approaches utilize text in a different manner. Several focus on *bill* text instead of speeches; in these approaches, the bill text determines the substantive content of the vote. Gerrish and Blei (2011, 2012) apply a topic model to bill text, in order to determine the proportion of each issue considered on each vote. They estimate a ‘general’ or ‘baseline’ ideology on one dimension, with issue ‘offsets’, assuming that legislators’ positions on the issues may deviate from the baseline but are still anchored to their general ideological leanings. For Lauderdale and Clark (2014), the text data of opinions on the court determine the proportion of each issue on each case, similar to Gerrish and Blei (2011, 2012). Unlike Gerrish and Biel though, Lauderdale and Clark (2014) estimate multiple dimensions, with the number being determined by the results of the topic model; they settle on 24, according to predictive behavior. Instead of treating votes as inducing a series of offsets from the same dimension, they recover positions on each of the identified dimensions.

The use of bill text in this way supplements the standard ideal point model, with Gerrish and Blei (2011, 2012) providing an intriguing connection between general ideological spaces and specific issues and Lauderdale and Clark (2014) effectively automating the inclusion of substantive information that is typically mechanical. An approach currently unexplored, though, is treating the bill text as *speech* data, informing the position of the proposal in the agenda-structure framework. That adds substantial complications to the model of Kim et al. (2018), but it may help to define the dimensions while also relaxing the requirement of identifying the entire agenda structure to recover proposal/status quo positions.

A final concern, general to all ideal point estimation, is the interpretation of the latent space. This concern may be even more pressing with text data, as the use of particular words may have clearer non-ideological intentions. Grimmer and Stewart (2013) illustrate the potential for ideal point approaches to recover non-ideological divisions that contradict validity checks (such as a reasonable separation of ideological distinct partisans). They present two examples, one where an ideological scaling makes sense (regarding German party platforms), and another that simply recovers language style from Senate press releases (Grimmer and Stewart, 2013: 292–4). Lauderdale and Herzog (2016) advance a solution (‘Wordshoal’) based on the Wordfish latent-variable model, but it is applied to each debate separately before aggregation into general ideological scores. The objective of debate-based estimates is to limit the effects of variation based on language considerations, stylistic choices, and topic relevance, in order to avoid the problem of conflation, as highlighted by Grimmer and Stewart (2013). Their approach of focusing on the debate as the unit of analysis is conceptually similar to the vote-based approaches of Gerrish and Blei (2011, 2012) and others, with the relationship of issue-specific positions ordered hierarchically to a general ideological position of commonality.

## CONCLUSION

Bayesian ideal point estimation facilitates the mundane and the spectacular. With the development of the Bayesian approach, one could run models on a desktop in only a few days (eventually a few hours), regularly provide visual accounts of the uncertainty in ideal points, test hypotheses using auxiliary quantities whose frequentist distribution would have been impossible to contemplate, conceive of extensions to the model, and be able to code up quickly and run them in BUGS/JAGS/Stan. The basics of the model were detailed in the first half of this chapter.

These mundane aspects of estimation have been critical to the application of ideal points, but I am particularly excited by the potential for spectacular advances within this framework, with some really exciting work in development. In this chapter, some of those changes have been detailed. There have been advances in exploring new sources of data and combining with traditional sources, greater attention to comparability, and advances in computation, with faster procedures and bigger data. The developments in the last section particularly highlight these advances and challenges. It seems to be exciting new territory, promising greater understanding of legislatures while simultaneously struggling with frustrating perennial issues. But underneath, the basic framework of CJR is always visible and the geometry of Poole and Rosenthal in the mind, while the common grammar of Bayesian estimation and inference are ever familiar.

## Notes

- 1 That it is acceptable for the underlying motivations of these belief systems to be vague is important. There is no overwhelming demand, for the most part, that the placements uncovered by the measurement models distinguish between, say, personal preferences, constituent demands, or partisan pressures, just that the resulting measures reveal their constraints and predict their behavior.

- 2 Of course, one disadvantage of this approach is characterizing uncertainty around the posterior modes. To optimize an intractable function, variational approximation estimates the function with the product of independent distributions. While this provides excellent coverage of the mode, it misses the tails of the distribution and thus underestimates the posterior variance.
- 3 Alternatively, Clinton (2007) describes how strong partisan agenda control could also bias estimates.
- 4 These deficiencies make frequent appearances in the literature on Congress and are discussed by Asmussen and Jo (2016).
- 5 Bailey also summarizes this research in a *Mischiefs of Faction* post, 'Just how liberal (or conservative) is the Supreme Court?', 22 February 2016, <https://www.vox.com/mischiefs-of-faction/2016/2/22/11094172/supreme-court-conservative-liberal> (accessed 24 November 2019).
- 6 While not used to identify members' position changes over time, announced positions do provide an improved basis for comparison by comparing judges, presidents, and members of Congress taking positions on the same cases over time
- 7 For an extremely intuitive summary of the approach, see Bolstad (2010: 35–42).
- 8 The variance for the proposal distribution is *adapted*; the researcher simply must recognize that the first 4,000 samples in `WINBUGS` could not be utilized. Similarly, there was an adaptive period of 500 samples for slice sampling.
- 9 In other contexts though, the model might face criticism over misspecification by Minhas et al. (2019), who argue that the LSM is unable to distinguish third-order relations; that might be important if one was trying to separate out ideological affinity from party affiliation.
- 10 Note, there is a disconnect between the structural and reduced forms, since the dimension weights  $a_{id}$  and ideal points  $x_{id}$  are part of the intercepts, yet their appearance in these terms is not accounted for in the estimation. The practical consequences are perhaps minimal, other than complicating the interpretation of these parameters and rendering the cutlines in the voting model unidentifiable; but future researchers might consider whether or not this possibly biases the estimates of the weights and/or ideal points.
- 11 Derived in the supplemental materials of Kim et al. (2018).
- 12 In the word-choice model, this is interpreted as talkativeness. For the voting model, this term reflects a propensity to vote 'Yea'. Outside of a government/opposition framework, it is difficult to justify (within a government/opposition

framework, one votes 'Yea' because they are part of the governing party, who determines what votes take place and the measure relates to party coherence).

- 13 In the likelihood, term choice and vote are independent, and the combined likelihood is separated in a 'melded' format, weights  $\frac{W+J}{2J}$  and  $\frac{W+J}{2W}$ , which rebalances the likelihood contributions of words and votes to 50/50. Kim et al. (2018) add a user-fixed term  $\alpha$  which allows a different weighting between 0 and 1 and suggestions for determining  $\alpha$ .
- 14 Presumably, 'party leadership' will be the government, opposition, and any disciplined crossbench parties, as well as individual independent legislators and members of ill-disciplined parties.

# Bayesian Model Selection, Model Comparison, and Model Averaging\*

Florian M. Hollenbach and Jacob M. Montgomery

## INTRODUCTION

Applied researchers are often interested in testing competing theories against each other. Most often, the goal is to determine whether and how a limited number of variables are related to a single outcome. The question in these cases is, ‘which of these theoretical accounts is most consistent with the data?’; or, more ambitiously, ‘which of these theories is most consonant with the true data generating process (DGP)?’ Despite the ubiquity and importance of this research task, many scholars are still uncertain as to how to proceed in these situations. The purpose of this chapter is to explain how this analytical objective can be accomplished effectively using Bayesian model comparison, selection, and averaging, while also highlighting the key assumptions and limitations of these methods. This chapter’s overall purpose is to provide readers with a larger set of tools for tackling this task and to discourage the kinds of haphazard (and often incorrect) practices

for comparing theories, often seen in the literature.

There are two interlocking problems in comparing and contrasting alternative theories via standard statistical methods. First, in many cases, the alternative theories are not ‘nested’ in a way that allows them to be tested simultaneously in a single-regression model. When this is true – and it often is – the common practice of placing all of the variables from all of the theories into a single regression is inappropriate and can lead researchers to incorrect conclusions. Yet, there appears to be no widely accepted framework in the methods literature that allows scholars to compare non-nested models for the purposes of theory testing.<sup>1</sup>

At the same time, researchers testing any theory need to ‘control for’ additional covariates in order to rule out potential confounding factors, shrink the standard errors for key coefficients, or improve model fit. They must also choose from among many potential modeling options, including functional

forms, link functions, and more. Yet, in many cases, theory offers limited guidance as to which or how many potential confounders should be included or which exact modeling strategy is most appropriate. This leaves scholars facing the challenge of having to choose among many different models and yet having little guidance as to how to arbitrate between them. In response, researchers often engage in a haphazard search through a large implied model space and report only a handful of results to readers for evaluation. Even worse, scholars may either intentionally or unintentionally try out alternative model specifications only until they find a result that confirms their research hypotheses (see Montgomery and Nyhan, 2010, for additional discussion).

What criteria should scholars use when choosing between competing models or when considering alternative modeling strategies or model configurations? In this chapter, we present a number of tools from Bayesian statistics that allow scholars to approach these challenges in a more principled manner. The Bayesian framework significantly facilitates this task, since the model configuration itself can be viewed as an unknown quantity to which Bayesian reasoning can be applied. We can use the tools of Bayesian statistics to compare the relative evidence in favor of various models to select the ‘best’ model, an approach that can be loosely labeled *model selection*. We can also examine posterior estimates to assess the degree to which a candidate model has adequately captured the true data generating process, which we label *model evaluation*. Finally, we can take a more agnostic approach and incorporate the uncertainty about the appropriate model configurations directly into final estimates, i.e., *model averaging*.

Below, we provide a broad overview of the tools available for model selection, evaluation, and averaging, with a special emphasis on theory testing. First, we briefly discuss ‘traditional’ approaches to model selection via Bayes factors and model-fit comparisons.

This latter category of tools includes approximations of Bayes factors, as well as criteria based on out-of-sample prediction. We then discuss the idea that no ‘correct’ model exists, and therefore researchers should incorporate the uncertainty about model configuration directly into their statistical approach. Specifically, we cover Bayesian mixture models, Bayesian model averaging, and the recently developed Bayesian stacking. Throughout the chapter, although we do provide some details of the mathematics, our focus is on providing a general intuition about these various methods along with their relative strengths and weaknesses. Readers interested in more thorough treatments of this subject are directed to the works cited at the end of the chapter. All code to reproduce the models and model-selection examples that we describe in this chapter will be available online.<sup>2</sup>

## MOTIVATING EXAMPLE: TESTING THEORIES OF CONGRESS

As our working example throughout the chapter, we will rely on Richman (2011): an article that appeared in the *American Political Science Review* that seeks to test competing models of policymaking in the US Congress. Specifically, Richman (2011) tests competing models that make predictions about which status quo policies are likely to be enacted as the composition of the House, Senate, and presidency shift (Brady and Volden, 1998; Krehbiel, 1998; Cox and McCubbins, 2005). Using novel estimates of status quo locations in different policy areas, policy changes in those areas, and the ideal points of pivotal actors, Richman (2011) empirically tests four competing theories.<sup>3</sup>

Richman (2011) estimates predictions about where the status quo in 42 policy areas *should be* according to each theory for the 103rd through to the 110th Congress.

Richman (2011) then estimates a simple regression for the status quo policy in issue area  $i$  at time period  $t$  using the following formula:

$$y_{it} = \beta_1 \text{prediction}_{it} + \beta_2 \text{inflation}_{it} + \epsilon_{it}$$

The main difference across models is, therefore, how the *prediction* variable is calculated. In all cases, the theory is that the  $\beta_1$  coefficient should be equal to 1, although the main criteria is determining whether the coefficient is positively related to the outcome as expected. Richman (2011) generates predictions for the status quo to be located at the position of the median voter of the house (*Model 1*), as predicted by the pivotal-politics theory (*Model 2*), by the party cartel model (Cox and McCubbins, 2005) with only negative agenda control (*Model 3*), and by a hybrid cartel theory that assumes some degree of positive agenda control by party leaders (*Model 4*). The only control variable considered in Richman (2011) is a measure of inflation to reflect the natural change in status quo positions in some policy areas, which results from inflation rates. Richman (2011) calculates two versions of the inflation measure: one for the first and second models and one for the third and fourth models. The two inflation measures differ based on the relevant policy area according to the relevant theory. Richman (2011) then evaluates the different models according to their ability to predict the status quo based on a linear model. Specifically, the models are ranked based on their individual  $R^2$  values.

We replicate the four models presented in Table 3 in Richman (2011) using the *brms* package in R (Bürkner, 2017; 2018).<sup>4</sup> The *brms* package provides users with a large number of pre-specified Bayesian models that are then estimated in Stan using C++ (Carpenter et al., 2017; Stan Development Team, 2017). Stan is a relatively young probabilistic programming language, similar in spirit to WinBugs. In fact, writing model code in Stan is quite similar to doing so in WinBug.

At this point, most common Bayesian models can be fit in Stan, and a fast growing number of R packages provide users with pre-programmed routines for an extensive number of models. Stan allows users to estimate models using fully Bayesian sampling via the Hamiltonian Monte Carlo (HMC) methods or approximating posterior means and uncertainty using variational inference. The HMC approach to Markov chain Monte Carlo (MCMC) methods is particularly attractive because of its high scalability and ability to succeed in highly dimensional spaces.<sup>5</sup>

For each of the four models described above, we estimate a standard Gaussian linear model, where  $y = X\beta + \epsilon$ , and  $\epsilon \sim N(0, \sigma)$ . We specify Gaussian priors with mean zero and a standard deviation of five for the regression coefficients. For the residual standard deviation ( $\sigma$ ), we keep the default half student t prior with three degrees of freedom and scale parameter 10. In addition to the four models presented in Richman (2011), we add two additional models. First, we estimate a model that includes all six possible covariates and a lagged dependent variable. Second, we estimate the model with all covariates and the lag DV but also add random intercepts for each congress and issue area. For the standard deviation of the random effects, we use the same half student t prior as above.

The median estimates and 95% credible intervals for the estimates in all six models are shown in Table 49.1. There are two aspects of these results that are notable. First, Richman (2011) correctly identifies that these competing theories cannot be tested within a single model and does not attempt to do so. The result, however, is that we end up with four non-nested models that must be compared against each other. To arbitrate between them, Richman (2011) makes interpretive claims based on the overall model fit (as assessed by  $R^2$  values). For instance, Richman (2011: 161) states that Model 2 ‘dramatically improves upon the predictions that can be made’ relative to

**Table 49.1 Evaluating theories of Congress: median estimates and 95% credible intervals for Table 3 in Richman (2011) (Models 1–4) and two garbage-can models**

Variable	Model 1	Model 2	Model 3	Model 4	Full model	Full model and RE
lag DV					0.59 (0.38,0.8)	0.39 (0.09,0.71)
Median only	0.5 (0.07,0.93)				0.02 (-0.25,0.29)	-0.13 (-0.61,0.24)
Pivotal politics		0.92 (0.66,1.17)			-0.72 (-1.22,-0.23)	-0.61 (-1.19,-0.08)
Party-cartel open rule			0.89 (0.72,1.06)		1.1 (0.23,1.94)	0.81 (-0.16,1.84)
Party-cartel closed rule				0.82 (0.65,0.99)	-0.4 (-1.1,0.34)	-0.11 (-0.96,0.71)
Inflation (median/pivot)	0.07 (-0.1,0.25)	0.05 (-0.1,0.19)			-0.01 (-0.11,0.09)	0 (-0.1,0.1)
Inflation (party)			0.06 (0.02,0.1)	0.07 (0.03,0.11)	0.07 (0.04,0.11)	0.1 (0.05,0.15)
Sigma	4.52 (3.99,5.17)	3.83 (3.38,4.41)	3.09 (2.74,3.54)	3.15 (2.77,3.62)	2.49 (2.19,2.86)	2.21 (1.85,2.69)
N	117	117	117	117	117	117
Random effects	No	No	No	No	No	Yes

Model 1. Likewise, in comparing Models 3 and 4, he concludes that ‘the differences in fit between the models is modest enough that no definitive conclusion can be drawn’ (Richman, 2011: 161). While the model fits superficially suggest that these conclusions are true, without a formalized approach to non-nested model comparison these competing claims cannot be formally tested. Fit statistics such as  $R^2$  are simply not designed to allow us to say clearly that one model is better than another in a statistical sense; i.e., there is no threshold we can establish for when  $R^2$  values are ‘different enough’ to show that one is statistically superior to another.

Second, as is nearly always the case, the models reported in Richman (2011: 160) are not the only ones that were considered:

I have also analyzed the data using a wide range of assumptions, including ordinary least squares, fixed effects by issue, random effects with and without AR(1) errors, panel heteroskedastic errors

with an AR(1) process, and dynamic GMM models without analytic weights. All analytic approaches produced statistically significant effects in the expected direction (except for the median model), and all produced the same relative ranking.

From this description, it seems likely that these alternative specifications were tried in response to or in anticipation of reviewer questions and serve as robustness checks for the main model. Nonetheless, they do indicate that there are other potential model configurations that were considered and could have been evaluated relative to the reported results, if appropriate criteria were available.

**HOW NOT TO TEST COMPETING THEORIES**

How can we arbitrate among these competing theories? Before answering, we discuss

one approach *not* to take: tossing everything into a single model and examining which coefficients are significant. As Achen (2005) shows, even in trivial models with only two covariates, this approach can fail to appropriately test between theories but may actively mislead researchers by, for example, switching the sign of key coefficients once we have conditioned on competing (and likely correlated) concepts. In short, simply combining variables from competing models in the hope that the results will somehow point to the ‘right’ theory is a deeply flawed approach to science. While under strict conditions it *can* be correct,<sup>6</sup> in a more general setting it is ill advised and conclusions based on this approach should not be trusted.

As an example, recall that Columns 5 and 6 in Table 49.1 show what happens if we simply drop all of the various predictions into a single model. Column 5 is the same standard Gaussian model with all six predictors and a lag DV included, and Column 6 also adds Congress and issue specific random effects. The results in this case are dramatic and revealing about the non-sensical nature of the approach. For instance, all four of the critical variables are hypothesized to be positive and significant. However, in the full model, several have credible intervals that now include zero. The *pivotal-politics* variable actually flips to become negative.<sup>7</sup> The party cartel (with open rule) has a 95% credible interval that excludes zero on Column 5 but includes zero once we include random effects (Column 6). In general, we get a mishmash of results that in some cases are hard to interpret and in others do not correspond with the theory at all.

Of course, the problem here is that these coefficients have no interpretable meaning, since the key explanatory variables are deeply inter-dependent. The coefficient for the *pivotal-politics* variable does not reflect the *independent* effect of this prediction, since a change in one variable almost necessarily implies changed values in the

other variables. After all, the variables are all functions of shared precursors (e.g., the median ideological position of the Senate or the position of president). In a causal setting, we might consider them to be post-treatment (Acharya et al., 2016; Montgomery et al., 2018), but even in the current setting there is no justification for including them all in the same model and no way to interpret the coefficients directly when we do.

## MODEL SELECTION AND BAYES FACTORS

The simplest approach to Bayesian model selection is via the construction of Bayes factors. This approach is attractive due to its simplicity, and perhaps for this same reason was among the earliest proposed Bayesian methods for model selection. For these same reasons, we present this approach first. However, we note up front that Bayes factors have been extensively criticized by some authors, leading to the alternative methods discussed below.

A (seemingly) simple way of evaluating models from a Bayesian perspective is nothing more than applying Bayes’ rule to model probabilities (Gill, 2009). Bayes’ rule is a formalization of basic human intuition as to how we can take evidence to inform our beliefs about the ‘true’ state of the world:

$$P(B|A) = \frac{P(A|B)P(B)}{P(A)} \quad (1)$$

Here,  $P(B)$  is our prior beliefs about  $B$  before any data is collected.  $P(A|B)$  is the conditional distribution of observing  $A$  given that we have observed  $B$ , which is simply another way of expressing the likelihood of a statistical model. Finally,  $P(A)$  is the marginal probability of observing  $A$ .

Bayes factors attempt to apply this same logic to the problem of using observed data

to inform our beliefs about the probability in favor of a specific model. Let  $\pi(\mathcal{M}_k)$  be the prior probability that model  $k$  is ‘true’, and let  $p(\mathbf{y}|\mathcal{M}_k)$  be the probability of observing the data  $\mathbf{y}$  under the assumption that  $k$  is true.<sup>8</sup> Further, assume that we are considering  $k \in 1, 2, \dots, K$  alternative model configurations. With a finite set of potential models, we can then calculate the marginal distribution of the data as

$$p(\mathbf{y}) = \sum_{k=1}^K \pi(\mathcal{M}_k) p(\mathbf{y} | \mathcal{M}_k). \quad (2)$$

By simply applying Bayes’ rule, we can express the posterior probability of any particular model  $k$  as

$$\begin{aligned} p(\mathcal{M}_k | \mathbf{y}) &= \frac{\pi(\mathcal{M}_k) p(\mathbf{y} | \mathcal{M}_k)}{\sum_{k=1}^K \pi(\mathcal{M}_k) p(\mathbf{y} | \mathcal{M}_k)} \\ &= \frac{\pi(\mathcal{M}_k) p(\mathbf{y} | \mathcal{M}_k)}{p(\mathbf{y})}. \end{aligned} \quad (3)$$

If we then want to compare two models (a vs b), we can construct a ratio between the two models’ posteriors. This has the advantage that the denominators will simply cancel out:

$$\begin{aligned} \frac{p(\mathcal{M}_a | \mathbf{y})}{p(\mathcal{M}_b | \mathbf{y})} &= \frac{\pi(\mathcal{M}_a) p(\mathbf{y} | \mathcal{M}_a)}{\pi(\mathcal{M}_b) p(\mathbf{y} | \mathcal{M}_b)} \\ &= \text{Prior odds}(\mathcal{M}_a; \mathcal{M}_b) \\ &\quad \times \text{Bayes factor}(\mathcal{M}_a; \mathcal{M}_b) \end{aligned} \quad (4)$$

Since the Bayes factor contains all of the ‘objective’ information about the models (i.e., information that is separate from the model priors), this has been the traditional quantity of interest. Higher values for this calculation represent evidence in favor of  $M_a$  and smaller values represent evidence in favor of  $M_b$ . Jeffreys (1961) made an early attempt to set thresholds for Bayes factors, where this evidence could be considered ‘conclusive’ or merely ‘suggestive’. A widely accepted threshold is that a Bayes factor of three is ‘substantial’ evidence in favor of  $M_a$  and values above 10 are considered ‘strong’.<sup>9</sup>

The advantage of the Bayesian approach to model evaluation is that estimating a posterior probability for each model allows us to talk about model selection in an intuitive way. Unlike alternatives such as likelihood-ratio tests that rely on confusing p-values and null hypothesis testing, we can talk directly about model probabilities. Statements like ‘there is a 90% chance that this is the best model’ have some possibility of making sense; i.e., we can directly assess various models and determine which one is most supported by the data and with what degree of certainty. Moreover, the models do not have to be nested to be comparable.

Despite these superficial advantages, however, the simplified description above obscures several complexities that make the problem of model comparison and selection difficult. To begin with, in almost all cases we are not just interested in choosing the right model but rather in estimating some set of model parameters  $\theta$  conditioned on our model choice and data; i.e., our actual learning target is often the posterior distribution,  $p(\theta_k | \mathbf{y}, \mathcal{M}_k)$ . Further, the presentation above makes implicit assumptions about prior structures for  $\theta$  that will not always hold. In more realistic settings, evaluating model fit based on Bayes factors comes with several additional difficulties that have, in combination, worked against their widespread adoption: computational intractability, prior sensitivity, incomplete accounting for uncertainty, and open model spaces.

### **Marginal Likelihoods**

In order to construct Bayes factors, we need to be able to calculate the probability of the data given the model after marginalizing out the model parameters. More concretely, let  $\theta \in \Theta$  be some set of model parameters of interest, let  $L(\theta_k) = p(\mathbf{y} | \theta_k, \mathcal{M}_k)$  represent the standard likelihood function for the data from model  $k$ , and let  $\pi(\theta_k | \mathcal{M}_k)$  be the prior

distribution for  $\theta_k$ .<sup>10</sup> In order to calculate model probabilities or Bayes factors, we need to marginalize out  $\theta_k$ :

$$p(\mathbf{y} | \mathcal{M}_k) = \int_{\Theta} p(\mathbf{y} | \theta_k, \mathcal{M}_k) \pi(\theta_k | \mathcal{M}_k) d\theta. \quad (5)$$

Unfortunately, the integral in Equation 5 is often not analytically tractable. Moreover, even where it can be approximated with fidelity for one model, the set of models being considered may be sufficiently large such that Equation 2 cannot be calculated in a reasonable amount of time. Note that in order to find the marginal distribution in Equation 2, we would need to complete these calculations  $K$  times, and without  $p(\mathbf{y})$ , individual model probabilities cannot be directly calculated.

### Approximations and BIC

Statisticians have developed several methods designed to approximate Equation 3 quickly. For example, one can use Laplace’s method to approximate  $p(\mathbf{y} | \mathcal{M}_k)$  using the following formula (Ando, 2010, 115):

$$p(\mathbf{y} | \mathcal{M}_k) \approx p(\mathbf{y} | \hat{\theta}_k, \mathcal{M}_k) \pi(\hat{\theta}_k | \mathcal{M}_k) \times \frac{(2\pi)^{\frac{p}{2}}}{n^{\frac{p}{2}} |J(\hat{\theta})|^{\frac{1}{2}}}, \quad (6)$$

where  $\hat{\theta}$  is the maximum likelihood estimator (MLE),  $p$  is the number of parameters in the model, and  $J(\theta) = -\frac{1}{n} \frac{\partial^2 \log L(\theta)}{\partial \theta \partial \theta^T}$  is a function of the Hessian of the log-likelihood such that the second term is related to the asymptotic covariance of the MLE.

This can be simplified further in instances where a large  $n$  and appropriate prior structure allow us to ignore the prior. In such cases, Schwarz (1978) proposes a simpler approximation of  $p(\mathbf{y} | \mathcal{M}_k)$ . Disregarding

portions of Equation 6 and that are constant in large- $n$  settings and taking the log, we get the Bayesian information criterion (BIC):<sup>12</sup>

$$\text{BIC} = -2 \log p(\mathbf{y} | \hat{\theta}_k) + p \log n,$$

where we let  $p(\mathbf{y} | \hat{\theta}_k, \mathcal{M}_k) = p(\mathbf{y} | \hat{\theta}_k)$  to simplify the notation. Likewise, we get

$$\log BF[\mathcal{M}_a; \mathcal{M}_b] \approx (\text{BIC}_b - \text{BIC}_a) / 2. \quad (7)$$

The advantage of using BIC is its simplicity. We can evaluate and compare models using straightforward calculations from the likelihood based on the MLE. The obvious drawback is that BIC will give inaccurate and even misleading approximations in small sample settings or when prior structures cannot be ignored (e.g., improper priors). Subsequent work has also raised questions about whether BIC can actually be considered an approximation of any valid quantity (Gelman and Rubin, 1995).<sup>11</sup> Indeed, Berger et al. (2003) shows that even in fairly simple models, BIC can lead to incorrect conclusions, even as  $n \rightarrow \infty$ .<sup>13</sup> For these reasons, we advise that researchers be cautious in interpreting BIC as a proper approximation of a Bayes factor or, even better, avoid the use of BIC altogether.

### Approximation via Simulation and Bridge Sampling

Several other approaches focus on approximating marginal likelihoods, using methods that take advantage of the simulation methods (e.g., MCMC) typically used to estimate posterior distributions of  $\theta_k$ . What these methods have in common is that they attempt to avoid the potentially high-dimensional integration problem in Equation 5 using Monte Carlo-like approximations.

One of the simplest approaches for simulation again rests on the Laplace method. Assume that we have  $s \in [1, 2, \dots, S]$  samples of  $\theta_k$  from model  $k$ , denoted  $\theta_k^{(s)}$ . We can then

approximate the posterior mode as (Ando, 2010: 170)

$$\begin{aligned} \hat{\theta}_k &\approx \max_s \{p(\theta_k^{(s)} | \mathbf{y})\} \\ &= \max_s \{p(\mathbf{y} | \theta_k^{(s)}, \mathcal{M}_k)\pi(\theta_k^{(s)} | \mathcal{M}_k)\}. \end{aligned}$$

The posterior covariance can be approximated as

$$\hat{V} \approx \frac{1}{S} \sum_{s=1}^S \{(\theta_k^{(s)} - \bar{\theta}_k)^T (\theta_k^{(s)} - \bar{\theta}_k)\}$$

where  $\bar{\theta}_k$  is the posterior mean. We can then get

$$p(\mathbf{y} | \mathcal{M}_k) \approx p(\mathbf{y} | \hat{\theta}_k)\pi(\hat{\theta}_k) \times (2\pi)^{\frac{p}{2}} |\hat{V}|.$$

More advanced examples of numerical approximations in the literature include reversible jump MCMC (Green, 1995),

Chib’s (1995) method, path sampling (Gelman and Meng, 1998), the harmonic mean estimator (Gelfand and Dey, 1994), and more. Each of these approaches has its relative advantages and disadvantages, but all can be technically difficult to implement. Further, estimators that rely on evaluations of the likelihood (e.g., the harmonic mean estimator) can be numerically unstable, since these are technically unbounded.

Perhaps the most generally useful approach within this family is bridge sampling (Meng and Wong, 1996; Meng and Schilling, 2002), which has a fairly ‘black box’ implementation available for applied researchers (Gronau et al., 2017a; Gronau et al., 2017b). The basic idea is to introduce a ‘bridge function’,  $h(\theta)$ , and a proposal distribution,  $\psi(\theta)$ . We can then set up the identity

$$\begin{aligned} 1 &= \frac{\int_{\Theta} h(\theta_k) p(\theta_k | \mathbf{y}, \mathcal{M}_k) \psi(\theta_k) d\theta_k}{\int_{\Theta} h(\theta_k) \psi(\theta_k) p(\theta_k | \mathbf{y}, \mathcal{M}_k) d\theta_k} = \frac{\frac{1}{p(\mathbf{y} | \mathcal{M}_k)} \int_{\Theta} h(\theta_k) p(\mathbf{y} | \theta_k, \mathcal{M}_k) \pi(\theta_k | \mathcal{M}_k) \psi(\theta_k) d\theta}{\int_{\Theta} h(\theta_k) \psi(\theta_k) p(\theta_k | \mathbf{y}, \mathcal{M}_k) d\theta_k} \quad (8) \\ p(\mathbf{y} | \mathcal{M}_k) &= \frac{\int_{\Theta} h(\theta_k) p(\mathbf{y} | \theta_k, \mathcal{M}_k) \pi(\theta_k | \mathcal{M}_k) \psi(\theta) d\theta}{\int_{\Theta} h(\theta_k) \psi(\theta_k) p(\theta_k | \mathbf{y}, \mathcal{M}_k) d\theta_k} \end{aligned}$$

For the denominator in Equation 8, we can use draws of  $\theta_k$  to approximate the integral numerically. Likewise, we can take draws from the

proposal density  $\psi(\theta_k)$  to accomplish the same task in the numerator. Assuming we take  $L$  draws from  $\psi(\cdot)$ , we can estimate Equation 5 as

$$p(\mathbf{y} | \mathcal{M}_k) = \frac{\frac{1}{L} \sum_{l=1}^L h(\theta_k^{(l)}) p(\mathbf{y} | \theta_k^{(l)}, \mathcal{M}_k) \pi(\theta_k^{(l)} | \mathcal{M}_k)}{\frac{1}{S} \sum_{s=1}^S h(\theta_k^{(s)}) \psi(\theta_k^{(s)})}.$$

Obviously, in order to implement this model, we must choose  $h(\cdot)$  and  $\psi(\cdot)$ . Meng and Wong (1996) provide an optimal choice for  $h(\cdot)$  in terms of the mean-squared error of the estimator. For efficiency, the proposal density will ideally be as close as possible to the posterior distribution. The bridge-sampling package relies on either a multivariate normal distribution, where the mean vector and covariance matrix are calculated from the full posterior for  $\theta$  and a

‘warped’ posterior (Meng and Schilling, 2002).

Once we have estimated  $p(\mathbf{y} | \mathcal{M}_k)$  for various models, we can then compare specific models by constructing Bayes factors. Once again, when comparing models  $a$  and  $b$ , we can get

$$BF[\mathcal{M}_a, \mathcal{M}_b] = \frac{p(\mathbf{y} | \mathcal{M}_a)}{p(\mathbf{y} | \mathcal{M}_b)}.$$

Alternatively, to maintain comparability with the BIC approach, we can calculate

$$\begin{aligned} \log BF[\mathcal{M}_a, \mathcal{M}_b] \\ = \log \{p(y | \mathcal{M}_a)\} - \log \{p(y | \mathcal{M}_b)\}. \end{aligned}$$

**Prior Sensitivity,  $\mathcal{M}$ -Closed Assumption, and Uncertainty**

Perhaps the greatest limitation of Bayes factors is that the results can be very sensitive to priors. The approach to model selection discussed above rests on the  $\mathcal{M}$ -closed assumption, meaning we are assuming that one of the  $\mathcal{M}_k \in \mathcal{M}$  is the *true* model, even if the researcher does not know which it is. Especially when this is untrue, Bayes factors will be driven by the choice of prior distributions chosen for  $\theta$ . Yao et al. (2018: 919) provide the following powerful example:

[C]onsider a problem where a parameter has been assigned a normal prior distribution with center 0 and scale 10, and where its estimate is likely to be in the range  $(-1, 1)$ . The chosen prior is then essentially flat, as would also be the case if the scale were increased to 100 or 1000. But such a change would divide the posterior probability of the model by roughly a factor of 10 or 100.

In essence, if we were to compare two models that are exactly the same except for one having a prior over  $\beta$  with standard deviation 10 and the other with standard deviation 100, the Bayes factor would strongly favor the first, despite the fact that the posterior estimates of  $\theta$  and even predictions for each observation would be essentially the same across models. Further, placing (most) improper vague priors on  $\theta$  – arguably the most agnostic approach to

model building – will lead to the Bayes factor not existing at all. This leads to the awkward result that the ultimate decision about model quality depends on choices we make about the prior structures on  $\theta$  parameters – choices that may be only incidental to the scientific question at hand.

A final concern is that some of these approaches to model comparisons are not ‘truly Bayesian’, in the sense that they rely on a single estimate of  $\hat{\theta}$  rather than reflecting the entire posterior. Even the approaches that leverage the full posterior over  $\theta$  do so only to marginalize the quantities away.

**Example Application**

Keeping these limitations in mind, we turn back to our running example. Based on the non-sensical results when including all covariates, we from now on only compare the four original models presented by Richman (2011). First, we calculate BIC for each of the four models, as presented in Table 49.2. As we can see, Model 3 has the smallest BIC value, which would indicate the highest model fit. This is in line with the evaluation by Richman (2011) based on the  $R^2$  values. Similarly, as with Richman’s evaluation, the difference between the BIC values of Models 3 and 4 is very small. Nevertheless, the BIC for Model 2 is only 50 points larger than that of Model 3. Thus, again, one would have to conclude that Model 3 seems to be slightly better than the other two models. In the bottom part of Table 49.2, we show the approximate Bayes factor

**Table 49.2 BIC and approximation to Bayes factor**

<i>BIC scores</i>			
<i>Model 1</i>	<i>Model 2</i>	<i>Model 3</i>	<i>Model 4</i>
696.3	657.2	607.2	611.5
Log Bayes factor approximation for Model 3			
$M_3: M_1$	$M_3: M_2$	–	$M_3: M_4$
44.4	25.0		2.2

**Table 49.3 Log marginal likelihood and Bayes factor using bridge sampling**

<i>Log marginal likelihood</i>			
<i>Model 1</i>	<i>Model 2</i>	<i>Model 3</i>	<i>Model 4</i>
-351.0	-332.5	-309.4	-311.5
Log Bayes factor via bridge sampling for Model 3			
$M_3: M_1$	$M_3: M_2$	-	$M_3: M_4$
41.7	23.2		2.2

(on the log scale), calculated as in Equation 7, for Model 3 compared to the three other models. The results lend additional support to the idea that Model 3 is clearly better than Models 1 and 2 while only being a slight improvement when compared to Model 4. On the original scale, the Bayes factor between Model 3 and Model 4 is nine; i.e., in the language discussed above, this could be considered ‘substantial’ but not quite ‘strong’ evidence in favor of Model 3 over Model 4.

Next we use bridge sampling, with a *bridge function* as in Equation 8, to first estimate the log marginal likelihood for the four models. We also generate estimations of the log Bayes factor comparing Model 3 to the others. The *brms* package again makes this very easy for applied users, as the estimations are integrated into the package. The top half of Table 49.3 shows the log marginal likelihood for each of the four models as estimated via bridge sampling. Similar to previous results, the differences are largest with respect to Models 1 and 2 compared to Models 3 and 4. The lower half of Table 49.3 presents the Bayes factor of  $\mathcal{M}_3 : \mathcal{M}_k$  on the log scale. For this exercise, the approximate Bayes factor using BIC and the estimation via bridge sampling are very similar. We note, however, that these different approximations are likely to diverge in more complicated settings.

**PREDICTIVE MODEL EVALUATION**

While model selection via Bayes factors and marginal model probabilities seems intuitive, as the above discussion indicates it is not always so straightforward in practice. This is

particularly true in instances where the model parameters  $\theta$  take on continuous values, requiring both informative priors and marginalization to complete the calculations. In addition to the difficulty of calculating the marginal likelihoods discussed above, Bayes factors in general are sensitive to priors on elements of  $\theta$  in ways that can be undesirable.

As an alternative, the literature contains a number of approaches intended to help scholars evaluate the quality of any given model based on their predictive capacity. Here, we follow the presentation in Gelman et al. (2013) and Gelman et al. (2014). The most common approaches are based on information theory, with the goal of minimizing the Kullback–Leibler (KL) divergence between the *true* (but unknown) data generating function and the predictive distribution implied by model  $\mathcal{M}_k$ .

Let  $\hat{\theta}$  be our current estimate for the model parameters,  $p(\tilde{y} | \hat{\theta})$  be predictions from model  $k$  for some new observation  $\tilde{y}$  that were not used to fit the model, and  $g(\cdot)$  be the *true* data generating function. Note that for the rest of this section we suppress the implied conditioning on the model for clarity. Rather than evaluating model fit based on *in-sample* performance, the idea is that we would like to choose the model that best fits *all* of the data, not just that which we have collected.

One way to summarize the predictive fit of a model is the log predictive density (lpd),  $\log\{p(\tilde{y})\}$ . This quantity has a nice feature in that, in the limit, the model with the lowest KL information also has the highest lpd (Gelman et al., 2014). For a single point, we can define the lpd as the point prediction from that point after marginalizing out  $\theta$ ,

$$\begin{aligned} \log\{p(\tilde{y}_i)\} &= \log E[p(\tilde{y}_i | \theta)] \\ &= \log \int_{\Theta} p(\tilde{y}_i | \theta) p(\theta | \mathbf{y}) d\theta. \end{aligned}$$

Note that the expectation is taken over the posterior of  $\theta$ , where the posterior is estimated based on the in-sample data  $\mathbf{y}$ .

We have to go further here, because the future data ( $\tilde{y}$ ) is itself unknown. However, we can again use Bayesian reasoning to calculate the expected log predictive density (elpd) as:

$$\begin{aligned} E[\log\{p(\tilde{y}_i)\}] \\ = \int g(\tilde{y}_i) \log\{p(\tilde{y}_i)\} d\tilde{y} = \text{elpd}. \end{aligned}$$

In this case, the expectation is taken in terms of the unknown function  $g(\cdot)$ .

For more than one data point, we can simply sum this value to create the expected log pointwise predictive density (elpdp),

$$\text{elpdp} = \sum_{i=1}^n E[\log\{p(\tilde{y}_i)\}]. \tag{9}$$

The model that scores highest on this value can be considered the ‘best’ model in terms of its predictive accuracy and, with large samples, optimal in terms of KL information. However, since this quantity cannot be calculated directly, we must again turn to approximations below.

Before moving onto specific approximations, however, it is helpful to define two additional quantities. First, if we assume some specific point estimate  $\hat{\theta}$ , we can calculate the elpd as  $E[\log\{p(\tilde{y}_i | \hat{\theta})\}]$ . Further, in this case and given standard *iid* assumptions, we can simplify the notation to get

$$p(\tilde{y} | \hat{\theta}) = \prod_{i=1}^n p(\tilde{y}_i | \hat{\theta}).$$

**Information Criteria**

In the particular case where we use the MLE, the elpd can be approximated accurately using the Akaike information criterion (AIC) (Ando, 2010).

$$AIC = -2 \log L(\hat{\theta}_{MLE}) + 2p,$$

where  $\text{elpd} \approx -\frac{1}{2} AIC$ . However, it is important to note that this assumes (i) we have not included informative priors on  $\theta$ , (ii) the posterior distribution for  $\theta$  can be represented as a multivariate normal, and (iii) the model is correct (the true data generating process corresponds to some unknown member of the specified parametric distributions) (Ando, 2010: 199). Thus, while it is simple to calculate, it is probably not applicable in many situations.

Note that AIC has two additive components, which is a feature of all of these similar criteria. The first represents the degree to which the model fits well given the data already collected; i.e., the in-sample fit. The problem, of course, is that models that better explain the data we have will *not* always be a superior representation of the underlying DGP. Instead, more complex models – models that include more variables, interactions, non-linearities, and the like – may simply capture random noise in the dataset, mistaking it for true information. More formally, improved in-sample model fit may actually decrease the ability of the model to explain (or predict) new observations generated by the same process.<sup>14</sup>

Following this logic, the second term in the AIC formula is a penalty term that punishes for complexity to work against selecting models that over-fit the data. Under the assumptions stated above, the penalty term in the AIC is exact. However, when we move beyond a world of flat priors and linear models, this penalty term will no longer be correct (Gelman et al., 2013).

The deviance information criterion (DIC) overcomes these issues by approaching the problem from a more strict Bayesian perspective. Spiegelhalter et al. (2002) proposed the following criteria:

$$DIC = -2 \log\{p(\mathbf{y} | \hat{\theta}_{EAP})\} + P_D$$

where  $P_D$  is a Bayesian measure of model complexity that is based on the posterior

mean  $\hat{\theta}_{EAP}$  and posterior covariance  $\text{Var}(\theta)$ . The exact penalty is

$$P_D = 2 \left( \begin{array}{l} \log \{ p(\mathbf{y} | \hat{\theta}_{EAP}) \} \\ - \int_{\Theta} \log \{ p(\mathbf{y} | \theta) p(\theta | \mathbf{y}) \} d\theta \end{array} \right).$$

Since the second term is simply the expected value for the log predictive distribution where the expectation is taken over the posterior of  $\theta$ , we can use Monte Carlo integration using the  $s = 1, \dots, S$  draws from the posterior,

$$P_{D(1)} \approx 2 \left( \begin{array}{l} \log \{ p(\mathbf{y} | \hat{\theta}_{EAP}) \} \\ - \frac{1}{S} \sum_{s=1}^S \log \{ p(\mathbf{y} | \theta^{(s)}) \} \end{array} \right).$$

An alternative approximation,

$$P_{D(2)} \approx 2 \text{Var}[\log \{ p(\mathbf{y} | \theta) \}],$$

has the advantage of always providing a positive value (Gelman et al., 2013).

**Model Evaluation Based on Pointwise Predictive Densities**

While both AIC and DIC aim to approximate (or proxy for) the out-of-sample fit, they are subject to two criticisms. First, the models use the same training data both to fit the model and evaluate the appropriate complexity penalty. This can bias estimates towards models that are too complex, leading researchers to the wrong decision. Further, both criteria use only a single point estimate (either the MLE or the EAP) to evaluate model fit. This means that we ignore the full posterior of the model parameters, making the methods not ‘fully Bayesian’, which can lead to problems, including negative estimates for the effective number of parameters (Vehtari et al., 2017: 1414).

From a Bayesian perspective, several other criteria are generally preferred for model evaluation. These allow us to make use of the full posterior distribution but also avoid the problems of prior sensitivity that plague Bayes factors discussed above.

These methods are also, to differing degrees, closely related to out-of-sample performance, which is more consonant with recent trends in model evaluations and further protects against over-fitting. For these criteria, we move towards evaluating fit based on how well predictive *densities* approximate the true data generating process for individual data points.

The goal is to try to evaluate each model based on its predictive accuracy, where accuracy is evaluated based on the predictive distribution rather than the point estimate. Let  $\tilde{y}$  be some set of data points we are trying to predict (either new data or a data ‘held out’ during fitting) and  $\mathbf{y}^{obs}$  be the data we are currently using to fit the model. We can then write the posterior predictive distribution as

$$p(\tilde{y}) = \int_{\Theta} p(\tilde{y} | \theta_k) p(\theta | \mathbf{y}^{obs}) d\theta = E[p(\tilde{y} | \theta_k)].$$

For similar reasons as those noted above, we want to evaluate the model based on some function of the logged value,  $\log \{ p(\tilde{y}) \}$ . Using  $s = \{ 1, \dots, S \}$  draws of  $\theta$  from a sampler, we can approximate using Monte Carlo integration. Summing over all observations in the held-out dataset, we then get the ‘computed log pointwise predictive density [clppd]’ (Gelman et al., 2013: 169):

$$\text{clppd} = \sum_{i=1}^n \log \left\{ \frac{1}{S} \sum_{s=1}^S p(\tilde{y}_i | \theta^{(s)}) \right\}.$$

For a fully Bayesian treatment, we would then *like* to calculate the elppd shown in Equation 9. The general problem is that since we cannot marginalize over the unknown function  $g(\cdot)$ , we must again settle for approximations based on clppd. When clppd is calculated within the sample, we will overestimate the elppd, which we then need to adjust (similar to the penalties for AIC and DIC discussed above). Alternatively, we might rely on true out-of-sample forecasts for calculating clppd. However, this comes

with the problem of either introducing error in the clppd as an estimate of elppd (because each  $\theta$  is estimated on a subset of the data and therefore our out-of-sample forecasts may be noisier) or imposing considerable computational requirements.

### WAIC

The widely available information criteria (WAIC, or alternatively the Watanabe information criterion) is intended to provide a computationally friendly way of evaluating the performance of models based on predictive distributions (Watanabe, 2010, 2013). To generate the WAIC, we compute the clppd within the training sample and then apply a penalty term for complexity:

$$WAIC = \frac{1}{n} \sum_{i=1}^n \log \{ p(\tilde{y}_i) \} - P_w.$$

As with DIC, the trick is to find the correct penalty term  $P_w$ . One approach is to let  $P_w = V/n$ , where  $V$  is the functional variance (Piironen and Vehtari, 2017b):

$$V = \sum_{i=1}^n \{ E[p(\tilde{y}_i | \theta)^2] - E[p(\tilde{y}_i | \theta)]^2 \}.$$

Gelman et al. (2013, Equation 7.12), however, recommend an alternative penalty equivalent to the summed variance of the log predictive density of each data point:

$$P_w = \sum_{i=1}^n \text{Var}_s \left[ \log \{ p(y_i | \theta^{(s)}) \} \right],$$

where  $\text{Var}_s[\cdot]$  is the sample variance function, and we calculate the variance across the  $S$  draws from the posterior.<sup>15</sup>

### Cross validation

Rather than trying to arrive at a correct penalty for complexity, another approach is cross-validation to reduce the bias from overfitting.<sup>16</sup> First, the data is split into  $A$  subsets (e.g.,  $A = 10$ ) of approximately equal size  $\left( \frac{A-1}{A} \times n \right)$ . The model is then estimated on

each of the subsets and predictions are made for the observations that were held out. Once completed  $A$  times, we now have out-of-sample predictions for each observation in the dataset. Based on this procedure, we can define a ‘cross validated predictive density’ (Ando, 2010):

$$\text{cvpd}_k = \prod_{\alpha=1}^A \int p(y_\alpha | \theta^{(\alpha)}) p(\theta^{(\alpha)} | y_{-\alpha}).$$

In this case, we ‘hold out’ observations in partition  $\alpha$  and calculate the posterior on  $\theta$ . Based on this distribution, we can then calculate the clppd for model evaluation.<sup>17</sup>

While relying on out-of-sample predictions does reduce the bias in our estimate of elppd, reducing the sample size during model fitting can decrease the accuracy of the overall model itself. Generally,  $A$  between 8 and 16 has been recommended as reasonable to trade off error and computational cost (Vehtari and Lampinen, 2002). Of course, estimating even a single Bayesian model, especially with large  $N$  or many parameters, can be computationally intensive and time consuming. Cross-validation requires repeatedly ( $A$ -times) estimating each of the models that one is interested in comparing. When we have many models to compare, cross-validating each can involve fitting thousands of total models. Since this can be parallelized easily, in simple cases cross-validation may be a good option. But even with modern computing, full cross-validation is only practical when comparing relatively few models and when each of the models is relatively computationally inexpensive. Further, depending on the type of dataset and estimated models (e.g., consider hierarchical data or spatial models), scholars have to give serious consideration as to how to partition the data for analysis (and for some there may be no clean approach to doing so).

### LOO-CV

The extreme case of cross-validation methods is leave-one-out cross-validation

(loo-cv). Here, the model is estimated  $n$  times, each time leaving out one observation in the estimation and predicting that particular left-out observation. As in cross-validation, the predictive densities for all separately left out and predicted observations are then evaluated using some criteria. This approach has been shown to have a number of good properties and, when feasible, is perhaps the best way to evaluate alternative models. Watanabe (2010) shows that WAIC is asymptotically equivalent to the Bayesian leave-one-out cross-validation (loo-cv). Some argue that WAIC and loo-cv 'give a nearly unbiased estimate of the predictive ability of a given model' (Piironen and Vehtari, 2017a: 712). Of course, since all models need to be estimated  $n$  times, loo-cv is likely to be too computationally intensive for many applied researchers.

To make loo-cv computationally tractable, Gelfand et al. (1992) and Gelfand (1996) suggested importance sampling leave-one-out cross-validation. Effectively, we want to avoid estimating each model  $n$  times and sampling a new  $\theta_i$  to create a predictive distribution for each left-out observation  $i$ . To do so, we approximate  $\theta_i$  using the posterior draws for  $\theta$ , taking into account the degree to which data point  $i$  affects the estimate. In the original approach, the importance ratio used to approximate the model with the left-out observation  $i$  would be  $r_i^s = \frac{1}{p(y_i | \theta^s)}$  (Vehtari and Lampinen, 2002; Vehtari et al., 2017). Thus, instead of having to estimate each model  $n$ -times, we only generate one estimate of  $\theta$  based on the whole data and then approximate the posterior for each of the data subsets by re-weighting with the importance ratios.

This strategy, however, can be problematic under several circumstances, such as for data with highly influential cases or high-dimensional models.<sup>18</sup> More recently, Vehtari et al. (2017) have suggested an improvement to importance sampling for loo-cv by

smoothing the importance ratios, such that extreme values are not too influential or problematic. This is done using the Pareto distribution with its heavy tails, i.e., 'Pareto smoothed importance sampling (PSIS)' (Vehtari et al., 2017: 1413).

Specifically, psis-loo-cv smooths the 20% largest, and therefore potentially problematic, importance ratios. To do so, first a generalized Pareto distribution is fit to the largest importance ratios. These potentially problematic ratios are then replaced with 'the expected values of the order statistics of the fitted generalized Pareto distribution' (Vehtari et al., 2017: 1415). Not only should the resulting smoothed weights perform better, the shape parameter of the fitted Pareto distribution can be used to check the reliability of the new importance weights. A large estimated shape parameter of the fitted Pareto distribution can indicate problems with the underlying distribution of the original importance samples. In that case, the estimates from the Pareto-smoothed importance sampling may also be problematic. One immediate advantage is that one can then identify those problematic observations. This allows scholars to then estimate the full leave-one-out posterior for those observations that were identified as problematic. We can then directly sample from this actual leave-one-out posterior  $p(\theta | y_{-i})$  for those observations. The full model evaluation would then be based on both psis-loo and full-loo estimates. Claassen (2019) has recently used psis-loo-cv for model evaluation in political science.

As Vehtari et al. (2017) argue, psis-loo-cv has considerable *computational* advantages over exact leave-one-out cross-validation. It also performs better than WAIC, traditional importance sampling, and truncated importance sampling loo-cv on a variety of models. For hierarchical models with few data points per group and high variation in the parameters between groups, however, the performance of WAIC and psis-loo decreases and exact loo-cv becomes more valuable.<sup>19</sup>

**Table 49.4** Information criteria for evaluating theories of Congress

	<i>Model 1</i>	<i>Model 2</i>	<i>Model 3</i>	<i>Model 4</i>
psis-loo-ic	687.6	650.1	600.7	605.3
WAIC	687.6	650.0	600.7	605.2
k-fold-ic	688.7	650.4	600.1	603.8

### Application

We now return to our example application from above and compare the different models in terms of WAIC, 10-fold cross-validation, and psis-loo. The *loo* package in *R* allows scholars to easily generate these model evaluation scores for models estimated in *Stan* (Vehtari et al., 2019). Moreover, the *loo* package is again integrated into the *brms* package and the information-criteria scores are readily available for our estimated models.

The *loo* package produces the expected log predictive density (elpd) as well as the information criteria on the deviance scale (i.e.,  $-2 \times \text{elpd}$ ) for all three information criteria. In Table 49.4, we present the different information-criteria scores on the deviance scale for the four models. First, in our simple example with 117 observations, two parameters per model, and an estimated Gaussian linear model, the values of the different information criteria for each model are quite similar to each other. For example, for Model 3, the WAIC score is 600.65, the psis-loo-ic score is 600.74, and the k-fold-ic score is 604. The same is true for the other three models, where the WAIC, psis-loo-ic, and k-fold-ic closely correspond with each other. In line with the results of the previous information criteria presented, Model 3 performs best, i.e., has the lowest information criteria scores.

Readers might wonder how to decide whether the evidence in favor of a particular model is strong enough to make a claim about it being the *best* model. As mentioned above, for the Bayes factor, a value of 10 or larger would, according to some, be

considered *strong* evidence in favor of the better model. As a first step in comparing two models in terms of the information criteria, we can calculate the difference in their scores. If we want to evaluate whether Model 3 should be strictly preferred to Model 1, we calculate  $\text{psis-loo-ic}_1 - \text{psis-loo-ic}_3 = 86.9$ . In Table 49.5, we present the psis-loo-ic scores of the individual models in the top four rows, but in the bottom part of the table, we present the calculated difference in psis-loo-ic scores between the four different models. Recall that positive values indicate a better score for the second model in the difference. As we can see, the second model is preferred for all comparisons except when comparing Models 3 and 4. The difference in psis-loo-ic scores again indicates that Model 3 performs better than Model 4. But is this difference large enough to strictly prefer Model 3?

Fortunately, the model-evaluation criteria discussed here allow us to calculate uncertainty estimates, which can be used to judge whether differences between models are large enough to draw conclusions. Each of these methods is estimated using functions applied to the individual observations in the data to create the information criteria; i.e., the total information criteria are combinations of  $n$  scores. Using the standard deviation of those  $n$  components, one can estimate an approximate standard error for the information criteria. For example, in the case of psis-loo-cv, we can estimate a standard error based on the standard deviation of the  $n$  individual components of the elppd:  $\widehat{\text{elpd}}_{i,loo}$  (Vehtari et al., 2017: 1426). Similarly, the individual components can be used to calculate an approximate standard error for the difference in information criteria scores.

**Table 49.5** Loo information criteria for evaluating theories of Congress with standard errors

Model	<i>psis-loo-ic</i>	<i>SE</i>
Model 1	687.6	17.5
Model 2	650.1	24.0
Model 3	600.7	24.1
Model 4	605.3	24.7
Differences and SEs		
$M_1 - M_2$	37.6	12.2
$M_1 - M_3$	86.9	16.4
$M_1 - M_4$	82.3	16.8
$M_2 - M_3$	49.3	9.5
$M_2 - M_4$	44.7	11.0
$M_3 - M_4$	-4.6	4.4

The top half of Table 49.5 shows the estimated  $\widehat{elpd}_{loo}$  score on the deviance scale for each of the four models as well as the estimated standard error. In the bottom half of the table, we present the difference in *psis-loo-ic* scores and the standard error for each difference. There is no clear and hard rule about how large the difference compared to its standard error would have to be to conclude that a model is strictly superior. One might take the general rule of thumb that we would like to see a difference that is *at least* twice the size of the standard error. It has been suggested, however, that these standard error estimates are an optimistic approximation and, especially for smaller sample sizes, might not be appropriate (Vehtari et al., 2017). When model differences are sufficiently small, scholars may prefer the less complex model that provides comparable fit. Again, both differences in information criteria and their standard errors are easily available in the *loo* package and integrated into the *brms* package.

Based on the results presented in Table 49.5, we would conclude that Model 3 is significantly better than Models 1 and 2. On the other hand, comparing Model 3 and Model 4 suggests that both do a similar job at explaining the variation in the data; i.e., there is no strong reason to prefer one to the other.

## FINITE MIXTURE MODELS, BAYESIAN MODEL AVERAGING, AND STACKING

In this section, we turn to a somewhat different approach for handling multiple potential models. In particular, we consider statistical approaches where each of the competing models is considered a component of an overarching model; i.e., we eschew the task of selecting or even comparing models and instead consider how much each *component* model contributes to the model combination. In the end, we may heuristically prefer the component that contributes the most, making this distinction seem somewhat arbitrary. However, from a statistical standpoint, the approaches we cover next can be seen as quite distinct from those discussed above.

Specifically, we return to the finite model-space approach discussed in the earlier section on model selection and Bayes factors.<sup>20</sup> We can then engage in model selection either by choosing the model that receives the most weight in this mixture or skipping the task of model selection entirely and attempting to make inferences that actually reflect our uncertainty about the true DGP.

### Mixture Models

One family of models attempts to assign each observation to one of the potential candidate models and estimate  $\theta_k$  based on this assignment (McLachlan and Peel, 2000; Imai and Tingley, 2012). Let  $p(y_i | \theta_k, M_k)$  represent the predictive distribution of observations  $i$  from model  $k$  and let  $\tau = [\tau_1, \tau_2, \dots, \tau_k]$  index which model actually generated each observation such that  $\tau_i \in [1, 2, \dots, K] \forall i \in [1, 2, \dots, n]$ . We can construct our mixture model as

$$p(y_i | \tau, \theta_k) \sim \sum_{k=1}^K p(y | \theta_k) \mathcal{J}(\tau_i = k),$$

where  $\mathcal{J}(\cdot)$  is the standard indicator function. We can then complete the model by placing

appropriate priors over  $\theta_k$  and a hierarchical prior structure on  $\tau$ ,

$$\pi(\tau) \sim \text{Multinomial}(\omega)$$

$$\pi(\omega) \sim \text{Dirichlet}(\alpha).$$

In this case, the  $\omega_i$  parameter represents the probability a generic observation is assigned to each model, and we can interpret the posterior estimate in a fashion similar to (but distinct from) the model probabilities shown in Equation 3. Likewise, we can look at the posterior distributions on the  $\tau$  vector to get an estimate of how many observations are assigned to each model.

One important factor to note is that the model parameters for each component  $\theta_k$  are estimated for observations ‘assigned’ to that component using standard Bayesian methods; i.e., we are imagining that all of the models are operating at the same time but that different units belong to each (Imai and Tingley, 2012).

In many cases, this can be desirable, although it can increase uncertainty for components that are assigned few observations. Scholars must also be careful in how they interpret individual parameters, as the parameters do not correspond to estimates for the entire population. Further, simultaneous estimation of model weights and model parameters can also lead to model degeneracy and identification problems during estimation. Standard regression models can be estimated in a fully Bayesian fashion using the `BayesMix` package in R or with alternative estimation routines (via the EM algorithm) using the `FlexMix` package. However, with attention paid to issues of identification, they can also be fit using `brms`.

### EBMA

Ensemble Bayesian model averaging (EBMA), largely deriving from the literature on forecasting, is different in that we fit component models separately using the entire

dataset and then combine them into a weighted ensemble (Raftery et al., 2005; Montgomery et al., 2012). In this case, we can divide our dataset into three partitions: a training set used to fit each individual model ( $\mathbf{y}^{\text{train}}$ ); a calibration used to determine the model weights ( $\mathbf{y}^{\text{cal}}$ ); and a true test set that we are hoping to accurately predict ( $\mathbf{y}^{\text{test}}$ ). We assume that each of the component models is fit to the training data (although the component models need not be statistical models at all). The calibration set represents observations that were predicted out-of-sample by each component model and allows us to appropriately weight them without having to develop penalties for complexity. The goal is then to combine the forecasts in order to make accurate predictions of the test observations.

Let  $w_k = p(\mathcal{M}_k | \mathbf{y}^{\text{cal}})$ , and  $p(\mathbf{y}^{\text{test}} | \mathcal{M}_k)$  represent the predictive pdf for the test set from model  $k$ . Our goal is then to generate an ensemble prediction,

$$p(\mathbf{y}^{\text{test}}) = \sum_{k=1}^K w_k p(\mathbf{y}^{\text{test}} | \mathcal{M}_k).$$

To complete the model, therefore, we need to estimate the model weights for each component. Formally, we need to find the values of  $\mathbf{w}$  that will maximize the log-likelihood function,

$$\mathcal{L}(\mathbf{w}, \Theta) = \sum_{i=1}^{n^{\text{cal}}} \log \left\{ \sum_{k=1}^K w_k p(\mathbf{y}^{\text{cal}} | \theta_k) \right\}$$

subject to the constraint that  $\sum \omega_k = 1$ , which can be calculated efficiently using an EM algorithm or gibbs sampler in the `EBMAforecast` package in R.

### BMA

As the name suggests, EBMA is closely related to Bayesian model averaging (Madigan and Raftery, 1994; Raftery, 1995; Bartels, 1997; Gill, 2004; Montgomery and Nyhan, 2010; Cranmer et al., 2017; Plümper

and Traummüller, 2018). In the traditional approach to BMA,<sup>21</sup> each model is again fit to the entire dataset. Model weights are calculated according to Equation 3.

Of course, this again leaves us with the problem of needing to estimate marginal likelihoods. One option is to use one of the several proxies discussed above, such as AIC or BIC. Another option is to select priors that allow for closed form solutions. For instance, Zellner’s (1986) *g*-prior is

$$\pi(\beta | \sigma^2) \sim \text{Normal}(\mathbf{0}, g\sigma^2(\mathbf{X}'\mathbf{X})^{-1}),$$

where  $\mathbf{X}$  is some set of covariates and  $\sigma^2$  is the variance for the residuals in a standard regression model.<sup>22</sup> This yields a marginal model likelihood of

$$p(\mathbf{y} | \mathbf{X}, \mathcal{M}_k) = \frac{\Gamma(n/2)}{\pi^{n/2}} (1 + g)^{-p} S^{-1},$$

where  $S$  is a function only of the data and the prior mean for  $\beta$ .<sup>23</sup>

The result is that for any quantity of interest, we can simply construct a weighted ensemble from the full posterior. For instance, to estimate the posterior distribution of a specific regression coefficient, we need only calculate

$$\begin{aligned} p(\beta | \mathbf{y}) &= \sum_{k=1}^K p(\mathcal{M}_k | \mathbf{y}) p(\beta_k | \mathbf{y}, \mathcal{M}_k) \\ &= \sum_{k=1}^K w_k p(\beta_k | \mathbf{y}, \mathcal{M}_k). \end{aligned}$$

For models where this coefficient is excluded, we will then have a point mass at zero. The rest will create an ensemble posterior that reflects our uncertainty based on the set of covariates. It also allows us to focus on two separate quantities of interest that are commonly confused in interpreting regression analysis. First, we might be interested in the posterior probability that some particular variable should be in the model. This will be the sum of the model weights where that variable is included. Second, we might be interested in the distribution of  $\beta$  conditioned on the fact that it is included in the model,  $p(\beta | \mathbf{y}, \beta \neq 0)$ .

### Stacking

BMA is based on the marginal likelihood of each model under an  $\mathcal{M}$ -closed assumption. Thus, there are several problems with the BMA approach that largely correspond to the issues with Bayes factors discussed above. First, model weights can be sensitive to prior specifications. Second, it is not always clear how to place priors on the probability of specific models, since seemingly innocuous assumptions can also affect weights in unintended ways. For instance, placing an agnostic prior that each coefficient has a 50% prior probability for inclusion biases the ensemble towards models that include 50% of the covariates. Finally, an underlying assumption of BMA is that the true model is included within the model space (i.e., the  $\mathcal{M}$ -closed case). BMA will place all of its posterior weight on this one model asymptotically.

Estimating model weights in stacking is done in a different two-step process. First, the candidate models are estimated based on the data available. Second, model weights are calculated for each of the estimated candidate models. In the original stacking, model weights are generated by minimizing the leave-one-out mean-squared error for each observation based on each model’s point prediction.

Yao et al. (2018) built on several recent developments to further develop stacking to use the full leave-one-out predictive distribution instead of the point estimates. Adjusting the notation in Yao et al. (2018), let

$$\hat{p}_{ki}(\tilde{y}_i) = \int_{\Theta} p(\tilde{y}_i | \theta_k, \mathcal{M}_k) p(\theta_k | \mathbf{y}, \mathcal{M}_k) d\theta.$$

Applying a logarithmic scoring rule,<sup>24</sup> we can then find the stacking weights for each model by solving the optimization problem:

$$\max_w \frac{1}{n} \sum_{i=1}^n \log \sum_{k=1}^K w_k \hat{p}_{ki}(\tilde{y}_i).$$

If we adopt the psis-loo-ic approximations above, we can simplify this further to give us

weights based on estimates of the elpd, providing stacking weights that can be constructed from a single posterior but which reflect each models' out-of-sample properties.<sup>25</sup>

Stacking has the advantage in that it does not assume  $\mathcal{M}$ -closed, but rather allows that the true DGP may not be well represented by any of the candidate models. Additionally, because weights are calculated based on the unit-specific elpd for each model, stacking takes into account when models have different strengths in predicting certain observations. One of the advantages of stacking is, therefore, that it is able to combine weights from models that are very similar to the better model, instead of splitting the weight between very similar models, as often occurs in BMA.<sup>26</sup>

### Application

As a last example based on our application, we generate stacking model weights based on the *psis-loo-ic* scores presented above. Stacking can be easily done using the *loo* package (Vehtari et al., 2019) and is integrated into *brms* (Bürkner, 2017). Once the *psis-loo-ic* scores are calculated, stacking weights are readily available. Additionally, a warning would be given if the Pareto-smoothed importance sampling is questionable for some observations and full leave-one-out resampling is then suggested for those observations.

As we can see in Table 49.6, stacking weights are highly concentrated on Model 3, even though – based on the information criteria – Model 3 and 4 performed quite similarly (see Table 49.5 above). This suggests that while BMA may have split the weight between Models 3 and 4 due to their similar performance, stacking combines the weights to the slightly better model. While Model 3 may be only slightly better than Model 4, the two models seem to be quite similar in the cases they predicted well; thus, adding

**Table 49.6 Model weights based on stacking**

<i>Model 1</i>	<i>Model 2</i>	<i>Model 3</i>	<i>Model 4</i>
0.04	0.00	0.96	0.00

weight to Model 4 beyond Model 3 must not improve predictive accuracy. The remaining weight (0.04) is assigned to Model 1. In this case, this model is weighted poorly because it is not as accurate as the others. However, it is still weighted more highly than Models 2 and 4 because it gives sufficiently different predictions.

### CONCLUSION

The current state of the literature when it comes to testing competing models is sometimes unsatisfactory. In many cases, the conclusions that researchers draw from their analysis are sensitive to modeling choices. Traditional null-hypothesis-testing strategies in particular lead to analysts focusing excessively or even exclusively on whether or not key variables are ‘significant’ in the models they consider. However, significance can change easily depending on parametric assumptions, the set of covariates included, and more. In total, in many cases, competing theories are not meaningfully tested against each other, and the conclusions we draw from our data are driven by modeling choices that are irrelevant or orthogonal to the scientific question at hand. Even worse, the a common practice we observe in the literature – simply tossing all variables from all theories into a single regression – is known to produce incorrect and misleading conclusions. In all, we are left with a picture that for a fundamental task for science – arbitrating between competing theories – standard practices are pushing researchers towards either building incorrect garbage-can models or haphazardly exploring the potential space of models with little guidance other than important p-values.

Throughout this chapter, we have provided researchers with a set of alternative strategies for arbitrating between theories and models. The advantage of the Bayesian framework in tackling this problem is that we can use the laws of probability to think clearly about model probabilities directly. There are no null hypotheses required and no misleading p-values. Instead, we can talk meaningfully about whether a given model is better either in terms of Bayes factors or KL divergence (an optimal criteria implied by Bayesian decision theory). While imperfect, we believe that this set of tools offers a superior approach to arbitrating among theories than do standard practices in the discipline.

With that said, it is important to keep the limitations of these methods in mind. In general, the appropriateness of these model-evaluation techniques depends on the specific model specification and settings in which they are used. Further, the use of information criteria or predictive accuracy for model selection, for example, should not be a substitute for theoretical considerations of which covariates are important to include, given the question asked. Similarly, these model-selection techniques are not able to distinguish between pre- and post-treatment variables. In fact, full garbage-can models may perform better on these scores, even though the associated results are not theoretically meaningful. Thus, as with all methodological tools, they should be used with the necessary understanding of the actual problem being considered and theories of how the data was generated.

Finally, given recent advances in this area in the field of statistics, we hope that this overview will renew attention in the field of political science to these questions. Surely, none of the methods above represent the last word on this topic. Nor does our presentation take into account many practical difficulties applied scholars face in practice such as clustering, spatial correlations, time-series, confounding requiring an identification strategy, and measurement error. Further research is

needed to evaluate the usefulness of these various methods in such circumstances.

## Notes

- \* Authors listed in alphabetical order. We thank Richard A. Nielsen, Bruce A. Desmarais, and Andrew Gelman for helpful comments on earlier drafts. All remaining errors are our own.
- 1 See Clarke (2001) for a review of some of the many methods in this area that have been proposed. Clarke (2007) provides further improvements to the Vuong test that allows for comparison of two non-nested models. Desmarais and Harden (2013) note that the Clarke test can be based on biased estimates and be inconsistent, but they suggest an alternative implementation using cross-validation. Our claim is not that there are no methods available, only that many applied scholars appear to be very uncertain about which, if any, method to use.
- 2 Code and data can be found on GitHub at <https://github.com/fhollenbach/BayesModelSelection>.
- 3 Our specific focus here is on Table 3 in the original paper. We deviate from Richman (2011) in not estimating panel corrected standard errors, as this sort of ‘correction’ does not easily translate into a Bayesian framework, and we want to present a very simple example. The *brms* package we use does allow users to estimate models with autoregressive terms or other solutions to serial correlation in time and space.
- 4 To have the same sample in all our models, we delete three observations that have missing data on the lagged dependent variable.
- 5 The intricacies behind Hamiltonian Monte Carlo go beyond the scope of this chapter; for a more thorough introduction to Hamiltonian Monte Carlo, see Neal (2011) and Betancourt (2017).
- 6 Imagine, for instance, that we had conducted a large experiment with 12 different treatment arms. In this case, simply tossing all of the variables into a single regression would indeed be an appropriate way to test the effectiveness of each treatment. However, social scientists are rarely, if ever, blessed with explanatory variables where the effects are strictly linear and co-linearity is sufficiently low to allow for this approach to work.
- 7 This is not a function of the lagged dependent variable being included. Without the lagged dependent variable but with all other covariates included, the estimate of the pivotal-politics coefficient is  $-1.37$  and the 95% credible interval ranges from  $-1.87$  to  $-0.86$ .

- 8 The assumption that the *true* model is in the model space is not necessary for methods of model selection discussed later.
- 9 If these two models have equal prior distributions, the models are nested, and we estimate them via maximum likelihood, then Equation 4 simply reduces to a likelihood ratio statistic.
- 10 The  $k$  subscript on  $\theta$  allows that each model under consideration may have a different set of parameters.
- 11 Despite the name, notice that BIC is primarily useful for evaluating the model fit from the MLE in an asymptotic setting where priors are irrelevant. Further, the motivation and derivation for BIC differs significantly from the other ‘information criteria’ covered below.
- 12 Note that some texts and software packages may define BIC as the negative of how we have defined it.
- 13 More advanced approaches for estimating marginal model probabilities include the generalized Bayesian information criterion (Konishi et al., 2004), which allows for more informative priors.
- 14 See Hastie et al. (2016) for a fuller discussion of the problems of in-sample and out-of-sample model fit. See Kung (2014) and Bagozzi and Marchetti (2017) for recent applications of AIC for model selection.
- 15 See Kim et al. (2018) for a recent application of WAIC in political science.
- 16 In most literatures, this approach is referred to as ‘k-fold’ cross-validation. However, to avoid notational confusion with the model space, we do not adopt this language here.
- 17 Note that each competing model should be fit based on the same partitioning of the data.
- 18 In particular, the variance of the importance weights may be too large or infinite, since the denominator is not bounded away from zero.
- 19 Similarly, for models with spatial or temporal dependence, psis-loo-cv is likely to be problematic. Ongoing work is considering possible approaches for these cases.
- 20 For reasons of space, we confine ourselves here to finite mixture models with a known number of potential components. However, we note that there is also a large literature on Bayesian models that can relax or eliminate this assumption.
- 21 For large model spaces, several scholars have developed stochastic samplers that simultaneously estimate the model probabilities and model parameters (George and McCulloch, 1993).
- 22 We also place an improper prior on  $\sigma^2$  of  $\frac{1}{\sigma^2}$ .
- 23 See chapter 5 in Ando (2010) for a complete proof.
- 24 We suppress discussion of alternative scoring rules for simplicity.

25 This last variant is referred to as pseudo-BMA.

26 Interested readers may want to consult the original article, introducing stacking via psis-loo (Yao et al., 2018) and the full discussion appended to the article.

# Bayesian Modeling and Inference: A Postmodern Perspective

Jeff Gill and Simon Heuberger<sup>1</sup>

## INTRODUCTION

Bayesian methods and Bayesian inference are now ubiquitous in the social sciences, including political science and international relations. The reasons for this are numerous and include: a superior way to describe uncertainty, freedom from the deeply flawed Null Hypothesis Significance Testing paradigm, the ability to include previous information, more direct description of model features, and, most recently, statistical computing tools that make model computations easy. Yet this is not a static area in social science methodology, and new methodological developments are published at a rapid pace. The objective of this *Handbook* chapter is to describe basic Bayesian methods, chronicle the recent history of their application in political science and international relations, and then highlight important recent developments.

The key tenets of Bayesian inference are that all unknown quantities are assigned probability statements, these probability

statements are updated when new information (data) are observed, and the results are described distributionally. This does not sound like a radical departure from traditional statistical thinking, but it constitutes a different way of thinking about uncertainty that is strictly probability based, eschewing assumptions like an unending stream of independent and identically distributed (IID) data. Furthermore, this paradigm comes along with some historical and practical conventions:

- Overt and clear model assumptions.
- A rigorous way to make *probability* statements about the real quantities of theoretical interest.
- An ability to update these statements (i.e. learn) as new information is received.
- Systematic incorporation of *qualitative* knowledge on the subject of interest.
- Recognition that population quantities are changing over time rather than fixed immemorial.
- Straightforward assessment of both model quality and sensitivity to assumptions.
- Freedom from the flawed null hypothesis significance testing (NHST) paradigm.

These come mostly from a different intellectual path than more conventionally accepted procedures, including relentless criticism during a roughly 100-year period by giants of the field. For the purpose of this exposition we divide the history of Bayesian statistics, as just described, into three eras: classical, modern, and postmodern. Each of these is discussed with attention to issues relevant to social science research. Our objective is to provide a chapter that is both introductory and a summary of recent research trends.

## CLASSICAL BAYES

Bayes' Law was published in 1763, but the classical era of Bayesian statistical inference occupied the middle of the 20th century up until 1990. Much has been written about this time (Gelman and Shalizi, 2013, Strevens, 2006) but the defining hallmark was a sense of principled philosophical correctness combined with analytical frustration. That is, it was not particularly difficult to write logical and mathematical arguments that demonstrated the inferential, and general scientific, superiority of Bayesian inference over classical methods for real problems, but it was often hard to execute this process for real and pragmatic data problems. Practical work often took incremental and modest directions based on what was mathematically possible. So, one sees publications during this time that give 'recipes' for broad classes of models that one could adapt to their specific question and therefore get results. The key problem here was the common creation of Bayesian models where the final joint specification of the model could not be mathematically decomposed into constituent parts to create a standard regression table of results.

Our starting point is much earlier. Bayes' (1763) famous essay was published two years after his death. The paper's release was facilitated by his friend Richard Price rather than Bayes himself (both are now buried in Bunhill Cemetery in central London). A reverend and amateur mathematician, Bayes developed a probability theorem that relates the order of conditional probabilities. It turns out that Laplace (1774, 1781) was developing similar ideas on the continent but communication was not without problem at the time. Let  $A$  and  $B$  be two non-independent events. Basic probability laws tell us that the conditional probability of  $A$  given  $B$  is given by  $p(A|B) = \frac{p(A,B)}{p(B)}$ , with  $p(A, B)$  being the probability of  $A$  and  $B$  both occurring and  $p(B)$  the unconditional probability that the event  $B$  occurs. We thus obtain the probability of  $A$  conditioned on  $B$  happening from  $p(A|B)$ . Conditional probability can also be defined in the reversed order, with  $A$  happening before considering  $B$ , that is,  $p(B|A) = \frac{p(B,A)}{p(A)}$ .

The joint probability remains the same in both directions, meaning that  $p(A, B) = p(B, A)$ . Since  $p(A, B) = p(A|B)p(B)$ , we can thus surmise that  $p(A|B)p(B) = p(B|A)p(A)$  and by rearranging  $p(A|B) = \frac{p(A)}{p(B)} p(B|A)$ .

The statistical application of Bayes' Law begins with the definition of the likelihood function (Fisher, 1925a, Birnbaum, 1962), which is nothing more than the joint probability of the observed data. Define the collected data  $X$  that is observed once and therefore treated as a fixed quantity. We assume that we know the respective probability mass/density function for these data to accurately describe the data-generating process:  $p(X|\beta)$ , conditioned on some unknown parameter  $\beta$  to be estimated. This joint function is then defined by

$$L(\beta|X) = \prod_{i=1}^n p(X_i|\beta) = p(X_1|\beta) \times p(X_2|\beta) \times \dots \times p(X_n|\beta). \quad (1)$$

The switching of the order of conditionality in this statement is not an application of Bayes' Law, but is Fisher's (1925a) recognition that once the data are observed, they are fixed for inferential purposes, and it is the unknown parameter of interest that is the focus of inference at this point. This perspective differs dramatically from canonical Frequentist inference whereby there is an unending stream of independent and identically distributed data available to the researcher (Gill, 1999).

Fisher (1925b) and others provide the standard and convenient inferential treatment of the likelihood function, which is to find the multi dimension mode of this – usually log-concave to the  $x$ -axis – function and to treat curvature around this mode as a measure of uncertainty. These procedures are incredibly well-established and well-accepted and need not be reviewed here. See Gill and Torres (2019) for a recent detailed exposition.

The next required quantity for Bayesian inference is the *prior distribution*: the presumed distribution of the parameters of interest before the current data for analysis are collected and analyzed:  $p(\beta)$ . Notice that this is not conditioned on anything explicitly in its formulation. In truth it is conditioned on previous knowledge about the effect of interest that is symbolized by the parameter  $\beta$  in the regression context. So if the effect of interest is size of nations' militaries and the outcome of interest is the proclivity to wage militarized conflict, then we would typically notate the magnitude (regression coefficient) of the former as  $\beta$  and the vector outcomes as  $Y$ . The likelihood function,  $L(\beta|X)$ , is central to Bayesian methods because it enables the researcher to find a most probable value  $\hat{\beta}$  by testing differing values of  $\beta$ . The value  $\hat{\beta}$  is the most likely to have generated the data given  $H_0$  expressed through a specific parametric form relative to other possible values in the sample space of  $\beta$ . In this regard, the likelihood function resembles the inverse probability,  $p(H_0|X)$ , but as we will see, this clearly is not the socially desired

value that readers sometimes quest for but is not provided under this framework: the probability of the null hypothesis given some data. Crucially, however, the produced likelihood function from this setup now matters only in relation to other likelihood functions with differing values of  $\beta$  since it is no longer bounded by 0 and 1.

Bayesian inference combines data information in the likelihood function with researchers' prior information. This is done by conditioning the prior on the likelihood using Bayes' Law,

$$\pi(\beta|X) = \frac{p(\beta)}{p(X)} p(X|\beta), \quad (2)$$

which 'flips' the order of the conditional distribution by using the ratio of the prior to the unconditional distribution of the data. Now recall the Bayesian maxim that once a quantity is observed, it is treated as fixed. Here the data are assumed to be observed once and fixed in perpetuity for that given collection. Therefore, the probability of observing the observed data is simply one:  $p(X) = 1$ . This means that the denominator in (2) can be treated as simply a normalizing constant to ensure that  $\pi(\beta|X)$  sums or integrates to one and is therefore a normalized distribution. Since we can always recover this normalizing information later in the inferential process, it is customary and convenient to express (2) with proportionality:

$$\pi(\beta|X) \propto p(\beta)L(\beta|X). \quad (3)$$

Here we have also used the more intuitive form of the likelihood function, as described above. So it is common to say that the posterior is just proportional to the prior times the likelihood. So Bayesian inference is codified by a compromise between prior information and data information.

One source of discomfort for Bayesians during this era was the specification of prior distributions for unknown parameters. This is primarily because non-Bayesian scholars of the era criticized prior specification as

‘subjective’ since it came from sources outside of  $X$ , as determined by the researcher. There were many aspects of this view that were misguided. First, all modeling decisions, in all statistical settings, are subjective. It is subjective what data to use. It is subjective what likelihood function to specify (e.g. link function). It is subjective which estimation procedure to use. It is subjective what software to use. It is subjective how to present results, and so on. In addition, prior specifications are opportunities to include qualitative information, known earlier research on a question of interest, values to be updated over time, and more. Also, prior distributions can be constructed to have many different mathematical properties. Despite all of these facts, the specification of priors remains as a pointedly discussed issue well into the 21st century. We will return to this topic at several points over the course of this chapter.

The difficult classical period of Bayesian statistics produced different strains of prior forms for different purposes. Sometimes these were in competition and sometimes they overlapped. Importantly, the bulk of the 20th century was a period when Bayesians needed to be very circumspect in selecting and describing prior selection since non-Bayesians routinely used this as leverage for criticism. Zellner (1971: 18) divides prior distributions during this time into two types: *data-based* (DB) types that are ‘generated in a reasonably scientific manner and which are available for further analysis’, and *non-data-based* (NDB) types that ‘arise from introspection, casual observation, or theoretical considerations’. The critical problem faced by Bayesians of the classical era is that ‘one person’s NDB prior information can differ from that of another’s’ (Zellner, 1971: 19). However, this issue is not limited to NDB priors: ‘It is possible that two investigators working with the same model and DB prior information can arrive at different posterior beliefs if they base prior information on different bodies of past data’ (Zellner, 1971: 19). Thus, something as simple as a difference of

opinion on relevant prior information divided some Bayesians and left the door open for the classical ‘subjective’ criticism in prior selection.

In truth there was a defined set of principled prior approaches that emerged from this challenging era. Proper Bayes is the group most accurately described by Zellner above: those that constructed prior distributions from compiled evidence, such as earlier studies or published work, researcher intuition, or substantive experts. This is a rich literature that seeks to be build on existing scientific knowledge but emboldens the subjective criticism. Empirical Bayes uses the data not only in the likelihood function but also to estimate these hyperpriors values (parameters of prior distributions). This can be done with or without a specific distributional form at this level (parametric versus nonparametric empirical Bayes, see Morris, 1983). This approach offends some Bayesians because the data are used in both right-hand-side elements of (Equation 3). Lindley (in Copas, 1969: 421) accordingly observed that ‘there is no one less Bayesian than an empirical Bayesian’. Reference Bayes seeks priors that move the prior as little as possible from the likelihood function (Bernardo, 1979) – minimizing the distance between the chosen likelihood and the resulting posterior according to a criteria like the Kullback–Leibler distance, which comparatively measures distributions (this is also referred to as dominant likelihood prior). Note that the term ‘reference prior’ sometimes confusingly also refers to a prior that is used as a default (Box and Tiao, 1973: 23). Related to this approach, but different in purpose, are priors that seek to minimize any sense of subjective information: diffuse or uninformative priors such as parametric forms with large variance or uniform specification (bounded and unbounded). These were often specified because it reduced arguments with non-Bayesians and sometimes led to easily calculated results.

Continuous unbounded uniform priors were referred to as ‘improper’ since they did

not integrate to one over the real line, yet they generally yielded proper posteriors due to a cancellation in Bayes' Law. Consider an unbounded uniform prior for a regression parameter defined by  $p(\beta) = hf(\beta)$  over  $[-\infty:\infty]$ . This is essentially a rectangle of height  $hf(\beta)$  and width  $k = \infty$ . So, re-expressing Bayes' Law with this prior gives

$$\pi(\beta | X) = \frac{p(\beta)p(X | \beta)}{\int_{-\infty}^{\infty} p(\beta)p(X | \beta)d\beta}, \quad (4)$$

which is Equation (2) with the replacement

$$\begin{aligned} & \int_{-\infty}^{\infty} p(\beta)p(X | \beta)d\beta \\ &= \int_{-\infty}^{\infty} p(\beta, X)d\beta = p(X) \end{aligned} \quad (5)$$

by the definition of conditional probability and the process of integration for  $\beta$ , which is hypothetical to us in practical terms but exists in nature. Therefore, replacing the definition of the improper rectangular prior gives

$$\begin{aligned} \pi(\beta | X) &= \frac{(hf(\beta) \times k)p(X | \beta)}{\int_{-\infty}^{\infty} (hf(\beta) \times k)p(X | \beta)d\beta} \\ &= \frac{k}{k} \frac{hf(\beta)p(X | \beta)}{\int_{-\infty}^{\infty} hf(\beta)p(X | \beta)d\beta} \\ &\propto f(\beta)p(X | \beta), \end{aligned} \quad (6)$$

where the cancellation of  $k / k$  occurs because these are the exact same flavor of infinity, otherwise it is undefined. Thus, the posterior is proportional to the likelihood times some finite prior (the  $h$  values can also be canceled or left off due to proportionality). A similar prior for a variance component is  $p(\sigma) = 1/\sigma$  over  $[0: \infty]$ . Unfortunately, as mathematically tractable as improper priors are, they did not overwhelmingly convince Bayesian skeptics, some of whom considered it a form of arithmetic trickery.

This classification of classical priors presents the most common forms but is by no means exhaustive. Others include maximum entropy priors, mixtures priors, decision-theoretic priors, conjugate priors, and more (O'Hagan, 1994). Conjugate priors can be informed or diffuse and provide an especially nice choice since, for a given likelihood function, the parametric form of the prior flows down to the posterior giving simple calculations. In decision-theoretic Bayesian inference (Gill, 2014), results are presented in a full decision-theoretic framework where utility functions determine decision losses and risk, which are minimized according to different probabilistic criteria. These approaches were especially appealing in an age with limited computational tools.

### MODERN BAYES

An important hallmark of the classical era of Bayesian statistics was the relative ease with which a joint posterior distribution that could not be integrated into the constituent marginal distributions could be produced with actual social science data and a realistic model based on theoretical principles. Consider the following example that motivated the work in Gill and Waterman (2004) using the data collected by Mackenzie and Light (1987) on every US federal political appointee to full-time positions requiring Senate confirmation from November 1964 through to December 1984 (the collectors of the data needed to preserve anonymity so they embargoed some variables and randomly sampled 1,500 cases down to 512). This survey queries various aspects of the Senate confirmation process, acclamation to running an agency or program, and relationships with other functions of government. A key question is why these executives last only about two years on average after assuming the position, given the difficulty of the process. This work hypothesizes that running a federal agency (or sub agency) is

considerably more stressful than alternative positions for these executives. The outcome variable of interest is stress as a surrogate measure for self-perceived effectiveness and job satisfaction, measured as a five-point scale from ‘not stressful at all’ to ‘very stressful’. Explanatory variables specified for the model are: Government Experience, Ideology, Committee Relationship, Career.Exec-Compet, Career.Exec-Liaison/Bur, Career.Exec-Liaison/Cong, Career.Exec-Day2day, Career.Exec-Diff, Confirmation Preparation, Hours/Week, and President Orientation (Gill and Casella, 2009, for detailed descriptions). A Bayesian random effects specification for ordered survey outcomes is specified, so latent variable thresholds for  $Y$  are assumed to be on the ordering:

$$U_i : \theta_0 \underset{c=1}{\iff} \theta_1 \underset{c=2}{\iff} \theta_2 \underset{c=3}{\iff} \theta_3 \dots \theta_{C-1} \underset{c=C}{\iff} \theta_C.$$

The vector of (unseen) utilities across individuals in the sample,  $U$ , is determined by a linear additive specification of  $K$  explanatory variables:  $U = -X'\gamma + \epsilon$ , where  $\gamma = [\gamma_1, \gamma_2, \dots, \gamma_p]$  does not depend on the  $\theta_j$ , and  $\epsilon \sim F_\epsilon$ . This means that the probability that individual  $i$  in the sample is observed to be in category  $r$  or lower is

$$\begin{aligned} P(Y_i \leq r | X_i) &= P(U_i \leq \theta_r) \\ &= P(\epsilon \leq \theta_r + X_i'\gamma) \quad (7) \\ &= F_{\epsilon_i}(\theta_r + X_i'\gamma), \end{aligned}$$

which is differently signed than in R: ‘logit  $P(Y_i = k - x) = \text{zeta}_k - \text{eta}$ ’ from the help page (there is no fixed convention on the sign). Specifying a logistic distributional assumption on the errors and adding the random effect term produces this logistic cumulative specification for the whole sample:

$$\begin{aligned} F_\epsilon(\theta_r + X'\gamma) &= P(Y \leq r | X) \\ &= [1 + \exp(-\theta_r - X'\gamma)]^{-1}. \quad (8) \end{aligned}$$

Prior distributions are given to be either semi-informed or skeptical:

$$p(\gamma_k) \sim \mathcal{N}(\mu_{\gamma_k}, \sigma_{\gamma}^2), k = 1, \dots, k$$

for each of the  $K$  explanatory variables,

$$p(\theta_j) \sim \mathcal{N}(0, \sigma_{\theta}^2), j = 1, \dots, C - 1$$

for the four latent variable thresholds, with assigned hyperparameter values  $\mu_{\gamma_k}, \sigma_{\gamma}^2, \sigma_{\theta}^2$

All this produces a joint posterior distribution according to

$$\begin{aligned} \pi(\gamma, \theta | X, Y) &\propto L(\gamma, \theta | X, Y) p(\theta) p(\gamma) \\ &\propto \prod_{i=1}^n \prod_{j=1}^{C-1} \prod_{k=1}^p \left[ \Lambda(\theta_j - X_i'\gamma + b_i) - \Lambda(\theta_{j-1} - X_i'\gamma) \right]^{z_{ij}} \\ &\quad \times \exp \left( -\frac{(\gamma_k - \mu_{\gamma_k})^2}{2\sigma_{\gamma}^2} - \frac{\theta_j^2}{2\sigma_{\theta}^2} \right), \quad (9) \end{aligned}$$

which is kind of ugly (and hard to marginalize). While this form tells us everything we need to know about the *joint distribution* of the model parameters, we need to marginalize (integrate) it for every one of these parameters to create an informative regression table. That is, this is a joint probability statement like  $p(A, B, C)$  for arbitrary example random variables  $A, B$ , and  $C$ , and we need to create the marginal (solitary) probability statements for each. Continuing the contrived example for one of these, say  $A$ , we get  $P(A) = \iint_{CB} p(A, B, C) dBdC$  from elementary integral calculus. Using  $P(A)$ , we can get the mean and standard error to present as the first and second column of a regression table for  $A$  in the conventional way. The key point is that it was easy in the middle of the 20th century to produce a model such as this whereby it was prohibitively difficult or impossible to integrate-out each parameter for a series of marginal posterior distributions to describe inferentially. This led Evans

(1994) to retrospectively describe Bayesians of the time as ‘unmarried marriage guidance councilors’ because they could tell others how to do inference when they often could not do it themselves.

This world, and *the* world, changed in 1990 with a review essay by Gelfand and Smith in the *Journal of the American Statistical Association*. In what is without a doubt one of the ten most important articles published in statistics, they found that a tool, *Gibbs sampling*, hiding in engineering and image restoration (Geman and Geman, 1984), solved this very problem for the Bayesians. Gibbs sampling replaced analytical derivation of marginals from a joint distribution with work from the computer. In this algorithm, the full conditional distributions for each parameter to be estimated are expressed with the conditionality on the other parts of the model that are relevant for this parameter. Then the sampler draws consecutively at each step with the latest drawn versions of the conditioned parameters until the Markov chain reaches its stationary (converged) distribution and these conditional draws can then be treated as marginal samples. This means that the marginal distributions of interest from complicated model specifications can simply be described empirically from a large number of draws sampled by the computer. The date of 1990 is not just important for the publication of this article, but also because, by 1990, statisticians (and others) were free from centralized mainframe computing (with attendant punch cards, JCL, batch processing, and other encumbrances) via ubiquitous and reasonably powerful desktop machines. The popularity of bootstrapping in the 1980s presaged this development for the same computational reason.

The general name for the new tool is *Markov Chain Monte Carlo* (MCMC), which includes Gibbs sampling as well as the *Metropolis-Hastings algorithm* that was dormant in statistical physics but has existed since the 1953 paper by Metropolis et al. in

the *Journal of Chemical Physics* (as was the slightly sexist, somewhat quaint, custom of the time in some of the natural science fields, where their wives typed the paper and were added as coauthors). The principle behind MCMC is that a Markov chain can be setup to describe a high dimension posterior distribution by wandering around the state space visiting sub-regions in proportion to the density that needs to be summarized. The linkage between ‘MC’ and ‘MC’ is the *ergodic theorem* that says that if the Markov chain is created according to some specific technical criteria and is run long enough such that it converges to its stationary (limiting) distribution, the draws from the path of the chain can be treated as if they are IID from the respective marginal distributions. Thus, in the stationary distribution, each step is recorded as a multidimensional draw as if from a regular Monte Carlo process, even though these draws are actually produced from a serial, conditional Markovian algorithm. Robert and Casella (2004), Gill (2014), and Gamerman and Lopes (2006) provide the necessary theoretical background, and Robert and Casella (2011) give an entertaining history of this development in statistics during the early 1990s.

A convenient way to visualize how the MCMC process works practically is given in Figure 50.1, which shows the general data structure as produced by running the Markov chain for a model with five parameters to be estimated  $[\theta_1, \dots, \theta_5]$  over  $m = 1, \dots, M$  MCMC simulations after convergence is asserted. The arrow on the right indicates the direction of the production of simulated vectors. The serial Markovian process produces one row at a time that is conditional on previous rows. Thus, row  $I_1$  is followed by row  $I_2$  on up to row  $I_{499999}$  and row  $I_{500000}$  (the second half of the full chain run of 1 million iterations) as the chain explores the six-dimensional space (five parameters plus posterior density). Each row is a sample, and the ergodic theorem states that under specific circumstances (met in practice with standard

**Figure 50.1** How Markov Chain Monte Carlo works

algorithms) in the converged state, each of these rows can be treated like an independent multidimensional draw from the posterior of interest produced by the Bayesian regression model. Inference is now produced by analyzing down columns for each parameter. From the ergodic theorem we can take the column vector, for say  $\theta_1$ , and summaries for this parameter are performed by simply applying means, variances, quantiles, etc. on the draws down the first column in this case. Thus the ‘MC’ (Markov chain) that produces the rows is later ignored and the second ‘MC’ (Monte Carlo) is used to get inferences.

To say that MCMC revolutionized Bayesian inference and general Bayesian work is to say that commercial air flights slightly improved global travel. It was in fact the tool that freed the Bayesians; no longer were models too complex for the marginalization of joint posteriors to create regression tables and other intuitive summaries. The result was a flood of Bayesian applications that were pent-up in researchers’ file drawers giving a Bayesian perspective to a wide swath of model types and general statistical approaches. What got relatively left behind in this revolution was introspection about the choice of priors. Actually, prior choice was sublimated down to diffuse normals, uniforms, and other vague forms since the focus had turned to issues of estimation: the 1990s saw an explosion of customized MCMC procedures, calculations of quantities of

interest from posterior samples (Chib, 1995; Chib and Jeliazkov, 2001), and a deeper understanding of Markov chain theoretical principles (Gilks et al., 1996; Polson, 1996; Roberts and Tweedie, 1996; Brooks et al., 1997; Roberts and Rosenthal, 1998; Brooks and Roberts, 1999; Robert and Mengersen, 1999; Neal, 2003). In the social sciences, applied Bayesian researchers defaulted almost exclusively to these diffuse forms and thus became *Bayesians of convenience* in the theoretical sense since prior informative was routinely ignored.

Returning to the example of political executives in the US government, Gill and Waterman (2004) used a Gibbs sampler (implemented in the BUGS language) to marginalize the model described in (Equation 9), running the chain for 1,000,000 iterations and disposing of the first 500,000 to feel assured that the chain was exploring its stationary distribution during the second period (a standard set of empirical and graphical diagnostics were used as well). The results are summarized in Table 50.1.

Notice in Table 50.1 that the results are given in terms of posterior quantiles only. For a traditional view of these results, readers can look at the posterior median (0.5) and the 95% credible interval ([0.025:0.975]) for each parameter estimated, as shown in the lighter grey columns, but many Bayesians prefer the more detailed descriptive view of the more posterior distributions given here, which incorporates all columns along with associated general probability statements. So, for instance, we can say that with President Orientation there is a 97.5% probability that this effect is above 0.2462, even if a 98% credible interval ([0.01:0.99]) covers zero. Bayesians tend not to be fixated with arbitrary thresholds, however. It is not directly in the table but from the sorted MCMC values for this parameter, we can see that there is only a 1.2% probability that this effect is negative. Increased levels of Committee Relationship are reliably associated with increased stress from these

results since all of the observed posterior quantiles are positive for this coefficient. This is a somewhat paradoxical finding but may be attributed to a closer relationship with the relevant oversight committee that is not voluntary but mandated by congressional concern over agency policies. We see another reliable but subtle positive relationship between *Career.Exec-Compet* and stress since the 95% credible interval is bounded away from zero. This may be because underlings challenge political executives' decisions or because, as career public servants, they know the agency and its mission or history better. There are other statistically reliable findings here as well. These statements are very Bayesian in that we are describing regions of the marginal posterior space for this variable in strictly probabilistic terms. There is no notion of confidence or p-values required. In fact, when people misinterpret standard statistical inference, it is often the Bayesian interpretation, such as we have done here, that is desired.

The modern Bayes era was typified with the ease of production of standard models

with standard assumptions that were beyond the abilities of Bayesians in the classical era. One after another, complex regression style models – including item response theory (IRT), multinomial probit, complex hierarchical forms, causal specifications, and more – were simply solved. Thus, the 1990s into the 2000s saw article after article in statistics as well as methodological social sciences that used MCMC tools to estimate increasingly intricate models from increasingly complex theories, all from a Bayesian perspective.

## POSTMODERN BAYES

It gradually became apparent that the MCMC revolution was about more than just estimating models that had frustrated Bayesians of the previous generation. It turns out that estimation with Bayesian stochastic simulations (MCMC) provides opportunities to extend modeling and to produce quantities of interest beyond regular posterior inference. So, if the modern Bayesian era is

characterized by freedom to estimate pent-up models from 100 years of frustration, then the postmodern Bayesian era is defined by a realization that Bayesian stochastic simulation does not just *allow* estimation (marginalization) of previously inestimable models, it also (almost inadvertently) gives additional inferential information that can be exploited for enhanced purposes. The underlying point is that empirical description, rather than just analytical math-stat description, of posterior parameters of interest gives distributional information that can be used for other purposes such as model checking, model comparison, and enhanced specifications. This section provides a sense of these new tools through several described examples.

**Poster Predictive Checks**

A very useful way to judge model quality is the posterior predictive check, an approach that compares fabricated data implied by the model fit to the actual outcome data. The general idea is that, if the predictions closely resemble the truth, then the model is fitting well. In addition, deviations from an ideal fit are often informative about where the model could fit better in terms of direction or category. In the most basic form, we are simply comparing (usually plotting) the  $y_i, \dots, y_n$  outcome values from the data with the  $\hat{y}_i, \dots, \hat{y}_n$  values produced from the model. In the case of a linear model, this is incredibly simple in the Bayesian or non-Bayesian context as  $\hat{y} = X\hat{\beta}$ , but with more complex specifications, it may require more involved calculations. In the non-Bayesian sense, or in the simplified Bayesian sense, we can often analytically calculate  $\hat{y}_i$  values and, importantly, measures of uncertainty for these values that allow us to measure or plot accuracy.

As it turns out, it is an ancillary benefit of the MCMC process that it is not only easy to calculate these posterior predictive values for the outcome variable, but it is also almost ‘free’ to get measures of uncertainty since

the empirical distributional descriptions of the estimated model parameters can be made to flow through to the predicted quantities. More specifically, for  $K$  explanatory variables (including a constant if appropriate) define  $\beta^{(s)} = \beta_{k=1, \dots, K, s=1, \dots, n_{sim}}$  for  $n_{sim}$  (a large) number of MCMC iterations collected after the assertion of convergence. In a fairly general sense, this lets us produce  $\hat{y}^{(s)} = f(X, y, \beta^{(s)})$  values from the Bayesian model specification (including prior distributions), giving  $n_{sim}$  values from the full distribution of the poster predicted values.

Returning to the public executives data from Gill and Waterman (2004), subsample  $n_{sample} = 10,000$  values from the total post convergence MCMC runs to create  $\bar{\beta}^{(s)}$  for the regression parameters and set  $\bar{\theta} = (\theta_{r=1}, \dots, \theta_{r=5})$  as the mean of the thresholds parameters across all of the 500,000 saved MCMC runs (although we can also make this component stochastic if desired). The first, and most elementary, summary uses the mean of the data vector  $\bar{X}$  to create an archetypal simplified data case (e.g. the mean taken down columns of the  $K$  explanatory variable matrix). Define first  $\bar{\mu} = \bar{X}\bar{\beta}^{(s)}$  temporarily averaging the simulated coefficient values, then for the ordered logit specification we create the cumulative and marginal outcome probabilities according to

$$\begin{aligned}
 P_{cumulative}(y \leq r) &= \left[ 1 + \exp(-\bar{\theta}_r - \bar{\mu}) \right]^{-1} \\
 r &= 1, \dots, 5 \\
 P_{marginal}(y = r) &= P_{cumulative}(y \leq r) - P_{cumulative}(y \leq r-1) \\
 &= P_{cumulative}(y \leq r), \quad r = 2, \dots, 4 \\
 P_{marginal}(y = 1) &= P_{cumulative}(y = 1) \\
 P_{marginal}(y = 5) &= 1 - P_{cumulative}(y \leq 4).
 \end{aligned}
 \tag{10}$$

This is illustrated in Figure 50.2 showing the outcome values and the threshold values. Thus, we have five ordered categorical probabilities averaged across cases and averaged across simulated estimations given by [0.0001, 0.0019, 0.0865, 0.9040, 0.0075]. This compares somewhat unfavorably to the

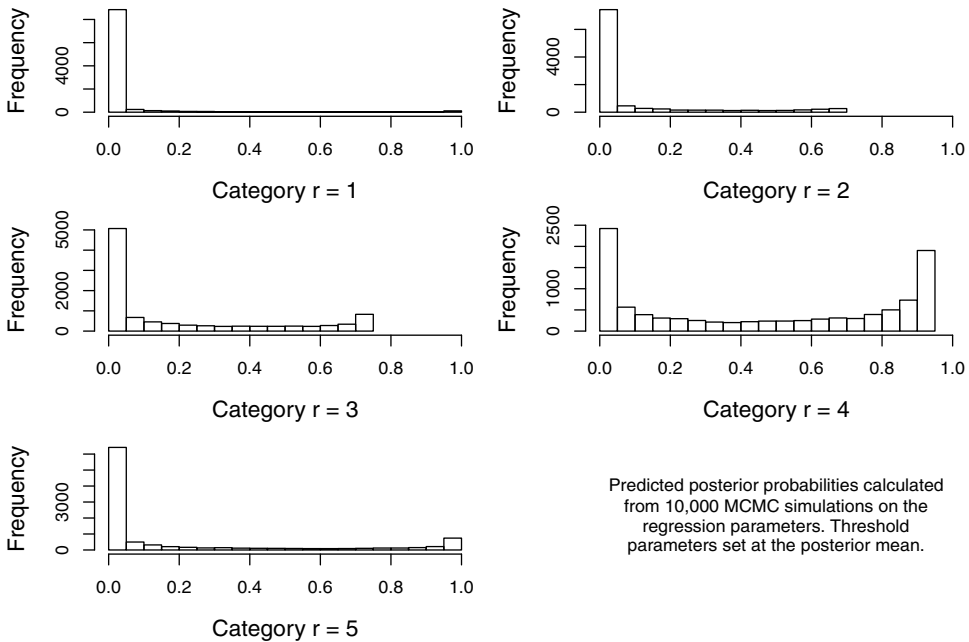

**Figure 50.2 Categories illustration**

distribution of actual outcomes in the  $n = 512$  size data: [51, 54, 96, 200, 131].

Now suppose we keep the mean vector of the data values but replace the mean of the MCMC parameter draws with the  $n_{sample} = 10,000$ . This is done exactly as just described, where (10) is done 10,000 separate times with 10,000 MCMC sub draws producing a  $(10,000 \times 5)$  matrix of probability vectors by row. From this we gain the measure of uncertainty on the parameter estimates that is provided by draws from the posterior distributions through the MCMC process. The result of this process is 10,000 draws

describing the unconditional probabilities for the complete sample of 512 individuals (averaged) for each of  $P_{marginal}(y) r = 1, \dots, 5$ . These are summarized in Figure 50.3. Notice that the marginal probabilities differ substantially across each category with interesting bunching at extremes in some categories reflecting strong covariate information that flows through these predictions.

This analysis provides useful information, but it is still an incomplete picture because variance across the 512 cases is still suppressed (averaged over). To unlock this added level of uncertainty, we make further use of the MCMC draws using the same procedure as done with the average person case but now expand the data structures to let the posterior variability in the estimation process flow down to individual level predictions that include individual level covariate differences. This is literally done in a loop in the code whereby each of the 512 cases is predicted instead of a mean case done at first above. Figure 50.4 shows a random selection of

**Figure 50.3 Posterior predictive probabilities by ordered outcomes**

**Figure 50.4 Posterior predictive probabilities by outcome categories**

10,000 of the 500,000 MCMC draws again (more can be done but it crowds the figure), where the resulting  $\hat{y}$  posterior predicted value is plotted against the  $y$  value for each of the 512 data cases, where each are jittered (the addition of random noise) to slightly separate cases visually for such categorical data. What we see here is a pretty good fit to the data whereby many of the cross-plotted points are on the main diagonal of the plot where  $y$  and  $\hat{y}$  take on the same values. What we also see is a slight underestimation for cases where the true observed values are in categories 4 and 5. This could not be shown without letting the full uncertainty flow down to the individual predictions, showing the usefulness of the distributional information from the MCMC simulations.

The point of this subsection is that the assessment of model quality through prediction is straightforward (easy actually) with MCMC output because the parameter estimation comes from a large number of draws from the posterior distribution of these parameters. Thus, each of these draws from the underlying Bayesian distributions of the model can be ‘flowed’ through to quantities of interest like outcome predictions with the uncertainty preserved through the empirical draws. Therefore, the MCMC process actually makes this process easier since complex mathematical-statistics analytical calculations are completely unneeded now, including

lengthy derivations, transformations, use of the delta method, and more.

### Hamiltonian Monte Carlo

Hamiltonian Monte Carlo (or analogously Hybrid Monte Carlo; henceforth HMC) is a modification of the standard Metropolis–Hastings algorithm that uses ‘physical system dynamics’ as a means of generating candidate values for a Metropolis decision to move to a new point in the state space. The Metropolis–Hastings algorithm (Metropolis et al., 1953) is a Markovian accept-reject procedure that moves through the multidimensional space of interest. The basic Metropolis–Hastings algorithm for a single selected parameter vector starts with a  $J$ -length parameter vector,  $\theta \in \Theta^J$ , to empirically describe target distribution of interest,  $\pi(\theta)$ , by ‘visiting’ substates proportionally to the density of interest. At the  $t^{th}$  step of the Markov chain ( $t$  stands for time), the chain is at the position indicated by the vector  $\theta^{[t]}$ . We then draw  $\theta'$  from a distribution over the same support, from a *proposal distribution* denoted  $q_t(\theta'|\theta)$ . This function must be ‘reversible’, meaning that  $\pi(\theta)p(\theta, \theta') = \pi(\theta')p(\theta', \theta) \forall \theta, \theta'$  in order to pick from a wide range of non-symmetric forms, where  $p(\cdot)$  is the *actual transaction function* – the probability of generating a candidate *and* accepting it – and  $\pi(\cdot)$  is the target density. We then decide to move with probability

$$\min \left[ \frac{\pi(\theta') q(\theta|\theta')}{\pi(\theta) q(\theta'|\theta)}, 1 \right]. \tag{11}$$

Importantly, rejecting  $\theta'$  means moving to  $\theta$  (the current position) as the new position in the time series of samples. An important feature of the algorithm is the flexibility of the choice of the proposal distribution. Many variations are based on strategic choices for this distribution. For example, the Hit and Run algorithm (Chen and Schmeiser, 1993)

separates the direction and distance decision in the proposal so that it can be optimized for highly constrained posterior structures and the algorithm does not reject a large number of candidate destinations.

The HMC algorithm exploits flexibility in the choice of candidate distribution by incorporating information about posterior topography to traverse the sample space more efficiently. Topography in this sense means the curvature of the target distribution, which is easy for humans to visualize in three dimensions and impossible for humans to see in the 8–12 dimensions that political science models often specify. The basic idea predates the modern advent of MCMC from Duane et al. (1987) and was developed in detail by Neal (1993, 2011).

Like the original Metropolis (1953) algorithm, Hamiltonian Monte Carlo comes from physics (Meyer, Hall and Offin 1992). Here we are concerned with an object’s trajectory within a specified multidimensional system as a way to describe joint posterior distributions. Now define  $\vartheta_t$  as a  $k$ -dimensional location vector and  $\mathbf{p}_t$  as a  $k$ -dimensional momentum (e.g. mass times velocity) vector, both recorded at time  $t$ . The Hamiltonian system at time  $t$  with  $2k$  dimensions is given by the joint Hamiltonian function

$$H(\vartheta_t, \mathbf{p}_t) = U(\vartheta_t) + K(\mathbf{p}_t), \quad (12)$$

where  $U(\vartheta_t)$  is the function describing the *potential energy* at the point  $\vartheta_t$ , and  $K(\mathbf{p}_t)$  is the function describing the *kinetic energy* for momentum  $\mathbf{p}_t$ . Neal (2011) gives the simple one-dimensional example

$$U(\vartheta_t) = \frac{\vartheta_t^2}{2} \quad K(\mathbf{p}_t) = \frac{p_t^2}{2}, \quad (13)$$

which is equivalent to a standard normal distribution for  $\vartheta$ . Commonly, the kinetic energy function is defined as

$$K(\mathbf{p}_t) = \mathbf{p}_t' \Sigma^{-1} \mathbf{p}_t, \quad (14)$$

where  $\Sigma$  is a symmetric and positive-definite matrix that can be as simple as an identity matrix times some scalar that can serve the role of a variance:  $\Sigma = \sigma^2 \mathbf{I}$ . This simple form is equivalent to the log PDF of the multivariate normal with mean vector zero and variance-covariance matrix  $\Sigma$ .

Hamiltonian dynamics describe the gradient-based way that potential energy changes to kinetic energy and kinetic energy changes to potential energy as the object moves over time throughout the system (multiple objects require equations for gravity, but that is fortunately not our concern here). The mechanics of this process are given by Hamilton’s equations, which are the set of simple differential equations

$$\begin{aligned} \frac{\partial \vartheta_{it}}{\partial t} &= \frac{\partial H}{\partial \mathbf{p}_{it}} = \frac{K(\partial \mathbf{p}_{it})}{\partial \mathbf{p}_{it}} \\ \frac{\partial \mathbf{p}_{it}}{\partial t} &= -\frac{\partial H}{\partial \vartheta_{it}} = -\frac{U(\partial \vartheta_{it})}{\partial \vartheta_{it}} \end{aligned} \quad (15)$$

for dimension  $i$  at time  $t$ . For continuously measured times these equations give a mapping from time  $t$  to time  $t + \tau$ , meaning that from some position  $\vartheta_t$  and momentum  $\mathbf{p}_t$  at time  $t$  we can predict  $\vartheta_\tau$  and  $\mathbf{p}_\tau$ . Returning to the one-dimensional standard normal case, these equations are simply  $d\vartheta_t/dt = p$  and  $dp/dt = -\vartheta$ .

There are three important properties of Hamiltonian dynamics that are actually *required* if we are going to use them to construct an MCMC algorithm (Neal, 2011). First, Hamiltonian dynamics is *reversible*, meaning that the mapping from  $(\vartheta_t, \mathbf{p}_t)$  to  $(\vartheta_{t+\tau}, \mathbf{p}_{t+\tau})$  is one-to-one and therefore also defines the reverse mapping from  $(\vartheta_{t+\tau}, \mathbf{p}_{t+\tau})$  to  $(\vartheta_t, \mathbf{p}_t)$ . Second, *total* energy is conserved over time  $t$  and dimension  $k$ , and the Hamiltonian is invariant, as shown by

$$\begin{aligned} \frac{\partial H}{\partial t} &= \sum_{i=1}^k \left[ \frac{\partial \vartheta_i}{\partial t} \frac{\partial H}{\partial \vartheta_i} + \frac{\partial \mathbf{p}_i}{\partial t} \frac{\partial H}{\partial \mathbf{p}_i} \right] \\ &= \sum_{i=1}^k \left[ \frac{\partial H}{\partial \mathbf{p}_i} \frac{\partial H}{\partial \vartheta_i} - \frac{\partial H}{\partial \vartheta_i} \frac{\partial H}{\partial \mathbf{p}_i} \right] = 0. \end{aligned} \quad (16)$$

This provides detailed balance (reversibility) for the MCMC algorithm. Second, Hamiltonian dynamics preserve volume in the  $2k$  dimensional space. In other words, elongating some region in a direction requires withdrawing another region as the process continues over time. This ensures that there is no change in the scale of Metropolis–Hastings acceptance probability. Finally, Hamiltonian dynamics provides a *symplectic mapping* in  $\mathcal{R}^{2k}$  space. Define first the smooth mapping  $\psi : \mathcal{R}^{2k} \rightarrow \mathcal{R}^{2k}$  with respect to some constant and invertible matrix  $\mathbf{J}$  with  $\mathbf{J}' = -\mathbf{J}$  and  $\det(\mathbf{J}) \neq 0$ , along with having Jacobian  $\psi(z)$  for some  $z \in \mathcal{R}^{2k}$ . The mapping  $\psi$  is symplectic if

$$\psi(z)' \mathbf{J}^{-1} \psi(z) = \mathbf{J}^{-1}. \tag{17}$$

Leimkuhler and Reich (2005: 53) give the following mapping in 2-dimensional space  $z = (\vartheta, p)$ :

$$\psi(\vartheta, p) = \begin{bmatrix} p \\ 1 + b\vartheta + ap^2 \end{bmatrix}, \tag{18}$$

with constants  $a, b \neq 0$ . The Jacobian of  $\psi(\vartheta, p)$  is calculated by

$$\frac{\partial}{\partial \vartheta} \frac{\partial}{\partial p} \psi(\vartheta, p) = \begin{bmatrix} 0 & 1 \\ b & 2ap \end{bmatrix}. \tag{19}$$

We check symplecticness by

$$\begin{aligned} & \left[ \frac{\partial}{\partial \vartheta} \frac{\partial}{\partial p} \psi(\vartheta, p) \right]' \mathbf{J}^{-1} \left[ \frac{\partial}{\partial \vartheta} \frac{\partial}{\partial p} \psi(\vartheta, p) \right] \\ &= \begin{bmatrix} 0 & 1 \\ b & 2ap \end{bmatrix}' \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} 0 & 1 \\ b & 2ap \end{bmatrix} \tag{20} \\ &= -b\mathbf{J}^{-1}. \end{aligned}$$

Thus we say that  $\psi(\vartheta, p)$  is symplectic for  $b = -1$  and any  $a \neq 0$ .

Everything discussed so far assumed continuous time, but obviously for a computer implementation in a Markov chain Monte

Carlo context, we need to discretize time. Thus, we will grid  $t + \tau$  time into intervals of size  $v$ :  $v, 2v, 3v, \dots, mv$ . We need a way to obtain this discretization while preserving volume, and so we use a tool called the *leapfrog methods*. The notation is more clear if we now move  $t$  from the subscript to functional notation:  $\vartheta(t)$  and  $p(t)$ , which is also a reminder that time is now discrete rather than continuous. To complete a single step starting at time  $t$ , first update each of the momentum dimensions by  $v/2$  with the following:

$$p_i \left( t + \frac{v}{2} \right) = p_i(t) - \frac{v}{2} \frac{\partial U(\vartheta_t)}{\partial \vartheta_i(t)}. \tag{21}$$

Now take a full  $v$ -length step to update each of the position dimensions to leapfrog over the momentum:

$$\vartheta_i(t+v) = \vartheta_i(t) + v \frac{\partial K(p_i)}{\partial p_i \left( t + \frac{v}{2} \right)}. \tag{22}$$

Then finish with the momentum catching up in time with the step:

$$p_i(t+v) = p_i \left( t + \frac{v}{2} \right) - \frac{v}{2} \frac{U(\vartheta_t)}{\partial \vartheta_i(t+v)}. \tag{23}$$

Notice that the leapfrog method is reversible since it is a one-to-one mapping from  $t$  to  $t+v$ . Obviously, running these steps  $M$  times completes the Hamiltonian dynamics for  $M \times v$  periods of total time. The determination of  $v$  is a key tuning parameter in the algorithm since smaller values give a closer estimation to continuous time but also add more steps to the algorithm.

A Metropolis–Hastings algorithm is configured such that the Hamiltonian function serves as the candidate-generating distribution. This requires connecting the regular posterior density function,  $\pi(\theta)$ , to a potential energy function,  $U(\vartheta_t)$ , where a kinetic energy function,  $K(p_i)$ , serves as a (multidimensional and necessary) auxiliary variable. This connection is done via the

canonical distribution commonly used in physics,

$$p(x) = \frac{1}{Z} \exp\left[-\frac{E(x)}{T}\right], \quad (24)$$

where  $E(x)$  is the energy function of some system at state  $x$ ,  $T$  is the temperature of the system (which can simply be set at 1), and  $Z$  is just a normalizing constant so that  $p(x)$  is a regular density function. In the Hamiltonian context (Equation 24) is

$$\begin{aligned} p(\vartheta, \mathbf{p}) &= \frac{1}{Z} \exp\left[-\frac{H(\vartheta, \mathbf{p})}{T}\right] \\ &= \frac{1}{Z} \exp\left[-\frac{U(\vartheta_t) + K(\mathbf{p}_t)}{T}\right] \\ &= \frac{1}{Z} \exp\left[-\frac{U(\vartheta_t)}{T}\right] \exp\left[-\frac{K(\mathbf{p}_t)}{T}\right], \end{aligned} \quad (25)$$

demonstrating that  $\vartheta$  and  $\mathbf{p}$  are independent. Finally, we connect the energy function metric with the regular posterior density metric with the function

$$E(\vartheta) = -\log(\pi(\vartheta)), \quad (26)$$

thus completing the connection. Notice that the  $\theta$  variables must all be continuous in the model, although Hamiltonian Monte Carlo can be combined with other MCMC strategies in a hybrid algorithm.

The Hamiltonian Monte Carlo algorithm uses two general steps at time  $t$ :

- Generate, independent of the current  $\vartheta_t$ , the momentum  $\mathbf{p}_t$  from the multivariate normal distribution implied by  $K(\mathbf{p}_t) = \mathbf{p}_t' \Sigma^{-1} \mathbf{p}_t$  with mean vector zero and variance-covariance matrix  $\sigma^2 I$  (or some other desired symmetric and positive-definite form).
- Run the leapfrog method  $M$  times with  $\nu$  steps to produce the candidate  $(\tilde{\vartheta}, \tilde{\mathbf{p}})$ .
- Accept this new location or accept the current location as the  $t + 1$  step with a standard Metropolis decision using the  $H$  function

$$\min\left[1, \exp(-H((\tilde{\vartheta}, \tilde{\mathbf{p}})) + H(\vartheta, \mathbf{p}))\right]. \quad (27)$$

While this process looks simple, there are several complications to consider. We must be able to take the partial derivatives of the log-posterior distribution, which might be hard. The chosen values of the leapfrog parameters,  $M$  and  $\nu$ , are also critical. If  $\nu$  is too small then exploration of the posterior density will be very gradual with small steps, and if  $\nu$  is too big then many candidates will be rejected. Choosing  $M$  is important because this parameter allows the Hamiltonian process to explore strategically with respect to gradients. Excessively large values of  $M$  increase compute time, but excessively small values of  $M$  lead to many rejected candidates. In both cases where the parameters are too small, we lose the advantages of the gradient calculations and produce an inefficient random walk. Finally,  $\sigma^2$  affects efficiency of the algorithm in the conventional sense of appropriating tuning the variance of the multivariate normal for the momentum. These can be difficult parameter decisions and Neal (2011) gives specific guidance on trial runs and analysis of the results. The Hamiltonian Monte Carlo dynamics are difficult to implement in complex multilevel generalized linear models that aim to apply full Bayesian inference. While these models can be carried out with BUGS or JAGS, this takes an enormous amount of time and computational resources. To circumvent this, a group of academics, among them Andrew Gelman and Bob Carpenter, developed STAN. STAN is written in C++ and, unlike BUGS and JAGS, employs reverse-mode algorithmic differentiation to implement HMC in a much faster way. It supports a range of functions (e.g. probability functions, log gamma, inverse logit) and integrates matrix operations on linear algebra. See <https://mc-stan.org/> for details and downloads.

### Bayes Factor Calculations

Another example where MCMC output makes mathematical calculations much easier is the calculation of the Bayes Factor

for non-linear regression models. This also follows the principle that MCMC simulation provides a natural distributional summary that can be used for multiple purposes besides the original purpose of simply producing marginal distributions from a complicated joint distribution from the Bayesian model specification. In the classical era, it was recognized that Bayes Factors were an extremely useful model assessment and comparison tool going back to Jeffreys (1983), but they were often very difficult to calculate for realistic regression-style models.

Bayes Factors start with observed data  $x$  for testing two models, with associated parameter vectors  $\theta_1$  and  $\theta_2$ :  $M_1: f_1(x|\theta_1)$   $M_2: f_2(x|\theta_2)$ . Here these parameter vectors can define nested or non-nested alternatives, unlike the more simple likelihood ratio test. With prior distributions,  $p_1(\theta_1)$  and  $p_2(\theta_2)$ , and prior probabilities on the two models,  $p(M_1)$   $p(M_2)$ , we can produce the odds ratio for Model 1 versus Model 2 by Bayes' Law:

$$\frac{\pi(M_1 | x)}{\pi(M_2 | x)} = \frac{p(M_1) / p(x)}{p(M_2) / p(x)} \times \frac{\int_{\theta_1} f_1(x | \theta_1) p_1(\theta_1) d\theta_1}{\int_{\theta_2} f_2(x | \theta_2) p_2(\theta_2) d\theta_2} \tag{28}$$

Bayes Factor

So, we are actually interested in the ratio of marginal likelihoods – (Equation 5) from the two models. By canceling and algebraically rearranging, we get the common form of the Bayes Factor:

$$BF_{(1,2)} = \frac{\pi(M_1 | x) / p(M_1)}{\pi(M_2 | x) / p(M_2)} \tag{29}$$

(Gill, 2014). As suggested by these forms, analytical calculation for reasonably realistic social science regression models can be challenging. Fortunately, this is direct and easy for most Bayesian generalized linear

models estimated with MCMC. Chib (1995) and Chib and Jeliazkov (2001), for instance, give a handy and generalizable recipe in the context of probit regression models. To begin, rearrange (Equation 4) and take logs for a single model (for the moment) using the log-likelihood:

$$\log p(x) = \ell(\theta' | x) + \log p(\theta') - \log \pi(\theta' | x). \tag{30}$$

Here  $\theta'$  is a completely arbitrary point in the appropriate sample space, such as a point in the high density region, for instance the posterior mean. To start, we use  $\pi(\theta' | x)$  from simulation for a generic MCMC estimation approach (details in Chapter 14 of Gill, 2014). Define the probability of the Metropolis–Hastings Markov chain as transitioning to an arbitrary point  $\theta'$  from a starting point  $\theta$  with the candidate-generating distribution that produces  $\theta'$  times the probability that it is accepted from above:

$$\alpha(\theta', \theta) = \min \left[ \frac{\pi(\theta') q_r(\theta | \theta')}{\pi(\theta) q_t(\theta' | \theta)}, 1 \right]. \tag{31}$$

This candidate-generating distribution produces  $\theta'$  times the probability that it is accepted from above:  $p(\theta, \theta') = q(\theta' | \theta) \alpha(\theta', \theta)$ , such that for any arbitrary point detailed balance is preserved,  $\pi(\theta) q(\theta' | \theta) \alpha(\theta', \theta) = \pi(\theta') q(\theta | \theta') \alpha(\theta, \theta')$ . Now take integrals of both sides with respect to  $\theta$ , realizing that  $\pi(\theta')$  is a function evaluation at an arbitrary point and can therefore be moved outside of the integration process, and, with some algebra, reach

$$\pi(\theta') = \frac{\int \Theta \pi(\theta) q(\theta' | \theta) \alpha(\theta', \theta) d\theta}{\int_{\Theta} q(\theta | \theta') \alpha(\theta, \theta') d\theta} = \frac{E_{\pi(\theta)} [q(\theta' | \theta) \alpha(\theta', \theta)]}{E_{q(\theta|\theta')} [\alpha(\theta, \theta')]} \tag{32}$$

which is simply the ratio of two expected value calculations: Chib and Jeliazkov (2001) observed that in the course of running an MCMC estimation process for marginal posterior distributions, we can get the marginal likelihood without extra trouble replacing (Equation 32) with its simulation version,

$$\pi_{sim}(\theta') = \frac{\frac{1}{M} \sum_{m=1}^M \alpha(\theta', \theta_m) q(\theta' | \theta_m)}{\frac{1}{N} \sum_{n=1}^N \alpha(\theta_N, \theta')}, \quad (33)$$

which uses known quantities readily at hand for some number of simulations  $M$ . Here  $\theta'$  is chosen arbitrarily but within a high-density region of the posterior distribution. Therefore, this process substitutes a challenging integration process with simulation of the posterior density at a single point by completing (Equation 30) with the simulated result

$$\log p_{sim}(\mathbf{x}) = \ell(\theta' | \mathbf{x}) + \log p(\theta') - \log \pi_{sim}(\theta' | \mathbf{x}), \quad (34)$$

where all of these quantities are easily available.

**Bayesian Nonparametrics**

We are concerned in this section with how *nonparametric priors* can enhance the increasing use of Bayesian models for the presence of unobserved heterogeneity, which is a common problem across the social sciences. Researchers commonly deal with the problem by specifying non-unique random effect terms  $\psi_j, j \in J < n$  to capture grouping or clustering information where the mapping from  $i = 1, \dots, n$  to  $j = 1, \dots, J$  is known.

Generally, the distribution of the  $\psi_i$  is unknown but safely assumed through custom or testing. The normal distribution is a useful default for both practical and asymptotic reasons. This convenience cannot be directly

tested through residuals analysis but affects overall model fit, which can be tested. In the Bayesian setting, a better and more flexible alternative exists as a so-called nonparametric Bayesian prior in which  $\psi_j$  is drawn from a vastly more flexible distributional setup, starting with

$$\begin{aligned} (Y_1, \dots, Y_n) &\sim f(y_1, \dots, y_n | \beta, \psi_1, \dots, \psi_n) \\ &= \prod_i f(y_i | \beta, \psi_i), \quad \psi_i \sim G, \quad i = 1, \dots, n, \end{aligned} \quad (35)$$

where  $f$  can be taken as normal and where a popular choice for  $G$  is the Dirichlet Process (DP),

$$\psi_i \sim G \sim \mathcal{DP}(\lambda, \phi_0), \quad i = 1, \dots, n, \quad (36)$$

with base measure  $\phi_0$  and precision parameter  $\lambda$ . In particular, the observations are modeled as

$$Y_i = X_i \beta + \psi_i + \epsilon_i, \quad (37)$$

where the  $\epsilon_i$  are treated as independent normal random variables and  $\psi_i$  indicates the random effects assignment for the  $i$ th case. Alternatively, specification of a link function turns this into a generalized linear model (GLM) in the classic sense,  $\hat{Y}_i = g^{-1}(X_i \beta + \psi_i)$ . Since the  $\psi_i$  are drawn from a DP distribution, they are not necessarily unique and thus can be represented by a  $K$ -vector,  $\eta$ , where  $K < n$ . Furthermore, the model can be written as

$$Y = X \beta + A \eta + \epsilon, \quad (38)$$

where  $\psi = A \eta$  and  $A$  is an  $n \times K$  matrix of zeros with a single one in each row which denotes the specific  $\eta_k$  assigned to  $\psi_i$  (Kyung et al., 2010).

Dirichlet process mixture models were originally formulated by Ferguson (1973), who defined the underlying process and derived the key properties. Blackwell and MacQueen (1973) then showed that the

marginal distribution for the Dirichlet process can be treated as that of the  $n^{\text{th}}$  step of a Polya urn process. Other key theoretical work includes Korwar and Hollander (1973) and Sethuraman (1994). The contributions that have particular importance for the likelihood function development are that of Lo (1984), who derives the analytic form of a Bayesian density estimator, and Liu (1996), who derives an identity for the profile likelihood estimator of  $m$ . This is an interesting sociology of science story in that these works mostly predated the computational tools that made the models possible for real datasets. Follow-on work that changed this state are typified by Escobar and West (1995), MacEachern and Müller (1998), and Jain and Neal (2004).

The model specified in (Equation 35) is actually a classical semiparametric random effects model and, with further Bayesian modeling of the parameters, can be implemented with MCMC. Unfortunately, the presence of the Dirichlet term makes the use of the standard Gibbs sampler somewhat complicated in non-conjugate situations such as with is the model that was developed in Gill and Casella (2009). These authors find that this approach can model difficult data and produce results that existing alternative methods fail to discover. They then account for unobserved, important clustering structures with the non-parametric process that do not necessarily reflect intervening or confounding variables

but still provide information about agency environment that was not explicitly available.

Gill and Casella (2009) introduced a GLMDM with an ordered probit link to model political science data, specifically modeling the stress, from the Gill and Waterman (2004) data already described here. Their Dirichlet precision parameter was not an influential model parameter and was therefore fixed at a value that made the MCMC sampler more efficient. Kyung et al. (2010, 2012), looked at the maximum likelihood estimation of the precision parameter and found that the standard approach to finding the maximum likelihood estimate, given in Liu (1996), could yield a maximum, a minimum, or even a ridge. Figure 50.5, from Kyung et al., (2010), shows some observed shapes of this likelihood function for simulated circumstances. Since likelihood estimation is not reliable for this parameter, Kyung, et al., (2010) proved that introducing a prior distribution on the precision parameter guarantees an interior mode and so stabilizes the estimation procedure.

Models with Dirichlet process priors are treated as hierarchical models (Gill and Womack, 2013) in a Bayesian framework, and the implementation of these models through Bayesian computation and efficient algorithms has had substantial progress. Escobar and West (1995) produced a Gibbs sampling algorithm for the estimation of posterior distribution for all model parameters and the

**Figure 50.5** Log-likelihood functions for configurations of component likelihoods

direct evaluation of predictive distributions. MacEachern and Müller (1998) developed a Gibbs sampler with non-conjugate priors by using auxiliary parameters, and Neal (2000) provided an extended and more efficient Gibbs sampler to handle general Dirichlet process mixture models with non-conjugate priors by using a set of auxiliary parameters. Teh et al. (2006) extended the method of Escobar and West for posterior sampling of the precision parameter with a gamma distributed prior. Kyung et al.(2011) extended these results to a generalized Dirichlet process mixed model with a probit link function. They derived a Gibbs sampler for the model parameters and the important subclusters of the Dirichlet process using new parameterization of the hierarchical model to derive a Gibbs sampler that more fully uses the structure of the model.

Again,  $\mathbf{X}_i$  are the covariates associated with the  $i^{\text{th}}$  observation,  $\boldsymbol{\beta}$  be the coefficient vector, and  $\psi_i$  be the random effect accounting for subject-specific deviation from the underlying model. Assume that  $Y_i|\boldsymbol{\psi}$  are conditionally independent, each with a density from the exponential family, where  $\boldsymbol{\psi} = (\psi_1, \dots, \psi_J)$ ,  $J < n$ . Based on the notation on McCulloch et al. (2008), the Generalized Linear Mixed Dirichlet Model is expressed as

$$\begin{aligned}
 Y_i | \boldsymbol{\psi} &\overset{ind}{\sim} f_{Y_i|\boldsymbol{\psi}}(y_i | \boldsymbol{\psi}), \quad i = 1, \dots, n \\
 f_{Y_i|\boldsymbol{\psi}}(y_i | \boldsymbol{\psi}) &= \exp\left[\{y_i\gamma_i - b(\gamma_i)\} / \xi^2 - c(y_i, \xi)\right],
 \end{aligned}
 \tag{39}$$

where  $y_i$  is assumed discrete valued. It is assumed that  $[Y_i | \boldsymbol{\psi}] = \mu_i = \partial b(\gamma_i) / \partial \gamma_i$ . Using the arbitrary link function  $g(\cdot)$ , we can express the transformed mean of  $Y_i$ ,  $E[Y_i | \boldsymbol{\psi}]$ , as a linear function,  $g(\mu_i) = \mathbf{X}\boldsymbol{\beta} + \psi_i$ . For the Dirichlet process mixture models, we assume that

$$\begin{aligned}
 \psi_i &\sim G \\
 G &\sim \mathcal{DP}(mG_0),
 \end{aligned}
 \tag{40}$$

where  $\mathcal{DP}$  is the Dirichlet Process with base measure  $G_0$  and precision parameter  $m$ . Blackwell and MacQueen (1973) proved that for  $\psi_1, \dots, \psi_n$  iid from  $G \sim \mathcal{DP}$ , the joint distribution of  $\boldsymbol{\psi}$  is a product of successive conditional distributions of the mixture form

$$\begin{aligned}
 \psi_i | \psi_1, \dots, \psi_{i-1}, m &\sim \frac{m}{i-1+m} g_0(\psi_i) \\
 &+ \frac{1}{i-1+m} \sum_{l=1}^{i-1} \delta(\psi_l = \psi_i)
 \end{aligned}
 \tag{41}$$

where  $\delta(\cdot)$  denotes the Dirac delta function and  $g_0(\cdot)$  is the density function of base measure. The likelihood function from Liu (1996) and Lo (1984) is produced by integrating over the random effects,

$$\begin{aligned}
 L(\boldsymbol{\theta} | \mathbf{y}) &= \frac{\Gamma(m)}{\Gamma(m+n)} \sum_{k=1}^n m^k \\
 &\sum_{C:|C|=k} \prod_{j=1}^k \Gamma(n_j) \int f(\mathbf{y}_{(j)} | \boldsymbol{\theta}, \boldsymbol{\psi}_j) dG_0(\boldsymbol{\psi}_j),
 \end{aligned}
 \tag{42}$$

where  $C$  defines the subclusters (not actual clusters in the social science since there is no penalty here for over-fitting in the algorithm),  $\mathbf{y}_{(j)}$  is the vector of  $y_i$ s that are in subcluster  $j$ , and  $\boldsymbol{\psi}_j$  is the common parameter for that subcluster. There are  $S_{n,k}$  different subclusters  $C$ , the Stirling Number of the Second Kind (Abramowitz and Stegun, 1972: 824–825). Now we consider again the  $n \times k$  matrix  $\mathbf{A}$  defined by

$$\mathbf{A} = \begin{pmatrix} a_1 \\ a_2 \\ \vdots \\ a_n \end{pmatrix},$$

where  $a_i$  is a  $1 \times k$  vector of all zeros except for a 1 in one position that indicates which group the observation is from. So, each column of matrix  $\mathbf{A}$  represents a partition of

the sample of size  $n$  into  $k$  groups. If the sub-cluster  $C$  is partitioned into groups  $\{S_1, \dots, S_k\}$ , then if  $i \in S_j$ ,  $\psi_i = \eta_j$  and the random effect can be rewritten as  $\psi = A\eta$ , where  $\eta = (\eta_1, \dots, \eta_k)$  and  $\eta_j \stackrel{iid}{\sim} G_0$  for  $j = 1, \dots, k$ .

The results of implementing the GLMDM model for the data in Gill and Waterman (2004) are given in Table 50.2 as posterior quantiles. Notice first that these results differ markedly from the previous analysis of these data with a conventional Bayesian ordered choice model as summarized in Table 50.1. The nonparametric specific is a fundamentally different approach that includes and leverages underlying heterogeneity by accounting for subclusters in the estimation process. For instance, the effect of the variable `Committee Relationship` and stress is reliably in the opposite direction: closer ties to the oversight committee are associated with lower stress levels, when accounting for group level latent heterogeneity. This actually makes sense when considering the wide range of relationship types, policy spaces, and administrative

histories that exist between congressional committees and administrative agencies. So, the Dirichlet process that accounts for such underlying grouping reveals a different type of relationship effect. Moreover, the previously seen, positive relationship between `Career.Exec-Compet` and stress is now overturned: there is a reliably negative finding here likely recognizing agency heterogeneity in senior staffing. The hours per week worked have a positive relationship with stress. This statistically reliable finding is shown in the tightly bounded and positive quantiles for `Hours/Week`. Interestingly, political executives who required preparation for the hearings on their Senate confirmation later provided lower stress scores. This reliable finding is likely related to the committee relationship variable.

**CONCLUSION**

The purpose of this chapter is to introduce the Bayesian inferential process with a focus

on its implementation in political science and international relations. It is designed to highlight the practical history of how results are obtained in Bayesian analysis over the course of time. The hope is that readers will see both the principled theoretical advantages of thinking ‘Bayesianly’ and the practical ease with which results can today be produced and extended.

Bayesian inference is characterized by the explicit use of probability for describing uncertainty, which means probability models (likelihood functions) for data given parameters and probability distributions (PDFs and PMFs) for parameters. From this basis, inference proceeds from inference for unknown values conditioned on observed data with the use of inverse probability with Bayes’ Law to describe the full distribution of the unknown quantities with this update. Probability statements lie at the heart of Bayesian analysis. Everything a Bayesian does not know for a fact is modeled with probability distributions. At the core setup of Bayesian analysis, prior knowledge informs a specified probability model, which is then updated by conditioning on observed data and whose fit to the data is evaluated distributionally. The Bayesian paradigm fits closely with the core tenets of scientific discovery: current theories form the basis of stated prior information and informative evidence from data collection have the ability to update our theories. Contrary to traditional statistical thinking, however, it constitutes a different way of thinking about uncertainty that is strictly probability based, eschewing assumptions like an unending stream of independent and identically distributed data.

In the sections above, we identified three clear historical eras in the development of Bayesian methods: classical, modern, and postmodern. The classical era lasted until 1990 and was characterized by a determination that philosophical correctness should be recognized but was tempered with the challenges of estimating models with realistically

large and complicated social science data. Unfortunately at the time, it was not hard to create logical and mathematical arguments that showed the superiority of Bayesian inference over more traditional methods, but it was very hard, if not impossible, to apply these arguments empirically.

Gelfand and Smith changed this state of the Bayesian world and ushered in the modern era in 1990. They discovered Gibbs sampling, a tool with its roots in engineering and image restoration. Aided by improvements and availability in computing power, Gibbs sampling replaced analytical derivation of marginals from a joint with large numbers of draws sampled by the computer. Together with the Metropolis–Hastings algorithm unearthed from statistical physics, Gibbs sampling solved Bayesians’ problems and became known collectively as Markov chain Monte Carlo. Thanks to MCMC, models were no longer too complex for marginalization of joint posteriors to create regression tables. MCMC revolutionized Bayesian inference, released decades of frustration, and led to countless Bayesian applications and publications.

Finally, the postmodern era began in the early 21st century when researchers realized the full potential of MCMC beyond the estimation of previously inestimable models. It gradually became apparent that Bayesian stochastic simulation could also be exploited for enhanced purposes, such as model checking and model comparison. The consequence of this realization was a number of tools designed to extend the reach of MCMC, such as poster predictive checks, Hamiltonian Monte Carlo, Bayes Factor calculations, and Bayesian nonparametrics. As a result, it is now possible to not only easily produce Bayesian results, but also to extend the Bayesian paradigm and its application far beyond model estimation alone. This makes the Bayesian inferential process extraordinarily useful in political science and international relations.

# Laboratory Experimental Methods

Rebecca Morton and Mateo Vásquez-Cortés

This chapter provides an overview of some leading work using experimental methods in political science. Given that experimental methods have become an increasingly important tool for political scientists – research in all subfields of the discipline can use and have used experimental methods – we will narrow the scope of the chapter to explore the design and implementation of laboratory experiments. Nevertheless, we will explore the use of experimental methods to study a wide range of political science questions.

The chapter is divided into three sections. The first section is dedicated to discussing some of the most important methodological issues regarding effective laboratory experiments. The second section of the chapter explores different types of lab experiments; in this section, we explain the differences between laboratory experiments from a political economics perspective and those from a political-psychology perspective, which are two of the main approaches used in laboratory experiments in political science. The last

section expands on new developments in lab experiments: we consider an expansion of the method to new topics like network analysis and emotions, as well as methodological developments such as lab-in-the-field experiments and virtual labs.

## **EXPERIMENTAL POLITICAL SCIENCE**

Experimental research is at the core of many scientific disciplines. In some cases, the findings and norms are hard to grasp without reference to experimental methods. In a growing number of areas, experiments are now a common and important element of the political scientist's toolkit. Especially in recent years, there has been a large expansion in the number of political scientists who view experiments as useful and informative. Political scientists across subfields now increasingly use one or more of the three major experimental methods: laboratory, survey, and field.<sup>1</sup>

Experiments appeal to political science because of their potential to generate stark and powerful causal claims and their ability to inform theoretically grounded empirical claims (Druckman et al., 2006; Morton and Williams, 2010). Experiments facilitate inference through two mechanisms: control of observable confounding factors and random assignment to treatments. The procedure of random assignment ensures that unobservable factors are equally likely to be present across treatment and baseline groups. Through these two methods, experiments are particularly useful in identifying the causal effects of variables of interest as discussed by Bowers and Leavitt (Chapter 41, this *Handbook*).

Additionally, experiments are an important tool in guiding theoretical advancements. Experiments influence theoretical developments as they provide means for studying preferences over institutions, political behavior, and other fundamental factors that might be hard to assess using non-experimental data. Finally, experiments facilitate causal inference and empirical tests of theories through the transparency and reproducibility of their procedures.

In what follows, we focus on the second aspect: the ability of experimental research to guide theoretical development. Given that this *Handbook* dedicates other chapters to field and survey experiments, we highlight the benefits and challenges of laboratory experiments as a tool for political scientists.

### ***Laboratory Experiments in Political Science***

Laboratory experiments provide many advantages. We want to emphasize four: control conditions, replication, multiple manipulations, and measurement of variables of interest.<sup>2</sup>

First, in the laboratory, it is relatively easy to measure subjects' behavioral differences when manipulations are compared and

subjects are randomly assigned to manipulations. In other experimental settings, like the field and Internet, the researcher often cannot correct for the lack of control of the environment in which manipulations take place and has to rely primarily on random assignment. If the environments in which the different manipulations take place vary systematically and this is not observed by the researcher, then the comparison between manipulations is more difficult to determine.<sup>3</sup>

Second, as research transparency becomes more of a norm within political science, so does the ability to explore previous findings through scientific replication. Because the reproducibility of experiments is an essential part of the scientific method, the inability to replicate the studies of other types of experiments has potentially grave consequences. By contrast, replication of laboratory experiments is often feasible. Since replication has become a major element in scientific advancement in political science, laboratory experiments provide one of the most accessible settings for replication, which allows researchers to evaluate the validity and scope conditions of their proposed causal relationships. Laboratory conditions are similar across different environments, and experimenters can replicate studies keeping most relevant factors equal. No other experimental setting provides such good conditions for replication as laboratory experiments. Most think of the standard student-subject pool used in laboratory experiments as a disadvantage since it is not generally representative of nonstudents in the area, the fact that it is similar and constantly renewing facilitates the scientific replication of previous results in different times and locations.

A third advantage of laboratory experiments is that the researcher can create rich environments that do not often exist in naturally occurring situations. For example, in the laboratory, the researcher can test different voting mechanisms and evaluate the potential benefits of approval voting as opposed to majority rule, holding the choices that are

before voters constant. It would be quite difficult to convince jurisdictions to randomly adopt both of these procedures simultaneously or find jurisdictions facing the same choices but randomly assign their voting rules. Recently, for example, Bassi (2015) and Bouton et al. (2016) explored the benefits of different voting mechanisms, using laboratory experiments.<sup>4</sup>

Fourth, the facilities of the laboratory allow for the measurement of brain activity and emotional responses, which are as important for different research questions as they are hard to measure without adequate equipment. Political scientists use fMRI equipment and skin-conductance measures to gather information that is relevant for political decisions, like partisanship and preferences for social welfare. For instance, Westen et al. (2006) and Amodio et al. (2007) measure neural responses to study partisan political judgments, and Aarøe and Petersen (2013) measure blood glucose levels to study preferences for social-welfare policies. These variables are difficult to obtain outside a laboratory.<sup>5</sup>

Finally, laboratory experiments are a powerful tool for observing behavior in cases where theory makes unclear predictions or does not make predictions at all. For example, laboratory experiments have been used to select over multiplicity of equilibria in theoretical settings. We can experimentally test if players are sufficiently patient for the amount of cooperation that can be sustained in equilibrium.<sup>6</sup> To do so, the researcher can create situations in the laboratory in which players repeatedly interact for an indefinite period of time by using random procedures to determine when the game will end. By varying the probability that the game will end, the researcher can manipulate the benefits of patience in order to determine the extent that subjects demonstrate patience.

Laboratory experiments usually follow a distinct pattern. After formulating a research question, the researcher chooses a design that answers the question based on the treatment variable(s), variation between subjects (when

we examine the differences between individuals) vs variation within subjects (when we examine the variability of a particular value for individuals in a sample), and the required number of independent observations. This design stage of an experiment is probably the most important step in experimental research: the better the design, the cleaner the results from the experiment and the less need for complex post-experiment statistical analysis in order to determine what we have learned from the study. If the study addresses a research question that is based on a formal theoretical model and wishes to evaluate the model, then ideally the experiment is designed to eliminate as many disconnects as possible between the theory's assumptions concerning the environment and the situation facing the subjects, so that the results of the experiment directly speak to the theory.

On the practical side, once the design is formulated, a researcher usually engages in three activities to prepare an experiment: 1) the writing of clear instructions for each of the treatments; 2) the preparation of a 'script' of a session; and 3) the creation of a computer program to measure the variables of interest.

The researcher also has to secure monetary funds to pay subjects when needed. The funds are usually used to cover participation fees and the cost of laboratory time, as well as computer programming in some cases. In the next section, we will explain how monetary incentives affect the experimental design.

Additionally, the researcher has to secure approval from ethical boards. Universities and laboratories have clear protocols that must be satisfied in every study that involves human subjects. The research has to make clear how the proposed study follows the rules of the protocols. Many journals now verify the commitment to ethical considerations before publishing any study.

Finally, when all the previous conditions have been satisfied, the researcher moves on to recruit subjects, pilot the activities, improve the design or instructions when needed, and run the experiment.<sup>7</sup>

Conducting a laboratory experiment from start to finish is a demanding activity prone to many practical restrictions.<sup>8</sup> Additionally, there are a number of criticisms of laboratory experiments. A usual point of concern is the generalization of the sample of experimental participants to a larger population of interest. The validity of laboratory studies has inspired some skepticism.<sup>9</sup> Before discussing these concerns, we highlight some key differences between internal validity and external validity, so we can better comment on the potential limitations of laboratory experiments.<sup>10</sup>

Internal validity is an evaluation about the truth of the inference or knowledge claim within a studied target population. Internal validity has three components: statistical (how valid are the statistical relationships observed and is the sample a random selection from the target population studied); causal (can we identify causal inferences in the sample); and construct (how much does the experiment truly test the theoretical research question addressed). In contrast, external validity evaluates the knowledge claim for observations beyond the target population studied. It has to do with whether we can generalize the results beyond the target population studied in the experiment. A third type of validity that is often confused with external validity is ecological validity, which has to do with the degree to which the environment abstracts from and is at variance with the naturally occurring world.

To understand why ecological validity is different from external validity, consider a simple voting experiment. We can make the voting experiment distinct from reality by having subjects engage in choices where instead of casting votes, they take tokens from different token bins where each subject can only take one token. The bin from which the most tokens are taken is declared the winner. Or, we can make the experiment close to reality by having the choices before the voters be labeled candidates or issues that are real in naturally occurring elections in their jurisdiction and using the actual voting equipment used in their local jurisdiction.

Importantly, the choice of whether to use the less ‘real’ tokens vs the more ‘real’ actual candidates does not affect the external validity of the study, since neither choice affects whether the experimental results generalize to a voting jurisdiction in which there are completely different choices before voting and often distinctively different voting procedures or equipment. Both environments can be equally ‘unreal’ to the external jurisdiction. In both environments, real humans are making real choices that can affect real earnings. Some may even argue that the experiment with tokens may be more ‘generalizable’, since it does not have the baggage of the local jurisdiction and is more neutral to other environments.<sup>11</sup>

Ultimately, the external validity of laboratory experiments is something that needs to be addressed empirically, as does the external validity of any empirical study outside the laboratory. All empirical research can only make inferences for the pool of subjects from which it is drawn. To make inferences beyond that subject pool, more experiments must be conducted. When a study is theoretically founded, the theory can be a guide to these subsequent studies. It is an empirical question that can only be answered empirically; it is not something that can be addressed through argumentation or theory alone or be justified based on the design of a single experiment with one target population.

This does not mean that the question of external validity is a minor one or should be ignored. The results of experiments that rely too much on a single target population (such as college students from westernized, educated, industrialized rich democracies (WEIRD)) may not generalize to other populations of interest, and it is a vital question as to whether the results generalize to nonstudents and subjects drawn from non-WEIRD populations. As the development of laboratories in countries such as Kenya (Nairobi Busara Laboratory), India (Nuffield Oxford Centre of Experimental Social Sciences at FLAME University in Pune), and the United

Arab Emirates (Social Science Experimental Laboratory at New York University Abu Dhabi) and ‘lab-in-the-field’ experiments (discussed below) expand, external-validity issues can be addressed.<sup>12</sup>

## **TYPES OF LABORATORY EXPERIMENTS IN POLITICAL SCIENCE**

Laboratory experiments in political science are based on two different and distinct heritages: psychology and economics.<sup>13</sup> Following other authors (Dickson, 2011; Morton and Williams, 2010), we focus on a number of important dimensions in which these two types of experiments differ: stylization, incentives, level of analysis, the role of theory, the use of repetition of tasks, and deception. These differences are largely due to some of the differences in research focuses and types of questions that experimentalists from the two heritages emphasize, as we will discuss below.

Laboratory research in economics tends to give an abstract description of the situation of interest. The roles and decisions that subjects make in the laboratory are usually labeled in neutral terminology. For example, Fehr and Gächter (2000) use neutral language and do not mention fairness, punishment, or other potentially charged terms when studying punishment in games of public-goods provision. In the same vein, in their study about voter turnout, Levine and Palfrey (2007) use labels *X* and *Y* instead of ‘vote’ or ‘abstain’. The main reason for using neutral language is to keep experimental control and avoid reactions from the subjects that the analysis cannot properly measure. Such control is deemed necessary to increase the internal validity of the experiment as an evaluation of economic theory. According to this argument, context-rich settings tend to have many factors that could affect subjects’ attention, influence their behavior, and potentially affect the outcomes of interest. That said, experimentalists in the economics tradition also often use non-neutral

language as well. More importantly, they sometimes explore the impact of context in experiments. For example, Aragonés and Palfrey (2003) conduct their experiment using both neutral language and language that is non-neutral and refers to the choices in their political terms – they find that the behavior is unaffected by the terminology used. The point is that such context might matter and should be something that the experimentalist investigates and studies; it is in itself a treatment.

By contrast, experiments in the psychology tradition try to evoke more contextually rich environments and put more emphasis on the descriptive realism of laboratory scenarios. For example, Levendusky (2013) uses a series of experiments to study the effect of the media on polarization. The study provides subjects with recent news capsules from political TV shows and realistic newspapers editorials. In another study, Brader (2005) recreates political advertisements using genuine ads from a naturally occurring, ongoing campaign. Making the ads as credible as possible was crucial for the study as the psychological mechanisms that the author explores are rooted in the experimental protocol.

Abstract experimental designs have advantages and disadvantages. Stylization can provide a higher degree of control and allow for a clearer definition of theoretical benchmarks that has to pass a hard test imposed by the neutral design. Experiments in this tradition, however, often face skepticism about the ecological validity of their inferences from political scientists who come from the psychology tradition.

Experimental economics usually offers subjects monetary incentives that depend on subjects’ decisions in the laboratory. Monetary incentives can be of much use when researchers want to reward accuracy and induce preferences over the choices that are before the subjects, as assumed in a theoretical model. In contrast, psychological experiments tend not to offer inducements that are conditional to subjects’ actions and give fixed amounts of cash payments or course credit.

In many cases, the research question of interest to political psychologists does not seem to straightforwardly yield itself to using monetary incentives. For example, at first blush it would seem that in the studies of Levendusky (2013) and Brader (2005), political attitudes are the relevant dependent variable, and offering monetary incentives to report one opinion over the other would appear not to be useful. That said, some studies are beginning to incorporate incentives in similar experiments by having subjects express their political attitudes though making monetary choices over contributions to interest groups, as in Haas and Morton (2018).

Monetary incentives can lead to better task performance, as shown by Camerer and Hogarth (1999), and more accurate responses, as demonstrated by Prior and Lupia (2008) in a survey experiment in which monetary rewards incentivized more precise answers to political knowledge questions. However, many psychological studies, such as Ryan and Deci (2000), have found that financial incentives lower task performance by crowding out intrinsic motivations.<sup>14</sup> More nuanced studies of the effects of incentives on task performance demonstrate that the effect appears to be heavily dependent on the size of the incentives and the task involved. Paying subjects small amounts of money, as in Ryan and Deci (2000), can have a negative effect. But as the size of the payment increases, the effect becomes positive. If the experimental game is complex, further increases beyond even standard payments can also have a positive effect.<sup>15</sup>

In game theory, the preferences of an individual are part of the game primitives. Therefore, in a study that is rooted in a game-theoretical model, the researcher wishes to induce in participants the same preferences that are assumed in the theory. In laboratory experiments, this is usually done through the use of monetary incentives. By controlling for the preferences using monetary incentives, the researcher can focus on other aspects of the study, such as consistency with theoretical equilibrium.<sup>16</sup>

Laboratory experiments in economics and psychology also differ in the level of analysis and the role of formal theory. In a typical economic experiment, subjects are participating in a game of interaction with each other, and the emphasis is typically in comparing subject behavior in such interactive situations to formally derived game-theoretic equilibrium predictions. Since in most economics style experiments, the researcher is interested in measuring behavior in a steady state, after learning about the environment and the game has subsided, subjects usually play the game repeatedly and the researchers often focus on analyzing behavior in the later periods. In psychological experiments, subjects are usually engaging in an individualized decision-theoretic task that they complete only once without interaction with others, and the goal is to compare their behavior with the predictions drawn from a non-formal psychological theory of behavior.

A final point in which economics-style and psychology-style laboratory incentives differ is the acceptance and use of deception. The consensus among experimental economists is to avoid most deception, while in the political-psychology research tradition, deception is seen as a useful tool in experimentation. There are potential advantages and disadvantages of using deception, which are not discussed here due to space limitations.<sup>17</sup>

The multifaceted nature of our subject of study, along with the varying strengths and weaknesses of different research methods, highlights the advantages of experimental political science. In what follows, we discuss two of the most promising directions for experiments in political science using laboratory settings: emotions and network analysis.

## NEW DEVELOPMENTS: TOPICS

As experimentation has increased in political science, many new avenues have been taken.

In this section, we focus on just two of these: analyses of social networks and emotions.

### **Network Analysis**

The study of social networks in political science is a fast-growing topic that has drawn a lot of interest in the discipline. Empirical research on social networks has lagged behind theory, however, and we still lack empirical validation for the large number of theoretical findings accumulated in the last decade. The main reason for this lag is related to the challenges involved with causal identification of the impact of network structure on behavior.

First of all, observational data on social networks is usually unavailable and incomplete, and it is often hard to make inferences based on incomplete data. This *Handbook* contains current methods to address data collection of relation data (Calvo et al., Chapter 30, this *Handbook*), network theory (Victor and Khwaja, Chapter 45, this *Handbook*), and estimation methods in networks (Schoeneman and Desmarais, Chapter 46, this *Handbook*). Second, even if we have complete data, it is hard to impossible to find exogenous factors able to affect network structure that are independent from outcomes of interest, generating severe endogeneity issues: when links in a network are created based on characteristics that are also correlated with what is being measured, it is hard to know whether a correlation in behavior across subjects connected in the network is the result of a social interaction effect or simply from the selection into the network.

Experimental research of social networks is growing in social science because experiments allow the causal identification of network-structure effects.<sup>18</sup> Moreover, experiments provide an invaluable tool to validate existing theoretical findings in general and how individuals use network information in particular. In what follows, we highlight the uses of laboratory experiments on

social networks that are particularly relevant in political science: network formation and information transmission.

As mentioned before, there are several challenges to identification in social networks with observational studies. This is particularly true of studies that look at network formation: since social network data encodes interactions in real life, it is often extremely hard – if not impossible – to find sources of exogenous variation in network structure. Laboratory experimentation on social networks is a particularly important tool as it can easily manipulate not only network structure (which can be chosen by the researcher) but also the formation of networks (manipulate incentives to create links with other participants). Given that observational studies have to rely on the empirically difficult problem of selection into the network, laboratory experiments provide a tool to study network formation that has several advantages over other methods. A host of experiments have successfully been used to study network formation (Caldara et al., 2014; Callander and Plott, 2005; Carrillo and Gaduh, 2012; Goeree et al. 2009).

Most of these papers study the costly decision to form links with other subjects in a context in which being connected is valuable. Studies vary the costs of forming links across agents and the extent to which links can be created unilaterally. Some of the results of these experiments can be exported outside the lab. For example, Goeree et al. (2009) argue that agents' heterogeneity in terms of linking costs is a major determinant of the predominance of star-like structures in real-life social networks, that is, structures in which a single agent is directly connected to all other peripheral agents.

Another avenue of research in laboratory experiments on social networks is on the topic of social learning. Opinions about new technologies, job opportunities, and political candidates are largely transmitted through social networks. Several studies have experimentally studied the transmission of information

in networks (see for example Çelen et al., 2010; Chandrasekhar et al., 2015; Choi et al., 2012) to understand how agents filter and use information they receive from neighbors.

All the studies mentioned above follow the economic tradition in laboratory experiments. For example, Chandrasekhar et al. (2015) study different models of social learning in networks where agents can update their guess about the state of the world according to Bayesian learning (sophisticated learners) or simply following the guesses of others (naïve learners).

Chandrasekhar et al. (2015) study different models of social learning in networks. After observing a signal, subjects guess the binary state of the world. In subsequent rounds, agents observe their network neighbors' previous guesses before guessing again. The models of learning that they study separates sophisticated from naïve learners based on the use of the information agents receive from their network. The lab sessions were conducted in Indian villages and in a high-ranked Mexican university. The laboratory experimental analysis abstracts from other important unobserved determinants of learning behavior. As the researchers explain, the laboratory experiment allows the researchers to prioritize studying fundamentals of learning behavior over analyzing the effect of confounders of such fundamentals.

The possibility of using exogenous network change to study causal links between network structures and other outcomes is exciting. Such an inquiry requires that the underlying change to the network is not directly correlated with the outcome of interest. Laboratory experiments facilitate the manipulation of network formation and structure to better understand causal relations. In other words, the network structure can be manipulated by the researcher while controlling other variables. For example, when studying coordination, Cassar (2007) keeps constant elements like number of players and number of connections and manipulates the structure of the network. Similarly,

Choi et al. (2011) vary network structure in dynamic public-goods game. In any other application, the network structure can be exogenously imposed by the experimenter.

The number of possible implementations of network structure and learning in networks is also a growing and exciting area of research. The described studies provide the fundamental tools that can be used to apply the laboratory methodology to politically relevant questions.

### **Emotions**

Increasingly, social scientists are using experiments to study the role of emotions in a wide variety of political phenomena. Studies have looked at the impact of emotions such as fear, anxiety, anger, and enthusiasm (for a review, see Valentino et al., 2011). For obvious reasons, most of these studies depart from psychology-style experiments and study questions related to voting, framing effects, and public opinion. However, there is a growing trend in the literature that applies known psychological findings into models of political economy. This research agenda departs from the rational-choice framework and includes psychological insights such as the effect of emotions.

Recently, Acharya et al. (2018), Lupia and Menning (2009), Minozzi (2013), Aldama et al. (2018), and Little and Zeitzoff (2017) incorporated ideas from psychology into political-economy models. Accordingly, recent research tries to incorporate psychological elements into what traditionally was economics-style laboratory experimental political science, which has been the testing ground for political-economy theories.

Myers and Tingley (2016) study the effect of a set of emotions on trust. The authors manipulate emotions using a common psychological method: the Autobiographical Emotional Memory Task (AEMT).<sup>19</sup> The method asks subjects to recall a wide variety of emotions and focuses them on the emotion

that the researcher wants them to experience. Then, they measure trust using the common economic-based trust game. Similarly, Hopfensitz and Reuben (2009) focus on the effect of emotions for social punishment. The authors highlight the role of emotions for cooperative behavior and propose a game-theoretical framework that captures how anger may motivate subjects to punish free riders. The measure of emotions comes from self-reported data.

Studying the effect of emotions on political outcomes is not new.<sup>20</sup> What is novel in these approaches is the combination of methods from economic-style and psychology-style laboratory experiments. These studies rely on laboratory applications of formal theory and psychology that are common in political science. As noted by Albertson and Gadarian (2016), there are two main challenges: manipulating emotions and isolating the impact of the emotions of interests (say anxiety), from other emotions that might be affected by the same manipulation (like fear).

We expect that the intersection of these two types of experiments, along with the adoption of technologies to measure emotions and neural responses in the lab, will be one of the avenues for future research in laboratory experiments in political science. The advancement of experiments that take elements from both traditions is also likely to change methodological debates presented in the previous section.

## NEW DEVELOPMENTS

In 2012, Druckman identified the three most prominent experimental methods in political science: laboratory, surveys, and field. Since then, the reduced cost and increased feasibility of digital field experiments has led to an increase in experimentation using different platforms. We focus here on two recent advancements that relate to laboratory experiments: lab-in-the-field and virtual labs.

A lab-in-the-field experiment takes place when subjects participate in a common physical location but the experimenter, to some degree, brings the laboratory to the subjects' natural environment (Morton and Williams, 2010). Lab-in-the-field experiments are now often used in political science (for recent studies, see Viceisza, 2016, and Gneezy and Imas, 2017). Taking the lab experiment from the university into different habitats of social interaction allows for the comparison of the lab results to those with different populations, while keeping constant other important aspects of the experiment. There are two important insights derived from this point: first, lab experiments in the field can be used as robustness checks of the results obtained in the lab; second, they can provide information about behavior across cultures and contexts, which overcomes common criticisms about the validity of laboratory experiments, as discussed earlier.

In this section, we are going to highlight how lab-in-the-field experiments can be used to complement traditional field experiments by providing reliable measures of variables of interests and to test theoretical models with new populations. These reasons contrast with the contextual advantages in which lab-in-the-field developed: usually, a lab-in-the-field experiment was seen as an appropriate methodological tool when researchers wish to conduct a traditional laboratory experiment and take advantage of a particular naturally occurring situation in the field.<sup>21</sup>

Lab-in-the-field experiments can be used for all of the same purposes as standard laboratory experiments. Moreover, lab-in-the-field experiments can be combined with standard field experiments to unpack mechanisms behind causal relations identified by field experiments (Gneezy and Imas, 2017). As such, they have been used to elicit, measure, and identify parameters associated with characteristics such as preferences, beliefs, and social norms. In particular, when there are reasons to expect that risk, time, and ambiguity preferences play an

important role, scholars rely on laboratory procedures to elicit and estimate those factors. Additionally, lab-in-the-field techniques provide incentive-compatible mechanisms through which subjects credibly rely on their social norms (preferences, trust, and reciprocity). This helps overcome difficulties in answering abstract questions and the social desirability biases, which make self-reports problematic.<sup>22</sup>

There are a number of noteworthy recent lab-in-the-field experiments on pro-social behavior and cooperation outside of the traditional laboratory. For example, Baldassarri and Grossman (2013) study whether group attachment and position in social networks affects pro-social behavior within in-groups. The study took place in rural communities in Uganda and used different variants of the dictator game to show that group attachment positively affects pro-social behavior. Also interested in pro-social norms, Gilligan et al. (2014) unpack the effects of wartime violence on social cohesion. Using public-good contributions, trust games, and altruistic giving, the authors measure pro-social motivation among communities affected by Nepal's ten-year civil war. Finally, Alexander and Christia (2011) look at the effect of ethnic diversity on cooperation with a sample of students from groups affected by conflict (Croats and Bosnians).<sup>23</sup> All three studies are examples of a lab-in-the-field approach that take full advantage of the methodology in that they examine an understudied population while using known laboratory methods to measure behavior.

An important implication of validating theories across populations and using laboratory methodologies to measure otherwise difficult to elicit variables is that researchers rely on standardized validated methods. This point is important because it ensures that results are comparable and replicable with known laboratory studies and also across other contexts. However, there are costs to using methods that may not be best simply because they were used previously. Developing new

strategies with students can be validated through several experiments, whereas in the field, new techniques may be constructed of other factors. It is important to be aware of cultural differences when developing the design of a lab-in-the-field study. For example, the population of interest in some of the studies mentioned above can exhibit large variation in levels of literacy and mathematical ability, which will limit the use of more complex elicitation methods.

Another advantage of using lab-in-the-field techniques is to test theories with a relevant population. Experiments that test theories in the lab typically use a convenience sample of undergraduate students, and sometimes it is assumed that behavior in the lab can be generalized to the relevant population. While most theories of human behavior are not specific to particular populations (for example, issues of pro-social behavior are important for all humans), some theories are particularly relevant to a specific subset of humans. That is, suppose that the theory concerns the behavior of lobbyists; a lab-in-the-field experiment conducted with actual lobbyists may seem a better test of the theory. Indeed, Potters and Van Winden (1996, 2000) conducted such an experiment with both lobbyists and students.<sup>24</sup> When using lab-in-the-field techniques, the researcher can test a theory with the relevant population, while having the advantage of studying behavior in a controlled setting. The lab-in-the-field evidence allows the researcher to isolate variations in individuals' motivations vs other types of effects, given that it is often difficult for some populations to participate in research activities in standard laboratory environments.

Virtual-lab experiments are conducted similarly to laboratory experiments, but the interactions between the experimentalists and the subjects and with each other takes place online or virtually. Most online survey experiments are essentially psychological virtual-lab experiments. In contrast, online economics experiments in which subjects

make interactive choices in a game situation are more distinctive and more complex to design, since it is often difficult to have subjects online at the same time as one another for a sufficient time period in order to participate in online simultaneous games. Hence, there can be less opportunity for subjects to engage in learning and repetition here than in the laboratory. Moreover, subjects may be less likely to believe that they are participating in a game with others when they are doing so virtually and cannot observe that there are others in the game, as they would be able to in a standard laboratory experiment. For a discussion of some of the issues involved in designing and implementing virtual-laboratory experiments, see Arechar et al. (2018).

## CONCLUSION

In this chapter, we have considered some elements of laboratory experiments in political science. After a description of the basic elements of this important research toolkit, we discussed the two heritages from which laboratory experiments in political science arise and how they differ on stylization and use of incentives. We then introduced two new developments that follow from these traditions: laboratory experiments with social networks and laboratory experiments with emotions. When relevant, we have shown how these new developments take elements from the traditional laboratory experiments. Finally, we have provided a brief introduction to lab-in-the-field experiments and also stressed their ability to complement the findings from traditional laboratory experiments.

Good experiments should be analyzed in light of theoretical motivations and be complemented with adequate econometric method. We believe that while the adoption of new technologies allows researchers to use different platforms to conduct randomized experiments, the laboratory methodology still has several advantages that make it the

most appropriate method to study several topics. In particular, using carefully designed laboratory methodology can increase our understanding of theory-oriented inquiries, provide information about the mechanisms behind behavior, and the effectiveness of potentially larger interventions.

As technology advances provide useful platforms to develop experiments, the laboratory setting not only remains the most advantageous method to study several topics but also provides the most effective tools to address several academic purposes.

While we recognize and celebrate the use of different platforms and methods to develop experimental research in political science, we should not overestimate their advantages. The laboratory enables experimentalists to have a degree of control over the experiment that is hardly achievable in any other setting. Similarly, other factors such as compliance and bundled treatments, which can be problematic in other types of experiments, are less of a problem in laboratory experiments. Finally, given the possibility to control the experimental conditions, factors such as the context, the location, and the time can be manipulated in the laboratory in a way that cannot be controlled in the field, for example.

## Notes

- 1 A proof of the growing expansion of experimental methods in the discipline is the new *Journal of Experimental Political Science*, JEPS, which exclusively publishes experimental research.
- 2 Some of these reasons have been explained in Morton and Williams (2010).
- 3 The level of control applies to individual and group experiments as well.
- 4 Additionally, researchers can use experiments as a complement to theory in order to determine the effect of different forces on complex situations where theory is impractical. For example, in economics, laboratory experiments have been used to test the performance of different auctions in order to sell spectrum rights. Although these experiments were grounded in theory, the results provide new insights for the development of new theoretical studies.

- 5 Some topics that are particularly important for political science, like deliberation, require subjects to be physically in the same space. See Karpowitz et al. (2012) for an example in which subjects debate under different group compositions.
- 6 Dal Bó and Fréchet (2011) study the conditions under which cooperation can be sustained in repeated games.
- 7 The analysis of results from laboratory experiments is beyond the scope of this chapter, but we encourage the reader to look at 'The Experimentalist's To Do List' section in Morton and Williams (2010).
- 8 This is not to say that other empirical methods are less demanding in terms of time and money.
- 9 See, for instance, the widely cited Sears (1986).
- 10 A full discussion can be found in Druckman et al. (2006) and Morton and Williams (2010).
- 11 Ecological validity is more likely to relate to internal validity, since high ecological validity arguably may increase the salience of the experiment to subjects and thus to results that are more statistically valid by reducing the variance in subjects' choices.
- 12 For a full discussion of the participation of students in laboratory experiments in politics see Druckman and Kam (2011).
- 13 There is a third heritage in experimental political science, statistical methods, but experimentalists who come from this tradition tend to be field experimentalists, not laboratory experimentalists. See Morton and Williams (2010).
- 14 Intrinsic motivation involves engaging in a behavior because it is inherently enjoyable and interesting, while extrinsic motivation refers to doing something because it led to separable outcomes.
- 15 Economists worry that subjects will not believe an experimenter if they expect that deception might be used based on past experience in the laboratory or the laboratory's reputation among other subjects. Such disbelief can lead to greater variance in behavior. That said, economists do not typically reveal to subjects the exact purpose of an experiment but usually use vague descriptions such as describing an experiment as one on decision-making. See the review in Morton and Williams (2010) and also Bassi et al. (2011).
- 16 The importance of inducing preferences was posited by Vernon Smith (1976) in what is known as induced value theory.
- 17 Chapter 13 in Morton and Williams (2010) has a comprehensive review.
- 18 For a recent review, see Choi et al. (2016).
- 19 The AEMT is not the only method to induce emotions in the lab. There are other methods such as having the subject watch movie clips and pictures and interact with confederates.
- 20 See Albertson and Gadarian (2016) for a recent review.
- 21 That is, for example, the motivation in Whitt and Wilson's (2007) study of Katrina victims.
- 22 Additionally, Gneezy and Imas (2017) note that the data generated using laboratory techniques in the field can help identify participants that will benefit from future potential intervention. Obviously, these variables may be relevant for different reasons depending on the research questions.
- 23 Lab-in-the-field experiments are also an important tool if researchers are interested in comparing results between different contexts. If there are theoretical reasons to expect that cultural differences will be important for an outcome of interests, running the same experiments in different contexts can potentially provide information of the relevance of the contexts. Research on the difference of the willingness to cooperate (Gächter et al., 2010) and engage in anti-social behavior (Herrmann et al., 2008) uses similar implementations in different populations.
- 24 See Potters and Van Winden (2000) for an example of an experiment conducted with both lobbyists and undergraduate students.

# Field Experiments on the Frontier: Designing Better

Betsy Sinclair

## INTRODUCTION

‘Leave no trace’ is a motto used to characterize outdoor ethics – the notion that when humans interact with the outdoors, they should minimize their impact on the natural landscape. The phrase is also appropriate for field experimenters, whose goals should jointly be to extract as much scholarly insight as possible from each experiment but also to minimize the disruption of their experiment on the political landscape. As field experiments have grown in popularity – Desposato’s (2016) latest estimate is that 25% of all articles in the *American Journal of Political Science* contain an experiment – experimenters are under increasing pressure to ensure their experiments do not disrupt politics and maintain high ethical standards.

There are rising concerns about field experimental ethics. Some have to do with sample size – Bertrand and Mulainathan (2004) sent 5,000 fictitious résumés to potential

employers. Was the sample size worth the lost productivity? Others deal with questions of consent. What about experiments that contact public officials or elected representatives, individuals for whom the Institutional Review Board guidelines provide a near-blanket exemption for research? Does the scholarly value of the experiment offset the lost time and public funds spent replying to audit studies? What if an experiment affected an election outcome?

These are questions that continue to challenge the research community. Most of the responses from scholars have been to think broadly about individuals who might be impacted or about the fairness of who is likely to benefit from experimentation. This chapter aims to turn the conversation to one place where the tools of social science can help increase the quality of our experiments: experimental design.

Experimental ethics and the ‘leave no trace’ principle suggest that through experimental design, it is possible to design better

experiments. Our aims should be to maximize the scholarly value from each endeavor while also minimizing disruption, which may imply minimizing sample size. There are risks in engaging in experimental research in terms of disrupting the political landscape, and there are also costs that experimental researchers impose on subjects, whether deliberately or accidentally. Yet, there are also very real risks of failing to learn about our political world and carefully understand cause and effect. Some experimental designs leave less of a trace – and gain more knowledge – than others. This chapter provides a brief overview of five experimental designs that are on the frontier of the field experiment community's use. While infrequently used by political scientists, they have broad support from biomedical researchers, Google Analytics, and psychologists as strategies that can be employed to strengthen research impact. In the following section, this chapter will introduce each of these strategies and discuss the benefits of each. The chapter concludes with a call for expanding the EGAP conference model to researchers presenting research in the design phase, as a way for our field experiment community to continue to design better.

## EXPERIMENTAL DESIGNS

Many field experiments merit a very simple design – the randomized-control trial – in which the units of observation (e.g. individuals, groups, institutions, states) are randomly assigned to treatment and control groups. The randomization ensures that every observation has the same probability of being assigned to the treatment group. This implies that the outcomes are identical in expectation, so we are then able to draw causal inferences based upon the Rubin Causal Model (Rubin, 1978). Let  $i$  be an observation,  $Y_0$  be the outcome if  $i$  is exposed to control, and  $Y_1$  be the outcome if  $i$  is exposed to treatment.

The treatment effect is the difference between the two potential states of the world:

$$\tau_i = Y_{i1} - Y_{i0}.$$

Averaging across our units of observation, we define the average treatment effect (ATE) as

$$ATE = E(\tau_i) = E(Y_{i1}) - E(Y_{i0}).$$

With a handful of assumptions (typically made in this context: exclusion restriction, monotonicity, and SUTVA), we can then estimate this quantity using our randomized data as

$$E(Y_{i1} | T_i = 1) - E(Y_{i0} | T_i = 0).$$

This design is tremendously attractive in that it is highly intuitive: by simply subtracting the average outcome in the control group from the average outcome in the treatment group, it is possible to estimate the effect of the treatment. The comparison is made between the treatment and control groups. Yet, this is not the only possible design for field experiments. This chapter explores several alternative designs that researchers may want to consider.<sup>1</sup> In particular, many of these alternative designs have clear advantages in terms of the intensity and exposure for the intervention for the target population – some designs may be able to produce equally valid inferences, for example, with smaller sample sizes, and others may be able to allow a more dynamic adjustment of the treatment protocol. What is important to note about the conventional randomized-control trial is that the relevant comparison to draw causal inferences is made between observations. This chapter will briefly present several of these alternative designs that are not frequently employed in political science research and encourage researchers to think broadly about the optimal research design for their experimental framework, particularly in cases where their designs may permit variability in measuring outcomes over time.

## ***Crossover and Stepped-Wedge Designs***

Many experiments consider the unit of analysis to be a cluster (e.g. a school, a family, a village, a precinct), and experiments that employ this feature are called cluster-randomized trials. In this context, the clusters – and not the individuals – are randomized to treatment and control. They are frequently employed when individual randomization is not possible because of concerns regarding spillover or logistical hurdles (for an example, see Paluck and Green, 2009). These experiments are typically costly in terms of sample size because analysis is conducted at the cluster level. That is, inferences are conducted by looking between clusters.

In a crossover design, every cluster will instead receive both treatment and control. Randomization occurs with respect to timing – the order of the interventions is randomized for each cluster. This has a clear advantage in that it improves the efficiency of the cluster-randomized trial, as it permits the researcher to leverage variation both between and within clusters. Yet, for perhaps obvious reasons, it is not always prudent to conduct an experiment based on a crossover design, as this experimental setup assumes the absence of carryover effects. That is, the estimated treatment effects are independent of the order in which the treatment was assigned.

In many cases, it is completely unrealistic and unreasonable to assume that the effects of the treatment will have fully disappeared by the time the control wave has started. Thus, an extension of the crossover design is a stepped-wedge design. In this framework, clusters switch from control to treatment in only one direction and at different points in time. These distinct time points are the ‘steps’ of the experiment. Each cluster is randomly assigned a point in time to switch from control to treatment, and by the close of the experiment, all clusters will have switched from control to treatment.

There are clear ethical benefits to this design, first and foremost being that all

clusters in the experiment will eventually receive treatment – assuming the treatment is a normatively positive good – then this design ensures that all communities in the experiment will eventually benefit from having participated in the trial. It may also expand the number of institutional collaborators for researchers. For example, as reported in Gerber et al. (2011), the Perry campaign was willing to participate in the randomization of advertisements into media markets, conditional upon all markets receiving their advertising message. Another feature of this design is that clusters act as their own controls, as they receive both the control and treatment conditions. Thus, a second ethical benefit of a stepped-wedge trial is directly attributable to its statistical power – because this experimental design leverages both between and within cluster comparisons, there is more statistical power and thus the experiment requires a smaller sample size than a cluster-randomized experiment (Woertman et al., 2013; Baio, 2015).<sup>2</sup> It may be that the researcher would like to minimize their impact in a community, and thus minimizing the experimental size poses a clear advantage. There are practical reasons to favor a stepped-wedge experiment as well – in terms not of minimizing but maximizing the capacity to deliver treatment. The size of the experimental population may be limited by a budget constraint due to the capacity of the research time. A stepped-wedge design maximizes the delivery of treatment by the research staff. A final note is that this design ensures that even if the experiment were to stop during the experiment (occasionally unexpected things happen in field experiments), this design would permit inferences, because of the random assignment to clusters over steps.

A stepped-wedge design also contains some risk – it requires that the treatment be delivered without variability across waves. If, for example, the experimental treatment involved auditing, then it is possible that the auditors would become more experienced by the final wave and thus would not deliver a

constant treatment. Additionally, there can be no shifts in the underlying population during the experimental window.

### ***Multi-armed Bandit and Adaptive Design***

In the context where an experiment could potentially compare – or want to compare – an arsenal of competing treatments, again the randomized-control trial may not be the optimal choice. A multi-armed bandit design may help the researcher identify the most promising treatment. Like the stepped-wedge design, this type of experiment requires the possibility that it be conducted across multiple waves. The principle argument for a multi-armed bandit experiment is that of efficiency: this design will help the researcher ascertain the most effective treatment by adapting the proportion of subjects over multiple waves of the experiment.

The intuition for the multi-armed bandit comes from slot-machine gambling – the intuition is that there is an arsenal of competing slot machines (the bandits), where the researcher is tasked with simultaneously estimating each slot machine payout (explore) and using the best slot machine to maximize winnings (exploit).<sup>3</sup> Each exploration costs money that could otherwise have helped generate winnings, so there is a tension between exploration and exploitation. In political science language, a campaign might be interested in sending mailers, canvassers, robo-calls, or social media advertisements across a variety of channels to potential voters in order to moderate support. How should the campaign best optimize the use of its resources? Similarly, it is under time pressure to find the right answer *quickly* and then allocate as many of its resources to that strategy as possible. In this case, a multi-armed bandit experiment may be appropriate and, in some contexts, arguably more ethical, particularly when the design needs to produce results with speed.

How does this work? In brief, the researcher allocates some portion of experimental subjects to the explore phase, and in the first wave, subjects are allocated equally across all waves. After the first wave, the outcomes are evaluated and then, based upon the rates of success across treatments, new subjects are re-allocated in the second wave. So, for example, if one treatment arm was three times more efficacious than all others in the first wave, it would receive three times more subjects in the second wave. This process repeats in the third wave, with the proportion of subjects for each treatment adjusted by considering the outcomes in all previous waves.<sup>4</sup> Eventually, not only is the optimal treatment arm discovered but the majority of subjects are assigned to this arm.

Like with the stepped-wedge design, there can be no shifts in the underlying population during the period of experimentation. For a long multi-armed bandit process conducted over the course of an election campaign, during which new information may emerge about candidates, this could be problematic. Finally, multi-armed bandit processes may struggle if no one treatment is superior to the others (Offer-Westort et al., 2019).

### ***Spillover***

Frequently, field experiments administer treatment that consists of information. Most field experiments make the assumption that there are no spillovers – known as the non-interference assumption (part of SUTVA). Yet, in instances where researchers have designed their experiment to account for the possibility of information spillover, they have found at least suggestive (if not compelling) evidence that spillover does take place, most likely between close social ties (Nickerson, 2008; Bond et al., 2012; Sinclair et al., 2012).

Hierarchical design, where the social structures are explicitly theorized and randomization is conducted based upon those

structures, allows not only estimation of treatment effects but also spillovers (Hudgens and Halloran, 2008; Sinclair et al., 2012). Essentially, hierarchical design requires a weaker assumption than non-interference. Specifically, the assumption is based upon the particular social model used but generally permits subjects to spill over their treatment to subjects in nearby geographic spaces. That is, the assumption is that there will be only the modeled spillovers.

There are other strategies to explicitly acknowledge the possibility of spillover, too. These include Aronow and Samii's (2015) strategy to explicitly assign treatment based upon network structure and Bowers et al.'s (2013) strategy to consider modeling the explicit dosage an individual would receive based upon the possible spillover. What all these strategies have in common, however, is that they require the researcher to articulate a theory about where spillovers are likely to occur.

There is tremendous value in designing an experiment to account for spillovers. Beyond the social science knowledge we could glean from a better understanding of the social transmission of political information, designing an experiment that accounts for the potential of spillovers also gives us a way to understand the broad impacts of our research. While institutional review boards consider the impact of research on those we contact, they do not consider the impact on those who are socially connected to those we contact. If our treatments are contagious – if they spill over into adjacent neighborhoods, precincts, or ZIP codes – then not only does it provide critical social science knowledge, it also helps us better understand our research impact.

The range of experiments for which we do not have estimates of spillover – which instead fall into the family of experiments where information is delivered to a randomly assigned group of individuals – is vast. For example, they include experiments where the information focuses on corruption (Ferraz and Finan, 2008; Chong et al., 2011), violence (Collier and Vicente, 2014), and voting

(Gerber et al., 2008; Sinclair et al., 2013). In each of these instances, these experiments may have impacted the family and friends of those contacted. Imagine instead if we knew what the spillover estimates looked like in these contexts! Whether hierarchical or otherwise, incorporating estimates of spillover into a research-design protocol allows not only the estimation of the social effect but also the capacity to understand who may inadvertently be affected by the experiment.

### ***Selective Trials***

A lively and ongoing debate regarding the external validity of field experiments (Deaton, 2010; Imbens, 2010; Deaton and Cartwright, 2018) generated a broad set of interest in the extent to which the experimental subjects themselves could be modeled in order to increase external validity. Selective trials offer one such strategy (Chassang et al., 2012): extending the randomized-control trial to estimate the degree of effort needed to be deployed by subjects if the results are to be generalized.

In short, the outcome observed by each subject is a consequence of her treatment assignment and effort. Yet, her effort is private information. Insight into that information can be gleaned via mechanism design, by charging a price for treatment: subjects first send a message to the researcher, revealing the price they would pay for treatment, and then once price is drawn from a distribution of possible prices, subjects are allowed to purchase the treatment if the price is below their message. The willingness to pay is a good instrument for estimating marginal causal effects (Heckman and Vytlacil, 2005), as willingness to pay is a good signal of effort. The aim of this additional feature is to disentangle the treatment effect from the effort effect (associated with the belief of the subject as to the efficacy of the treatment). This has the clear benefit of increasing the external validity of the experiment, given that it demonstrates the

value the subjects of the experiment place on the treatment.

Apart from the logistical hurdles of implementing a selective trial design in the field, it may also be the case that the subjects may not play dominant strategies (in which case their messages would not be good signals of their actual effort).

### ***Causal Mechanisms***

Randomized-control trials allow us to make inferences about whether the treatment causes the outcome. However, they frequently do not tell us how and why the treatment causes the outcome. The how and why components are the pieces we refer to as causal mechanisms – the causal pathway from treatment to outcome. Many times, the variable that was manipulated – or can be manipulated – is not the mediator but rather the treatment variable.<sup>5</sup> Imai and Yamamoto (2013) suggest a strategy to elicit causal-mediation effects via research design. For example, they propose a parallel design where in one half of the sample, treatment is randomized, the mediator is measured, and the outcome is measured. In the second half of the sample, treatment is randomized, the mediator is randomized, and the outcome is measured. In this framework (with a consistency assumption), the ACME is identified. While many mediators are simply not easily manipulable, there are other strategies that can nudge variation, such as encouragement designs (Imai and Yamamoto, 2013; Imai et al., 2013).

Not every experiment can manipulate a mediator. But, for those where manipulation is possible, it transforms the randomized trial into one that reveals not only whether the treatment causes the outcome but also how and why. This chapter argues that when experiments take place, we should squeeze all possible knowledge out of that endeavor. Learning everything we can about a treatment ensures that the experiment produces the most knowledge possible for future scholars.

### **CONCLUSION**

As the community of scholars begins to consider the impact of field experiments on the world at large – and the ethics of field experiments – it is important to recognize that ethics and experimental design are inherently and deeply intertwined. The scholarly value of a study is deeply associated with its design – and this chapter suggests five strategies that are at the frontier of field experimental research in political science, but which can augment research designs. By minimizing our impact on the world while maximizing our scholarly insights, we can design better and more ethical field experiments.

This chapter has explored five potential strategies for extending field experiments to the frontier of our discipline. Each have clear ethical arguments as well as practical ones. The stepped-wedge design permits greater flexibility with institutional partners. Instead of asking organizations to provide a control group – which can be challenging unless there is a binding budget constraint that prevents them from contacting all experimental subjects – a stepped-wedge design ensures that all subjects will receive treatment, just at randomly varying times. This research design has the added benefit of improving statistical power and, in some cases, researcher efficiency.

Adaptive designs – typically framed as multi-armed bandit designs – can quickly ascertain the most productive treatment arm. Much of the experimental work that happens in the field experiment community occurs in the developing world, where resources are scarce and quick improvements in policy can truly have life-changing outcomes for experimental subjects. So, whether the experimental treatment options involve de-worming drugs vs school uniforms vs teacher photographs to study school attendance or a myriad of media channels to contact potential donors, a multi-armed bandit design can expedite the learning process.

Many field experiments surely have treatments that spill over from one individual or community to another – particularly when

that treatment is information. As an academic community, we have few estimates of these effects. Designing experiments to measure spillover not only allows the research community to accumulate knowledge about contagion but also ensures that researchers are aware of the impact their research has on those who are not explicitly part of the study.

Selective trials offer one strategy to increase the generalizability of our experiments. There will surely continue to be ongoing debate on the merits of estimating an average treatment effect for a specific population, and by pushing our research to think carefully about the ways in which the underlying population would otherwise seek out the treatments – and at what cost – is one way to consider the potential impacts these experiments could have more broadly.

Finally, embedding causal-mediation analysis into experimental work, when possible, allows us to better understand the causal process. If there are ways to do additional experimentation, such as the parallel design advanced by Imai and Yamamoto (2013), it may be possible to embed causal-mediation analysis into a conventional randomized-control trial. Each study that makes this choice increases our knowledge of the world around us.

Research-design choices are challenging choices. Recently, an experimental community – EGAP – has grown, which challenges researchers to design better by encouraging them to present research designs in advance of starting an experiment. These conversations push scholars to think more broadly – and arguably more ethically – about the experiments they are likely to conduct. Software, such as DeclareDesign,<sup>6</sup> makes this easier for researchers to accomplish. This chapter has suggested only five possible designs that are used infrequently – although they are generally applicable to both survey and field experimentation. Finding the right design requires a research community. The EGAP model should be extended to all major political science conferences, so that researchers are strongly encouraged to present research at

the design stage. By working collaboratively, we can continue to design better, stronger, richer, and more ethical experiments.

## Notes

- 1 We can also define the average treatment effect among the treated (ATT) as

$$ATT = E(\tau_i | T_i = 1) = E(Y_{i1} | T_i = 1) - E(Y_{i0} | T_i = 1)$$

- 2 A stepped-wedge design could also be considered at the individual level, allowing the researcher to draw from both within and between variation. Indeed, repeat measures on individuals produces a powerful experimental design, although it requires the researchers to be able to measure the subject's outcomes at each wave in the experimental design.
- 3 Multi-armed bandit experiments are used by Google Analytics to place advertisements because of their efficiency relative to randomized-control trials (Whittle, 1980) and are increasingly employed in medical trials (Chin, 2016).
- 4 For more detail and a technical explanation, please see Offer-Westort et al., 2019.
- 5 For example, Brader et al. (2008) vary ethnic cues to evaluate their effect on immigration attitudes. They expect that this effect is manipulated by anxiety. Based upon the methodological innovation of Imai et al. (2012), it is possible to calculate the average causal-mediation effect (ACME), assuming sequential ignorability.

# Field Experiments, Theory, and External Validity

Anna M. Wilke and Macartan Humphreys

## INTRODUCTION

In a recent study, Yeh et al. (2018) report on the first randomized control trial that tests whether there are health benefits from wearing parachutes when jumping out of airplanes and helicopters. The authors find no evidence of benefits from wearing parachutes. A potential weakness of the study is that, in order to protect human subjects, the airplane and helicopter used for the trial were small, stationary, and grounded. For critical readers this detail might raise flags about whether we can generalize from this study to other applications of interest.

Of course, Yeh and colleagues meant their study as a joke. It is *obvious* that you cannot learn anything about effects in realistic situations from this experiment. We think, however, that it is not entirely obvious why it is obvious. The experiment lacked external validity, perhaps, because the ‘target’ applications of interest involve planes that are in flight and far from the ground. The sample of

jumps is not *like* the population of jumps out of an aircraft that we are interested in. Yet we might not have that concern were the plane in the air but not in flight – for example, if it were attached to a large crane, even though in this case, too, the study would not be like the target applications of interest. Why would we be less concerned? The reason is that our determination of ‘likeness’ depends on a prior model of how things work – in this case that falling at speed is a key mechanism that is interrupted by parachutes and that speed depends on the height from which you jump. So, it seems, a theory is used to assess external validity.

This chapter is about such theories and the role they play in assessing external validity. We are motivated by persistent concerns with field experimental approaches, which have seen an explosion in political science in the last 15 years (Druckman, et al., 2011<sup>1</sup>; Grose, 2014). Core concerns are that experimental results lack external validity and are disconnected from theory. As in the parachute

example, these two concerns are deeply interrelated. Put differently, the charge is that political scientists are doing parachute experiments from stationary planes without knowing it.

In the following sections, we describe these concerns and review strategies to address them. We begin by introducing a stylized example that we draw on throughout the chapter. We then review challenges that arise from a weak connection to theory and limited external validity and describe approaches to address these. Finally, we extend our example to illustrate opportunities and risks of parametric structural estimation with experimental data, an approach that links estimation closely to theoretical models and that, in principle, allows for inferences that go beyond those available with design-based approaches alone.

## PRELIMINARIES

### *A Running Example*

Throughout this chapter, we will make use of a stylized example of a fictitious field experimental study that seeks to explain bargaining outcomes. We imagine a study of the bargaining process between taxi drivers and customers. See Michelitch (2015) and Castillo et al. (2013) for existing studies of this kind.

We assume we want to explain why some taxi customers have to pay higher taxi fares than others. We start with a simple theory that says that taxi prices are determined by three variables: whether the customer or the driver makes the first offer, how many offers and counteroffers can be made before bargaining breaks down (the number of bargaining rounds), and the behavioral ‘type’ of the customer.

Whether the customer makes the first offer might be thought of as linked to the customer’s identity, assertiveness, or skills. Skilled negotiators, for example, may be more likely

to approach the driver with an offer. How long bargaining can continue may depend on contextual factors such as the competitiveness of the taxi market. Finally, customers may behave in different ways. Some customers may be ‘rational’ decision makers in the narrow sense that they seek to maximize their material gains from the bargaining process. Others may seek to follow established fairness norms. For simplicity, we presume that taxi drivers are always of the first type.

With this theory in mind, we imagine running a field experiment that focuses, first, on the effect of making the first offer. Suppose we recruit a sample of taxi customers, provide each of them with the same sum of money and ask them to negotiate a taxi fare for a certain distance. Taxi customers can keep whatever they do not spend on the ride. We randomly assign half of the taxi customers to approach the driver with an offer (‘move first’) while the other half is instructed to ask the driver for a price (‘move second’). Additionally, we will imagine being able to control for how long bargaining can continue. We will assume players have common knowledge over endowments and types.

This example is certainly contrived. But it has the advantage that it draws on simple and well understood theoretical models, which makes the example useful for demonstrating core ideas and for walking through the development and use of structural models. One should not infer, however, that models of this form are always so simple to set up and estimate.

### *What We Mean by Theory*

Critics worry that a disconnect from theory limits the types of inferences that can be drawn from experimental research (Card et al., 2011; Deaton and Cartwright, 2018; Harrison, 2014; Huber, 2017).

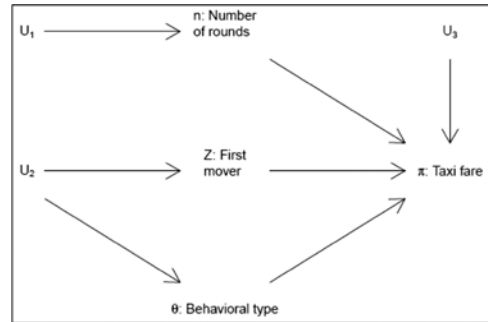

What is theory? Conscious that the term is used to mean very different things in different research communities,<sup>2</sup> we will make use

of a quite simple notion of theory: by theory we will mean a set of general claims about the causal relations among a set of variables, from which more specific claim (for instance, about a case) can be deduced under the supposition that the theory is true.<sup>3</sup> For instance, if theory *T* says that all taxi customers who make the first offer end up paying a lower fare than those who let the driver make the first offer, then the specific claim ‘this customer will pay less if she makes the first offer’ follows from the theory. Theory *T* is not very deep; it is little more than a proposition. Yet, theory *T* itself could be implied by a deeper theory, for example a claim about equilibrium offers in a class of bargaining games (of which we take the taxi game to be an instance). We thus treat depth as a property of a theory and not as part of the definition of theory.

Drawing on work by Pearl (2009) and the treatment in Humphreys and Jacobs (2017), we think it useful to distinguish between three ‘levels’ of theory that differ in the specificity with which they describe the relations between variables. Even though, in practice, not all theories will neatly fall under one of these levels, this classification helps organize our thinking about theories and theory development.

**Level 1:** Level 1 theories identify variables of interest and specify the structure of causal relationships between them. Examples are non-parametric structural equation models or causal DAGs (Directed Acyclic Graphs) (Dawid 2010).<sup>4</sup>

Figure 53.1 shows an example of a causal DAG for the Level 1 version of our simple bargaining model. The graph lists the variables that the theory considers and the structure of relations between these variables. An arrow from *A* to *B* means that, in some situations, a change in *A* induces a change in *B*. There are unobserved factors  $U_3$  that affect the taxi fare and unobserved factors  $U_2$  that affect both, whether the customer makes the first offer and the customer’s behavioral type. The Level 1 version of our theory also contains information about which variables do not affect each other. For example, the

**Figure 53.1** A directed acyclic graph (DAG) for a non-parametric bargaining model

number of rounds for which bargaining may continue is determined by unobserved factors  $U_1$ , but these unobserved factors do not have a direct impact on any of the other variables in the model.

Note that although the theory involves many substantive claims, it has no implications for effect sizes or even whether or not variables interact with each other to produce outcomes.

**Level 2:** rather than simply specifying the qualitative structure of the causal relationships between variables, a theory may contain statements about the functional form of these relationships. These might be qualitative statements about marginal effects, for example: ‘making the first offer in taxi bargaining reduces the price that the customer has to pay’. Alternatively, a Level 2 model may contain fully specified functional relations,  $f = f_1, f_2, \dots, f_n$ , one for each endogenous variable.

For instance, a parametric bargaining model might add to the Level 1 model the following functional relationship between the number of possible bargaining rounds  $n$ , the customer’s first-mover status  $z_i$ , the customer’s behavioral type  $\theta_i$  and  $\pi_i$ , the taxi fare paid by customer  $i$ :

$$\pi_i = \theta_i(z_i\omega + (1 - z_i)(1 - \omega)) + (1 - \theta_i)\phi + u_3$$

where  $\omega = \sum_{t=2}^n (-1)^t \delta^{t-1}$  is the taxi price predicted by the Rubinstein (1982) bargaining

solution under the assumption that taxi bargaining follows an alternating offers protocol with  $n$  possible bargaining rounds, that customers and drivers act rationally, and that the customer gets to make the first offer. This representation normalizes the ‘pie’ that the customer and driver are bargaining over to 1. In the context of our running example, we can treat  $\omega$  as the share of her endowment that a rational customer ends up paying to the driver if she moves first.  $\delta$  stands for a discount factor (see the section ‘Illustration of a Parametric Structural Model Connecting Theory and Experimentation’ for more details). This Level 2 version of our theory implies that rational customers ( $\theta_i = 1$ ) pay the price implied by the Rubinstein bargaining solution. This price depends on whether customers go first ( $z_i = 1$ ) or second ( $z_i = 0$ ). Non-rational customers ( $\theta_i = 0$ ) insist on giving the driver some share  $\phi$  of their endowment, irrespective of whether they go first or second. The last term,  $u_3$ , is a random disturbance.

This theory is not well motivated, but, as is well known, the behavior of rational types can be derived from a more complex Level 2 model that fully specifies the extensive form of the bargaining game and allows for a richer characterization of optimal behavior (e.g. offers and responses in every period). We provide this motivation below.

Unlike a Level 1 theory, the Level 2 theory *can* make claims about the values of endogenous variables given the values of exogenous variables. However, even a Level 2 theory might not be enough to make claims about the average effects of treatments.<sup>5</sup>

**Level 3:** a still more fully specified model might add assumptions about how the set of unobserved exogenous variables  $U$  is distributed. A theory that specifies all of these elements is called a probabilistic causal model by Pearl (2009).

Note that a Level 3 model implies a Level 2 model and a Level 2 model implies a Level 1 model, but the converse is not true. Note

also that starting from a Level 1 model, one could use data to develop a Level 2 or a Level 3 model.

### ***What We Mean by External Validity***

The most common external validity critique holds that findings from field experiments may not tell us much about processes in contexts other than the one where the findings were generated (Lucas, 2003). Many discussions of threats to external validity focus on whether the study population is sufficiently similar to a *target* population of interest. This framing gives rise to what might be the more useful term, ‘target validity’. Can we make claims to a particular target of inference (Westreich et al., 2018)?

More broadly, Cronbach and Shapiro (1982) describe four dimensions along which studies may differ from their inferential targets, in terms of units, treatments, outcomes, and settings (collectively, ‘UTOS’). Using the language of causal models, we can distinguish three of these four dimensions. Units and contexts are equivalents in the language of causal models.

Let  $W$  denote an observed or unobserved collection of background variables;  $Y$  and  $V$  denote outcomes, and  $Z$  and  $X$  denote treatments. The question about units and contexts is:

- What can we infer about the distribution  $\Pr(Y = y|Z = z, W = w)$  from our knowledge of  $\Pr(Y = y|Z = z, W = w)$ ? For instance, what does an experiment in a place with competitive taxi markets tell us about the effect of moving first in taxi bargaining when taxi competition is low?

The treatments question is:

- What can we infer about the distribution  $\Pr(Y = y|Z = z)$  from our knowledge of  $\Pr(Y = y|X = x)$ ? For instance, what does a study

of the effect of moving first in taxi bargaining on prices tell us about the effect of an increase in taxi competition on prices?

The outcomes question is:

- What can we infer about the distribution  $\Pr(V = v | X = x)$  from our knowledge of  $\Pr(Y = y | X = x)$ ? For instance, what do we learn from the impact of moving first in taxi bargaining on taxi fares about the effect of moving first on the duration of taxi negotiations?

## CONCERNS AROUND THEORY AND EXTERNAL VALIDITY IN FIELD EXPERIMENTS

### *Why Worry About Theory?*

We can distinguish at least four worries that result from weak connections between theory and experimental research. Two relate to the applicability of findings and two, more fundamentally, to the orientation of research.

#### *Undefined scope: units and settings*

As in the parachute example, without theory, researchers will not have the information needed to think through which units and settings are ‘similar enough’ to a given study environment in order to license the transportation of results.<sup>6</sup> The concern might be less severe if experiments use random samples from the target population of interest and produce homogeneous results within strata. However, if such conditions do not hold and researchers do not have access to theory, they may be at a loss about what broader inferences they are licensed to draw.

#### *Undefined scope: treatments and outcomes*

It is often not feasible to experimentally evaluate all relevant versions of a particular

intervention or to examine all outcomes of interest. Target inferences may then require extrapolation to effects of treatments, or effects on outcomes that were not studied by an experiment. For example, field experiments tend to involve versions of interventions that have a lower dosage or shorter time horizons than target applications. Similarly, field experiments sometimes examine effects on proxies of ultimate outcomes of interest. Consider, for instance, a study that shows that information changes attitudes of voters but does not feature data on actual voting behavior. Making inferences to voting behavior then requires understanding how attitudes affect voting (among those for whom information affects attitudes).

These two worries illustrate the connection between theory and external validity. Unaccompanied by theory, experimental results do not give a handle on how to extrapolate out of sample or make inferences to other relations of interest. Weak connection to theory leaves open the question of whether and how results can be generalized.

The next two concerns relate to the questions being asked.

#### *Restrictive estimands*

Experimental research largely limits itself to estimating variants of the average treatment effect. By the magic of the linearity of expectations, random assignment lets one estimate average differences between outcomes in treatment and control conditions by looking at the differences in average outcomes in treatment and control groups. However, many questions of interest are not summaries of average treatment effects. Consider, for example, questions about so-called ‘causes of effects’ as opposed to ‘effects of causes’. Imagine a field experiment that randomly assigns individuals to go first in bargaining. Randomization does not, in general, let researchers answer the question: ‘Knowing that individual *A* made the first offer, what is the probability that she would have paid a

higher price had she not made the first offer?' Murtas et al. (2017) show that, although this quantity is not identified, bounds around this probability can be tightened by drawing on theoretical knowledge about the variables that mediate the relationship between the treatment and the outcome of interest (even if such mediators are not observed).

### *The point of empirical work is to learn about theories*

The point of research, critics argue, is to understand *how* things work. In other words, the *goal* is to develop theory. Engaging in research while ignoring theory is thus missing the point. Experimentalists, in this view, are too often satisfied with 'black-box' accounts that do not go beyond causal relations between variables. Deaton (2010), for instance, advocates for a more explicit focus on the usage of causally identified empirical work to test hypotheses that are derived from a lower-level theory in order to learn about the validity of the theory itself, and not just to generate a case-specific estimate.

Subsequently, we will explore in more detail some of the ways in which researchers have responded to these worries.

### *Why Worry about External Validity?*

Some of the concerns around external validity apply to all research. In general, empirical work does not ever draw on a random sample of the units to which inferences might be made – if only because we want to make inferences to future events from past events. In a sense, experiments can be thought of as case studies and, hence, as facing challenges that affect all case study research.

Beyond that, however, there are ways in which experiments are especially vulnerable to external validity concerns. Through experimentation, researchers alter the world to make it amenable to study. A core worry is

that, in doing so, researchers actively create distance to target environments.

### *Threats arising from control*

Insofar as experimenters control the conditions of an experimental study, they risk orchestrating environments that differ from the target environment in ways that researchers might not be aware of.

Experiments may, by design, hold relevant variables constant at typical levels. For example, suppose we are interested in both the effect of going first in taxi bargaining and the effect of increasing the number of possible bargaining rounds. Say we randomly assign taxi customers to go first and also vary for how long bargaining can continue. An experiment of this kind allows us to estimate the effect of additional bargaining rounds among customers who have been assigned to go first or second. Yet, this effect may differ from, say, the effect among those who actually choose to go first outside our experiment. Voluntary first movers may be systematically different from other customers. A design that randomizes who goes first provides no information about who would have gone first outside the experiment and, as a consequence, makes it impossible to obtain effect estimates among this group without further assumptions.

In addition, *how* variables are controlled can matter. The process of random treatment assignment in itself may have consequences. For instance, voters might not reward a politician for patronage if they know that patronage was distributed at random, precisely because rewards normally result from the information communicated by a transfer rather than by the transfer itself (see also the treatment in Mesquita and Tyson, 2019). The problem here is an exclusion restriction violation.

### *Threats arising from selection*

Very often, neither the sites nor the subjects of experimental studies are randomly selected. Especially for experiments that depend on

partnerships with government or other implementing partners, site selection tends to be contingent on the willingness of partners to participate. Yet, governments that are willing to assess anti-corruption interventions, for example, may be fundamentally different from those that are not. The problem is akin to that in medical studies where subjects who are willing to participate tend to be those most likely to stick to regimens. See Allcott (2015) for an example of how bias can arise from non-random site selection.

Problems can also arise if experimentalists study treatments, or variants of treatments, that are amenable to manipulation but wish to make inferences to treatments that are not (Thelen and Mahoney 2015). A common example is a situation in which a small scale intervention is studied – because it is feasible – though the target of inference is the effect of a large scale intervention (Bold et al. 2013).

### *Threats arising from inferential strategies*

External claims from experiments can sometimes be rendered difficult by the fact that common approaches to analyzing experimental data implicitly assume that the target of inference is the sample estimand, even if this is not always explicitly stated.

Randomization inference, for instance, can be used to calculate exact  $p$ -values – but only under the assumption that all variability comes from assignment processes within the sample and not from the selection of the sample itself. Similarly, at least under the assumption of constant effects, clustering standard errors at the level of treatment assignment can produce confidence intervals with the correct coverage. Yet, this approach implicitly assumes that study units have not been randomly sampled in a clustered way. Suppose, for example, that a study randomly samples a set of schools and assigns an intervention on the classroom level. In this case, clustering might have to be performed at levels above the level of assignment – though

this analysis strategy is not common practice (Abadie et al., 2017).

To be clear, these are ways in which the tools of experimental analysis tend to orient researchers towards sample inference, even though, in principle, approaches that focus on population inference can certainly be employed with experimental data.

## **THE PLACE OF THEORY IN EXPERIMENTAL RESEARCH**

In practice, experimentalists can employ a range of strategies to combine theory and experimental work (or not). We discuss six of these.

### ***Strategy 1: Push Back – Experimentation Obviates the Need for Theory***

A first response to the critique that experimental research tends to be atheoretical is unapologetic. The absence of theory is a strength. As characterized by Heckman (1991), the ability to dispense with theory was, if anything, a motivation to engage in experimentation. That you can find out whether democratic institutions cause growth without having to assume a model of human behavior is remarkable, and to be celebrated. The identification of average causal effects is not possible from observational data without a model that tells you which variables you should or should not condition on (Pearl, 2009). An experiment removes much of this model dependence.<sup>7</sup>

This response leaves open the question of how experiments can be used to learn about theories. Moreover, despite the remarkable ability of experiments to identify average treatment effects under minimal assumptions, there are quantities that cannot be learned from an experiment. Both topics are discussed in more detail below.

### **Strategy 2: Use Theory as a Helper for Inference**

One strategy for bringing experiments together with theory is to use theories to draw inferences that could not be drawn based on experimental data alone. Consider the following examples:

- 1 *Transportation of results to other settings.* Suppose we conduct an experiment at a site *A* and we would like to use our treatment effect estimates to learn about the treatment effect at site *B*. Unless site *A* was randomly chosen from some population of sites that also contains site *B*, our experimental data alone do not speak to whether and how transportation from *A* to *B* is possible, unless additional assumptions are made. We discuss in the section ‘Strategy 6: Formal Transportation’ how a causal model can help answer these questions and provide an example in the section ‘Illustration of a Parametric Structural Model Connecting Theory and Experimentation’.
- 2 *Predicting the effects of other treatments.* Many causes of theoretical interest cannot be experimentally manipulated. Similarly, it is often prohibitively expensive to evaluate all policy-relevant variations of an intervention with an experiment. One solution is to make use of a structural causal model that serves as the basis for the extrapolation of estimates from a single, possibly small-scale experiment to the effect of a different intervention or of the same intervention at a larger scale. Todd and Wolpin (2006), for example, use a structural causal model to extrapolate estimates of the effect of a randomized school subsidy program in Mexico to the effects of similar programs with different subsidy schedules. See ‘Illustration of a Parametric Structural Model Connecting Theory and Experimentation’ for an example.
- 3 *Inferences to unidentified causal quantities.* There are causal quantities that cannot be estimated without additional assumptions, even when the treatment of interest has been randomized. For instance, as noted above, while the ‘causes of effects’ estimand is not identified by randomization, randomization can be used to generate upper and lower bounds. Dawid et al. (2019) show how these bounds can sometimes be tightened if we measure the values of mediators

through which the treatment affects outcomes. In short, knowing that *X* causes *Y* through *M* may improve our inferences about whether *X* caused *Y* for a particular unit.

### **Strategy 3: Use Theory as a Helper for Design**

Apart from helping with inference, theories can provide guidance for various aspects of experimental design. For example:

*Site selection:* causal models may help us decide where to run an experiment. We may want to choose, for instance, a site that allows results to be transported to as many other settings as possible. As we discuss in the section ‘Strategy 6: Formal Transportation’, causal models provide guidance on the extent to which an experiment conducted in one setting will be informative for treatment effects in other settings. Alternatively, if our aim is to test a causal model (see the section titled ‘Strategy 5: Use Experiments to Put Theories to the Test’), we may consider contexts for which the model’s predictions differ from the predictions of alternative models.

*Treatments:* causal models may help researchers decide which treatments to implement. If the aim is to test a causal model, we would obviously like to randomize causes relevant to the model. If the aim is to estimate the parameters of a structural model (see ‘Strategy 6: Use Experiments to Estimate Structural Models’), additional treatments can sometimes help with the identification of model parameters other than the effect of the treatment itself (DellaVigna, 2018).

*Sampling:* in the section ‘Strategy 3: Exploit Variation Within Studies’, we describe a way of transporting treatment effect estimates from a setting *A* to a setting *B* by calculating weighted averages of estimates within subgroups. Crucial for our ability to use this strategy is that our subject pool in setting *A* contains enough subjects in each subgroup to estimate treatment effects within these groups. Prior knowledge of

a causal model that tells us the dimensions along which treatment effects vary can help us design a sampling strategy that achieves this goal.

*Random assignment:* the same considerations affect the way in which we assign units to treatment conditions. Being able to estimate effects in a subgroup requires a sufficient number of treated and untreated subjects in this subgroup. We can fix the number of treated subjects in each subgroup by assigning treatment within blocks. Causal models thus help with the design of blocking schemes. In the presence of spillovers, causal models can also help decide how to allocate units across experimental conditions in order to maximize statistical power (Bowers et al., 2018).

*Measurement:* a causal model can help assess which covariates need to be measured in setting  $A$  and  $B$  in order to be able to transport treatment effect estimates from  $A$  to  $B$ . A causal model can also give us guidance on which variables we need to measure if we would like to bound our estimates of the probability of causation (see point 3 in the previous section).

#### **Strategy 4: Use Experiments as Building Blocks of Theories**

A fourth approach is to think of the ability of experiments to identify average treatment effects as an opportunity for inductive learning about theories. Being able to claim that  $X$  causes  $Y$  already establishes a theory of sorts. Beyond that, researchers sometimes stitch experimental results together to form more elaborate theories.

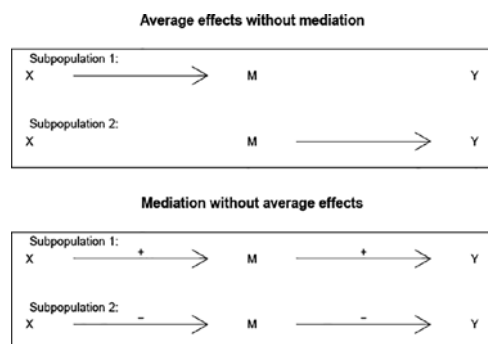

Imagine that we run our experiment that randomizes whether customers make the first offer in taxi bargaining. Moreover, suppose that we also find a way to randomly vary how many offers and counter-offers can be made before bargaining breaks down. For the sake of the argument, assume that the customers in our experiment are a random sample

from the population of interest. From this experiment, we could obtain estimates of the average treatment effect of going first for different numbers of bargaining rounds and of the average treatment effect of additional bargaining rounds conditional on whether the customer goes first. Even without prior knowledge of the causal model presented in the section ‘What we Mean by Theory’, we could use these estimates to ‘piece together’ the functional relationship between moving first, the number of bargaining rounds and the expected taxi fare in the population of interest.

Unfortunately, things become more complicated when causal models are slightly more complex. Consider an effort to establish that  $X$  causes  $Y$  through  $M$  by stitching together estimates of the effect of  $X$  on  $M$  and the effect of  $M$  on  $Y$  (Imai et al., 2011; Green et al., 2010).

Figure 53.2 shows two problems one might run into.

- 1 Even if a treatment  $X$  has an average treatment effect on a variable  $M$  and  $M$  has an average treatment effect on  $Y$ ,  $M$  might not be a mediator of the relationship between  $X$  and  $Y$  for any unit. For example, as in the upper panel of Figure 53.2,  $X$  may affect  $M$  among some set of units and  $M$  may affect  $Y$  among another set of units, but these sets may not overlap.

**Figure 53.2** The hazards of trying to stitch experimental results together to form a theory

- 2 Even if a treatment  $X$  has no average treatment effect on a variable  $M$ , and  $M$  has no average effect on  $Y$ ,  $M$  may mediate the relationship between  $X$  and  $Y$  for every unit. Such a situation could arise, as in the lower panel of Figure 53.2, if the effects of  $X$  on  $M$  and of  $M$  on  $Y$  have opposite signs in two subpopulations and therefore offset each other.

The broader take away is that there are limits to the extent to which experiments enable us to learn about causal models from empirical observation alone. Even if we were able to randomize all variables in a model, we would not be able to recover many causal quantities of theoretical relevance.

### **Strategy 5: Use Experiments to Put Theories to the Test**

Rather than seeking to *generate* theories, experimentation could focus on ‘selecting’ theories. Indeed, for many, the falsification of theories is what science is all about – at least in principle (Lakatos, 1970).

Experiments are useful for theory testing because they allow for valid statistical tests of hypotheses about causal effects. Of course, testable implications of theories can take many forms. Our theory about bargaining, for example, implies a correlation between the number of bargaining rounds and whether a customer moves first once we condition on the fare that the customer has to pay.<sup>8</sup> One advantage of implied causal relationships, however, is that they are often consistent with a smaller set of alternative theories. For example, imagine an alternative model according to which the number of bargaining rounds has a causal effect on whether the customer moves first. Both our model and the alternative model are consistent with the finding that the number of bargaining rounds and the customer’s first-mover status are correlated conditional on the taxi fare, but only one of them is consistent with the finding that the number of bargaining rounds causes the customer to move first. In short, being able to

test hypotheses about causal effects is essential for our ability to empirically distinguish causal models.

Perhaps the most common way of using field experiments for theory testing proceeds as follows:

- 1 Derive claims about marginal effects from a causal model, for example: ‘Making the first offer has a non-zero (positive or negative) effect on the price that the customer has to pay’.<sup>9</sup>
- 2 Design and implement an experiment to test a specified null hypothesis that is inconsistent with the claim (such as: making the first offer has a zero effect on prices).<sup>10</sup>

Recent work has pushed further on what can be done with testing. In particular, work in the tradition of Fisher (1935) and Rosenbaum (2002; 2010) has explored the potential of using experiments to test a set of more elaborate causal models against each other (see Bowers et al., 2013). More elaborate here means that these models specify a functional relationship for treatment and outcome for every unit conditional on one or more model parameters. For example, one of the simplest such models entails that going first adds the same constant  $\tau$  to the taxi price for all customers. A more complex model may specify that the taxi price is given by  $\pi_i = \alpha_i + \tau'z_i + \beta s_i$ , where  $\tau'$  is a constant effect of going first,  $s_i$  is the number of other customers in the same shared taxi who go first,  $\beta$  is a constant marginal effect of each additional first mover in a taxi and  $\alpha_i$  is the price that the customer pays when she and all other taxi passengers go second. Fisherian inference proceeds by hypothesizing specific values for the parameters in the model (e.g.  $\tau' = -0.2$  and  $\beta = -0.1$ ) and testing the null hypothesis that the assumed model and parameter values are correct. The same test is performed for a grid of parameter vectors for any given model and, also, for different models. For example, one could compare the  $p$ -value associated with a constant additive treatment effect model with  $\tau = -0.5$  to the

$p$ -value associated with the more complex model with  $\tau' = -0.2$  and  $\beta = -0.1$ .

In a recent application, Ichino et al. (2013) use this approach to test two different agent-based models of how party agents who aim to rig the voter registration process react to the placement of observers at randomly selected voter registration centers. They demonstrate how the close connection between the causal model of interest and the null hypotheses that are being tested facilitates learning about the causal model. They also show, however, that the wholesale rejection of one model for another is often impossible, since different models can imply the same distribution of outcomes for some values of their respective parameters.

### **Strategy 6: Use Experiments to Estimate Structural Models**

An approach that has been the norm in economics in the past (Heckman, 1991) and seems in the process of making a comeback (DellaVigna, 2018) is to use field experiments for the *estimation* of structural models. In the section ‘Illustration of a Parametric Structural Model Connecting Theory and Experimentation’, we demonstrate some of the advantages and pitfalls of this approach using our stylized example theory of bargaining. Here, we highlight the main points.

1 *Building a structural model*: the basis for structural estimation is typically a decision-theoretic or game-theoretic model from which the equations that link exogenous and endogenous variables in the model can be derived. A key step towards the specification of a model that can be estimated is the modeling of heterogeneity. For example, below we derive the taxi fare that a customer pays as a deterministic function of three variables (the customer’s behavioral type, the number of possible bargaining rounds and whether the customer gets to make the first offer) and of the customer’s discount factor, a parameter that we seek to estimate. Naturally, it seems unrealistic

that every subject in a real-world experiment would behave exactly in accordance with these functions. The DAG in Figure 53.1 represents this idea through the arrow that points from the unobserved variable  $U_3$  into  $\pi$ . Structural models explicitly incorporate such heterogeneity, typically by allowing for random shocks to the utility of players, for random implementation errors or for heterogeneity in model parameters (DellaVigna, 2018). Usually, these models assume that this heterogeneity follows a particular distribution.

- 2 *Identification*: in order to estimate them unambiguously, the parameters of a structural model need to be identified, i.e. the distribution of data should only be implied by one set of parameter values. If more than one set of parameter values can generate the same distribution of data, then we cannot distinguish true and false parameters from each other even with infinite data and even if the true data generation process is well captured by the assumed model. Sometimes, additional assumptions about functional forms or distributions are required for the purpose of identification.
- 3 *Estimation and extrapolation*: the estimation of the model parameters can be performed using one of various methods including Maximum Likelihood Estimation (MLE), Generalized Method of Moments (GMM), or Bayesian approaches. A key advantage of structural estimation is that the resulting estimates, together with the model, can subsequently be used for various extrapolations (e.g. towards the effects of the same treatment in other settings or the effects of different treatments) that go beyond what could be learned from experimental data alone.
- 4 *Theory dependence and cross-validation*: whether such inferences will be misleading depends, of course, on the extent to which the model itself is a good approximation to reality. Crucial to the extrapolation of results to other settings is often the assumption that the parameters of a model are ‘structural’ in the sense that they do not vary across settings (Acemoglu, 2010). For example, we estimate a discount factor which captures the extent to which individuals value the future relative to the present. In order to predict treatment effects for other settings, we need to assume that the players in these other settings have the same discount factor. Yet, individuals may not necessarily place the same value on the future in all contexts.

In response to such concerns, researchers can assess the sensitivity of their estimates to alternative assumptions and cross-validate their models in various ways. If we believe that certain parameters are indeed structural, one way to validate a model is to compare the resulting estimates of, say, the discount factor to estimates of the same parameters from other studies. Another possibility is to make predictions for other settings and compare those to actual data from these settings. See Martinez et al. (2017) and DellaVigna et al. (2017) for examples. In the section 'Illustration of a Parametric Structural Model Connecting Theory and Experimentation', we illustrate how the ability of experiments to obtain unbiased estimates of average treatment effects can sometimes be helpful for cross-validating a structural model.

## SIX STRATEGIES TO ADDRESS EXTERNAL VALIDITY CONCERNS

Below, we review six strategies that researchers have used to address the issue of external validity. While some of these approaches treat external validity as an empirical question, most of them draw, in some way or the other, on prior theoretical knowledge to determine whether and how the results from an experiment can be generalized.

### ***Strategy 1: Push Back – Researchers Should Focus on Sample Effects***

The first response is to ignore concerns over external validity and limit claims to sample effects. One justification for this, touched on already, is that empirical research in social science should be about testing general theoretical propositions and not about estimating effects. As long as a proposition applies to a sample, results from the sample can be declared consistent or inconsistent with the proposition even if they are not in other ways representative of a population.

### ***Strategy 2: Claim a Bellwether***

A second response is to assert that the case studied is in some way *especially* informative for other cases. Researchers often claim that their experiment is 'ideal' in some sense. This might mean that it is typical in some way, or that it is atypical in an informative way.

Say that we choose to run an experiment at a site that has some value on background variable  $X$ , and that we have good reason to believe that the causal effect of interest is decreasing in  $X$ . Then:

- 1 finding a positive effect in a location with a high value of  $X$  is informative for the claim that effects are in general positive in the target population;
- 2 finding a negative effect in a location with a high value of  $X$  is not very informative for the claim that effects are in general negative in the target population;
- 3 finding a positive effect in a location with a low value of  $X$  is not very informative for the claim that effects are in general positive in the target population;
- 4 finding a negative effect in a location with a low value of  $X$  is informative for the claim that effects are in general negative in the target population;
- 5 finding a positive (negative) effect in a location with a typical (e.g. modal) value of  $X$  is informative for the claim that effects are in general positive (negative).

Claims 1 and 4 are strong because the case is atypical. Claims 2 and 3 are weak because the case is atypical. Claim 5 is strong because the case is typical.

$X$  here could be any characteristic of the experiment including properties of the treatment. For example, we may expect treatment effects to increase in the intensity of the intervention or decrease in its scale.

Critically, claiming inference from unusualness (or typicality) depends on prior beliefs about the distribution of effects as a function of selection criteria, here  $X$ . Justification, or at least articulation, of these beliefs is needed to assess these claims. Pre-existing theoretical knowledge can help in this regard. A more

empirical approach might be to elicit beliefs (e.g. from prospective research consumers) about the *ranking* of effects across a set of cases, including the case at hand.

Note that, given these considerations, the *ex post* informativeness of an experiment is not the same as its *ex ante* informativeness. You may not be wise spending resources to search for a positive treatment effect in a setting with a high value of  $X$ , for example, since the chances of finding such an effect are small. But if you find it, such a result is highly informative.<sup>11</sup>

### Strategy 3: Exploit Variation within Studies

A third approach is to use variation in effects *within* a study site to justify claims that go beyond the study site.

The simplest approach is to identify relevant dimensions along which the study site differs from the target site and to demonstrate that there is no heterogeneity in effects along these dimensions within the study at hand.

If there is heterogeneity along such dimensions, one possibility is to use weighting or propensity score subclassification estimators to estimate effects for the target population using variation in the study population. See Kern et al. (2016) for an assessment of several such approaches.

The general idea is to identify a set of strata across which effects vary, estimate effects for each of these strata in the study population, and take a weighted average of the resulting estimates where the weights correspond to the share of subjects in each stratum in the target population.

For intuition, say you undertake a study in location  $A$ . You want to make a claim for target site  $B$ . In site  $A$ , one third of subjects are young and two thirds are old. In site  $B$ , it is the reverse. The strategy is to estimate the effect separately for young and old subjects in  $A$  and then calculate a weighted average of these group-specific estimates using the proportion

of young and old subjects in site  $B$ . Let  $\hat{\tau}_O^A$  and  $\hat{\tau}_Y^A$  be the respective treatment effect estimates among old and young people in setting  $A$ . Suppose we learn from study  $A$  that  $\hat{\tau}_Y^A = 1$  and  $\hat{\tau}_O^A = \frac{1}{4}$ . The overall treatment effect estimate in  $A$  is given by  $\hat{\tau}^A = \frac{1}{3} \times 1 + \frac{2}{3} \times \frac{1}{4} = \frac{1}{2}$ . For site  $B$ , we estimate the treatment effect to be  $\hat{\tau}_B = \frac{2}{3} \times 1 + \frac{1}{3} \times \frac{1}{4} = \frac{3}{4}$ .

This approach depends on many assumptions, formalized in Pearl and Bareinboim (2014) and Tipton (2013). Most obviously the support of  $B$  must be a subset of the support of  $A$  – i.e. for any stratum in  $B$  for which one wants to generate estimates there should be a corresponding stratum in  $A$ . You cannot estimate effects for, say, a co-ed school based on estimates obtained from an experiment in a boys-only school.

More substantively, you need to be willing to assume that the distribution of effects within each stratum is the same in the two populations. This claim is most easily made when the study sample is itself a random draw from the study population. Yet, even in such an ideal case, one has to worry about how spillovers work not just in the study population but also in the target population (Tipton, 2013).

Finally, this approach has implications for how one can design the study sample in  $A$  to facilitate inference to target  $B$  (see Tipton and Peck, 2017).

### Strategy 4: Exploit Variation across Studies

A fourth strategy is to design studies so that they can feed into meta-analyses that seek to make broader claims. A common approach is to think of a superpopulation of cases with effects drawn from a common distribution:

$$\tau_j \sim f(\mu, \sigma)$$

The interest is in learning about the expectation of the superpopulation effects,  $\mu$ , but also

the variation in effects  $\sigma$ . A single study drawn randomly from a population can give an unbiased, but noisy, estimate for  $\mu$  and says nothing about  $\sigma$ . Multiple comparable studies can provide tighter estimates of both  $\mu$  and  $\sigma$ .

Here, the external gains from a study operate through complementarities with other studies. Yet, up until recently, only few topics in political science had generated a large enough set of comparable experiments to allow for a meta-analysis. Initiatives that encourage the co-ordinated implementation of experiments on the same topic in various contexts – such as the ‘Metaketa’ projects – seek to address this problem (Dunning et al., 2018).

Meta-analyses can also include a more systematic analysis of treatment effect heterogeneity across studies. Vivaldi (2019), for example, finds that experiments implemented by governments tend to have smaller effects than those implemented by non-governmental actors. Ultimately, such results can become useful for theory development.

### **Strategy 5: Cross Validation**

A fifth approach used in Dunning et al. (2018) and Coppock et al., (2018) treats external validity as an empirical question.<sup>12</sup> Dunning et al. (2018) ask: do research consumers *in fact* update inferences for out-of-sample estimands? They gather results from multiple related experiments and assess whether exposing research consumers to the findings makes them update their beliefs about effects in studies they have not been informed about, and whether updating goes in the right direction. Coppock et al. (2018) assess empirically whether the results from online samples are *in fact* consistent with what we know from representative samples (and vice versa). They find that they are and attribute this to low effect heterogeneity. One could engage in a similar kind of exercise using a single study by analyzing whether results estimated on a non-random subsample correspond to those in the rest of the

study. Results will depend on the degree of effect heterogeneity.

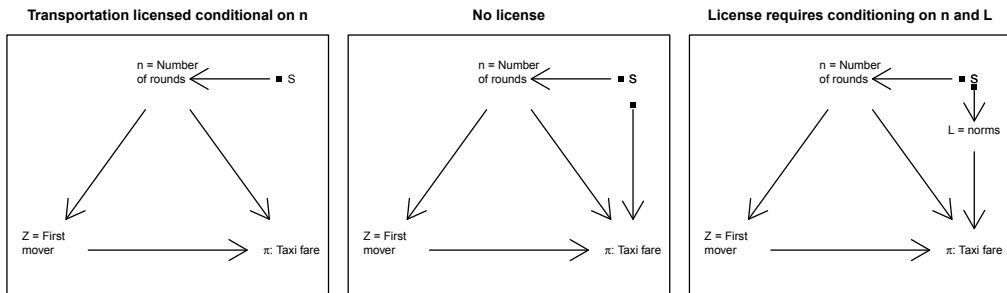

This empirical approach gives, in some sense, an iron clad answer to the question of external validity. Yet, it has an obvious shortcoming: *checking* external validity requires already knowing the target estimand. One can make external claims, and check whether the claims are correct, but this establishes the claim to external validity only in cases in which it is not needed. Put differently, you do not know whether the claim for external validity itself is externally valid outside of the test set.

### **Strategy 6: Formal Transportation**

The last approach we consider uses causal models to formally justify – or ‘license’ – claims to external validity. This is an example of the use of theory discussed in the section ‘Strategy 2: Use Theory as a Helper for Inference’. Pearl and Bareinboim (2014) develop a framework in which researchers provide a causal model and the associated DAG for their study population and then represent the ways in which the target population differs from the study population as a set of ‘selection’ nodes that are the origins of arrows that point into nodes in the original DAG. This representation of differences makes it possible to assess whether there is a weighting strategy that allows inference to the target population. The assessment is, of course, conditional on the model.

To illustrate, imagine first that two sites share a common causal model relating the taxi fare, the number of bargaining rounds, and whether the customer makes the first offer. Say, for instance, data on taxi bargaining is generated in Kenya and one wants to make inferences to Somalia. Figure 53.3 displays the corresponding DAG.

We are interested in the effects of the customer being the first mover on the taxi price. We know that the average effect of moving first depends on how long bargaining can

**Figure 53.3** Three selection graphs

continue before negotiations break down. In the first graph in Figure 53.3, the selection variable ‘ $S$ ’ characterizes the differences between Kenya and Somalia suggesting that there is a difference in bargaining rounds between these sites. Perhaps the taxi market is more competitive in Kenya and, as a consequence, drivers and customers are more likely to separate if they cannot reach an agreement after a small number of offers and counter-offers. If this is an accurate characterization of the differences between these sites, then results can be transported using a strategy much like that described in ‘Strategy 3: Exploit Variation Within Studies’: re-weight the estimates from Kenya using information on propensities for bargaining to break down after a specific number of rounds for a given customer-driver interaction. The ability to use this strategy requires – beyond the model being right – (a) that the range of bargaining rounds in Somalia is also present in Kenya, and (b) that we have data about the distribution of this variable in both contexts. There are thus gains from implementing experiments in places with wide variation and in gathering data about distributions of variables out of sample.

The implications of this framework extend further, however. Say that the differences between Kenya and Somalia are those depicted in panel 2 (Figure 53.3). In this case, these differences extend to how order of play and bargaining protocol affect outcomes.

Average effects could be different in these sites which would prevent extrapolation even with complete data. In graph theoretic terms, the reason is that there is no set of variables that you can condition on that ‘ $d$ -separates’ the selection variable from the outcome.

Say, finally, that we have a model that tries to explain the differences in effects via some specified intermediate variable, as in the third panel. The selection graph in the third panel can be interpreted as saying that the (conditional) effect of moving first on the taxi price is different in Somalia because there are different norms in Somalia that moderate this effect. If so, we can now get good estimates of effects in Somalia by conditioning not just on the likelihood of bargaining breaking down after a specific number of rounds but also on a measure of norms. We re-weight by finer strata. Formally, conditioning on norms now separates the selection node  $S$  from the outcome.

This logic captures the core elements of Theorem 2 in Pearl and Bareinboim (2014): Let  $Z$  denote a stratum. The strata-specific causal effect of  $X$  on  $Y$  is transportable from one graph to another if conditioning on  $Z$  produces independence between the outcome  $Y$  and the set of selection nodes  $S$ .

The gains from this framework are two-fold. First, it becomes possible to state justifications for transportation in terms of independence relations between variables, which are statements that can then be

assessed empirically. Second, given a justification, there is clarity on the set of variables for which data should be gathered to calculate stratum level causal effects.

That said, to our knowledge, the framework cannot be used to extrapolate from findings on the effects of one treatment to the effects of another, which, in principle, is possible with parametric models (see sections ‘Strategy 6: Use Experiments to Estimate Structural Models’ and ‘Illustration of a Parametric Structural Model Connecting Theory and Experimentation’).

As far as we know, the Pearl and Bareinboim (2014) framework has not yet been used within political science.

### **ILLUSTRATION OF A PARAMETRIC STRUCTURAL MODEL CONNECTING THEORY AND EXPERIMENTATION**

We now return to our example experiment on taxi bargaining and use it to walk through the logic of estimating a simple parametric structural model. Recall that, in this example, we are interested in why some taxi customers end up paying more than others. According to our Level 1 theory illustrated in Figure 53.1, there are three variables that directly affect our outcome of interest: the number of rounds for which bargaining can continue, whether the customer gets to make the first offer, and the customer’s type. We begin by further developing this theory into a Level 2 theory in the form of a parametric structural model. We then illustrate how we would turn our Level 2 theory into a Level 3 theory and estimate it using simulated data. Finally, we highlight four possible benefits of the approach.

#### ***Setting Up and Estimating a Structural Causal Model***

We will assume that the taxi bargaining process can be captured by a standard alternating

offers bargaining game with complete information (Rubinstein, 1982). A customer and a driver take turns in making offers of how to divide a pie. We think of the pie as the unit endowment that we provided to the customer. For simplicity, we assume that the size of the pie is known to both players. Whoever moves first makes a suggestion on how to divide the pie. For example, if the customer moves first, she may say ‘I will pay you 0.2 and keep 0.8 for myself’. The second player decides whether to accept or reject this offer. If the second player accepts, each player receives the share of the pie that the offer allocated to her (e.g. the customer pays 0.2 to the driver and keeps 0.8 for herself). If the second player rejects, the game moves to the next round and the second player gets to make an offer which the first player can accept or reject. If no agreement is reached, bargaining ends after  $n$  rounds and both players receive a payoff of 0. We might imagine, for example, that customers have to pay the endowment back to us if they do not secure a ride.

To capture preferences about time, we assume that players discount their payoffs at a rate of  $0 \leq \delta \leq 1$ . If they reach an agreement in round 1 and a player receives an amount  $x$ , the player will value this amount at  $x$ . If the same agreement is reached in period 2, the player will value the amount at  $\delta x$ ; in period 3 she will value the amount at  $\delta^2 x$  etc.

The standard solution for rational players is found via backwards induction for a finite number of bargaining rounds  $n$ . Suppose that  $n = 1$ , i.e. the player who goes first gets to make a take-it-or-leave-it offer. Since both players know that there will be no second round, the first mover will take the entire pie for herself. The second player will accept, since she will receive a payoff of 0 anyway, irrespective of what she does. Let’s consider  $n = 2$ , i.e. there can be one offer and a counter-offer. We already know that, in the second round, the second-mover will be able to take the whole pie of 1 for herself (again, the other player will receive 0 irrespective of whether she accepts or rejects the offer).

Seen from the first period, the second mover knows that she can achieve  $\delta \times 1$  by rejecting the first mover's offer. In the first period, the first mover will therefore offer exactly  $\delta$  to the second mover and the second mover will accept. Letting  $\pi_n^j$  denote the equilibrium share paid by player  $j$  in an  $n$ -round game, the first mover in a two-round game gives  $\pi_2^1 = \delta$  to the second mover and keeps  $1 - \pi_2^1 = 1 - \delta$  for herself. The same logic can be applied to  $n = 3, n = 4$  etc.<sup>13</sup>

In the infinite version of the game, the optimal solution involves offering an amount

so that the receiver is indifferent between accepting and moving on to the next round of the infinite game in which she would offer the same amount; i.e. we seek an offer  $\pi_\infty^1$  such that  $\pi_\infty^1 = \delta(1 - \pi_\infty^1)$  which implies  $\pi_\infty^1 = \delta / (1 + \delta)$ .

Note that, in this model, agreement is always reached in the first period irrespective of the number of possible bargaining rounds  $n$ .

The top panel of Table 53.1 summarizes the price that a rational customer should pay according to this model depending on the

**Table 53.1 Equilibrium prices for first ( $\pi_n^1$ ) and second ( $\pi_n^2$ ) moving customers and average treatment effect ( $\tau_n$ ) of the customer moving first for games with  $n$  possible rounds**

Rational customers			
	$\pi_n^1$	$\pi_n^2$	$\tau_n = \pi_n^1 - \pi_n^2$
$n = 1$	0	1	-1
$n = 2$	$\delta$	$1 - \delta$	$2\delta - 1$
$n = 3$	$\delta(1 - \delta)$	$1 - \delta(1 - \delta)$	$2\delta(1 - \delta) - 1$
$n = \infty$	$\frac{\delta}{1 + \delta}$	$1 - \frac{\delta}{1 + \delta}$	$2 \frac{\delta}{1 + \delta} - 1$
Behavioral customers			
	$\pi_n^1$	$\pi_n^2$	$\tau_n = \pi_n^1 - \pi_n^2$
$n = 1$	$\frac{3}{4}$	$\frac{3}{4}$	0
$n = 2$	$\frac{3}{4}$	$\frac{3}{4}$	0
$n = 3$	$\frac{3}{4}$	$\frac{3}{4}$	0
$n = \infty$	$\frac{3}{4}$	$\frac{3}{4}$	0
Population with share $q$ of behavioral customers			
	$E(\pi_n^1)$	$E(\pi_n^2)$	$\tau_n = E(\pi_n^1 - \pi_n^2)$
$n = 1$	$q \frac{3}{4}$	$q \frac{3}{4} + (1 - q)$	$-(1 - q)$
$n = 2$	$q \frac{3}{4} + (1 - q)\delta$	$q \frac{3}{4} + (1 - q)(1 - \delta)$	$(1 - q)(2\delta - 1)$
$n = 3$	$q \frac{3}{4} + (1 - q)\delta(1 - \delta)$	$q \frac{3}{4} + (1 - q)(1 - \delta(1 - \delta))$	$(1 - q)(2\delta(1 - \delta) - 1)$
$n = \infty$	$q \frac{3}{4} + (1 - q) \frac{\delta}{1 + \delta}$	$q \frac{3}{4} + (1 - q) \left(1 - \frac{\delta}{1 + \delta}\right)$	$(1 - q) \left(2 \frac{\delta}{1 + \delta} - 1\right)$

number of rounds  $n$  and on whether the customer moves first ( $\pi_n^1$ ) or second ( $\pi_n^2$ ).

We are interested in the effect,  $\tau_n$ , of being able to make the first offer on the price paid in an  $n$  round game. This effect simply equals the difference between  $\pi_n^1$  and  $\pi_n^2$  (see the last column of Table 53.1).

So far, we have only considered the behavior of rational players. Yet, according to our causal model, customers – though not drivers – can be of different types. In this stylized example, we assume that there are some norm following customers who always pay  $\frac{3}{4}$  of the pie to the driver and keep  $\frac{1}{4}$  for themselves, irrespective of the number of bargaining rounds or whether they go first or second. As can be seen in Table 53.1, the treatment effect of going first on the price paid is always 0 for norm following customers. We assume that a customer's behavioral type is not observed by the researchers and that the share of norm followers in the population of customers is  $q$ .

Ultimately, we are interested in the average treatment effect of the customer going first on the taxi fare. In order to make predictions about this effect, we need to add estimates of  $q$ , the distribution of rational and norm following types to our Level 2 model. As displayed at the bottom of Table 53.1, the population-level average of the price paid by customers who move first or second is just a weighted average of the price paid by rational customers and the price paid by norm following customers. Accordingly, since the average treatment effect among norm followers is zero, the average treatment effect in the population is just the proportion of rational customers  $(1 - q)$  times the predicted treatment effect among rational customers.

Subsequently, we focus on  $n = 2$  and  $n = \infty$ . Note that the model produces interesting heterogeneity: from the table we see that  $\tau_2 > \tau_\infty$  for  $\delta > 0$ ,<sup>14</sup> though  $\tau_2$  and  $\tau_\infty$  may differ in sign and  $\tau_\infty$  may be larger in absolute value. In the extreme case when  $\delta$  is close to 1,  $\tau_2$  is close to  $(1 - q)$  and  $\tau_\infty$  is close to 0.

### *Taking the model to data*

Our Level 2 model makes predictions about average taxi fares as a function of whether the customer moves first, the number of bargaining rounds and two model parameters, the discount factor  $\delta$ , and the share  $q$  of norm followers in the population. Suppose we have run our taxi bargaining experiment that randomly assigns customers to make the first offer in a place where  $n = 2$  or  $n = \infty$ , how can we use these data to get estimates of the model parameters,  $\delta$  and  $q$  and estimates of treatment effects  $\tau_n$ ?

We do so by using the model's equilibrium predictions to motivate a data generating process that describes the probability of observing any data given a set of parameter values. We then rely on MLE to find estimates of  $\delta$  and  $q$ . The same could be achieved through various other estimation methods, including GMM or Bayesian approaches.

An obvious challenge in using real world data to estimate the parameters of a model is that the real world might produce data that are inconsistent with an overly simple model. For this reason, it is generally necessary to allow for a stochastic component that can render all data *possible*, even if improbable. In the DAG in Figure 53.1, the idea that observed taxi fares may deviate from the predictions in Table 53.1 is captured by the node  $U_3$ . We can think of  $U_3$  as representing factors other than the number of bargaining rounds, whether the customer moves first and the customer's behavioral type that also affect the price a customer pays.

What could be sources of  $U_3$  in the context of our model? There are multiple possibilities here. In his review of structural estimation in behavioral economics, DellaVigna (2018) discusses the three most common ways in which researchers incorporate heterogeneity in their models. First, it is sometimes assumed that the actors in the model receive an unobserved utility shock which generates heterogeneity in how they behave. Second, we can imagine that there is heterogeneity

in some of the parameters of the model. Imagine, for example, that instead of a fixed number,  $\delta$  is a random variable that follows, say, a beta distribution in the population of interest. Individuals would then be heterogeneous in their  $\delta$  which, in turn, would result in heterogeneity in the way in which the customer's endowment is divided. A final possibility is to assume that individuals make implementation errors.

The last interpretation fits well with our example. Imagine that players attempt to act in accordance with the model but make random mistakes when dividing the endowment. As a consequence, the prices that get paid are not always the ones predicted by the model.

To estimate our model via MLE, we need to be specific about the distribution of these implementation errors. Here, we assume that the price paid by a given customer is a draw from a beta distribution that is centered on whatever price the model predicts for this customer. The beta distribution is a natural choice in this case, since it is defined on the interval  $[0,1]$ , just like the shares of the endowment that customers pay as a result of the taxi bargaining process. The distribution has two parameters,  $\alpha$  and  $\beta$ , that control its

shape. The mean of the beta distribution can be expressed as a function of these parameters,  $\mu = \frac{\alpha}{\alpha + \beta}$ . In turn, we can write the two parameters as  $\alpha = \kappa\mu$  and  $\beta = \kappa(1 - \mu)$ . In this way, we can model  $\mu$ , the mean of the distribution, as a function of the variables in our model. Specifically,  $\mu$  will depend on:

- customer  $i$ 's treatment status  $z_i$ , where  $z_i = 1$  if the customer has been randomly assigned to go first and  $z_i = 0$  if the customer has been randomly assigned to go second;
- customer  $i$ 's (unobserved) behavioral type  $\theta_i$ , where  $\theta_i = 1$  if the customer is rational and  $\theta_i = 0$  if the customer is a norm follower; and
- the number of rounds  $n \in \{2, \infty\}$  for which bargaining can continue.

Thus,  $\kappa$  enters the model as a new parameter that describes the variance of the distribution of prices but not its mean. It is of some substantive interest in that it captures how close behavior is to the Level 2 model predictions.

Using this parameterization and the predictions of the model, we can write down the likelihood given the observed prices paid by  $N$  customers in our experimental subject pool (where we use subscript  $i$  to denote individuals):

$$\Lambda(q, \delta, \kappa | \pi) = \prod_{i=1}^N \left( q \text{Beta} \left( \pi_i \mid \frac{3}{4}\kappa, \frac{1}{4}\kappa \right) + (1-q) \text{Beta}(\pi_i \mid \mu_i\kappa, (1-\mu_i)\kappa) \right)$$

$$\mu_i = \begin{cases} z_i\delta + (1-z_i)(1-\delta) & \text{for } n=2 \\ z_i \frac{\delta}{1+\delta} + (1-z_i) \left( 1 - \frac{\delta}{1+\delta} \right) & \text{for } n=\infty \end{cases} \tag{1}$$

$z_i = 1$  with probability .5 for all  $i$

A couple of features are noteworthy: first, the assumed data generating process that underlies the likelihood function reflects that customers are randomly assigned to go first; hence  $z_i = 1$  with probability  $\frac{1}{2}$  for all units. Second, we do not need to know a customer's

behavioral type  $\theta_i$  in order to compute the likelihood, which is fortunate as we do not observe this characteristic. Instead, the joint probability distribution is simply a mixture between a beta distribution with mean  $\frac{3}{4}$  and a beta distribution with mean equal to

the predicted price paid by rational customers, conditional on whether they go first or second. The weight on each of these distributions is given by the share of norm followers,  $q$ .

**Estimation and inferences**

Now that we have equation (1) in hand, we use standard MLE approaches to find the values for  $q$ ,  $\delta$  and  $\kappa$  that maximize the likelihood of the data we observe in our experiment.

Once our analysis is set up, it is easy to inquire into how well this procedure works. Suppose our model is correct. We can find out how well we recover the model parameters using the following steps: (a) simulate data using draws from the data generating process described above; (b) perform the estimation; and (c) compare the estimates to the parameter values assumed during the simulation. By repeating these steps many times, we can figure out whether our estimates are, on average, correct and how variable they are.

In practice, we use the R package `DeclareDesign` for this exercise (Blair et al., 2018). We provide all code for the declaration and diagnosis of this model in supplementary material.

The simulations involve (a) imagining that we have run an experiment that randomly assigns taxi customers to make the first offer, either in a setting where bargaining can continue for two rounds ( $n = 2$ ) or in a setting where bargaining can continue indefinitely ( $n = \infty$ ); (b) using a maximum likelihood estimator to estimate  $\delta$ ,  $\kappa$  and  $q$  in either setting; and (c) drawing inferences regarding treatment effects using the parameter estimates. This last step is done by referring to the last column of Table 53.1. For example, with estimates of  $\hat{q} = 1/2$  and  $\hat{\delta} = 4/5$ , we would predict a treatment

$$\text{effect of } \hat{\tau}_\infty = \frac{1}{2} \left( 2 \frac{\frac{4}{5}}{1 + \frac{4}{5}} - 1 \right) = -\frac{1}{18} \approx -0.06$$

for a setting where bargaining can continue indefinitely.

For each estimand-estimator pair, we then report the expected bias (which simply equals the difference between the estimand and the mean estimate across all simulations).

In Table 53.2, we report the estimates of model parameters and in Table 53.3, we report estimates of average treatment effects, comparing those generated from parameter estimation to those generated using a simple difference-in-means estimator. In each case  $MLE_2$  indicates estimates obtained from the maximum likelihood estimators that take data from a 2 period game and  $MLE_\infty$  indicates estimates obtained from the maximum likelihood estimators that take data from an  $n = \infty$  period game. Correspondingly,  $DIM_n$  indicates estimates obtained using the difference-in-means estimator and data generated in a setting with  $n$  possible bargaining rounds.

We recover unbiased estimates of  $q$  and  $\delta$ , irrespective of whether we use data from a setting with  $n = 2$  or  $n = \infty$ . The estimates of  $\kappa$  are slightly biased. Moreover, our estimates of model parameters allow us to

**Table 53.2 Estimation of model parameters using the correct model**

Estimand	Estimator	Estimand value	Bias
$\delta$	$MLE_2$	0.80	-0.00
$\delta$	$MLE_\infty$	0.80	0.00
$\kappa$	$MLE_2$	6.00	0.04
$\kappa$	$MLE_\infty$	6.00	0.03
$q$	$MLE_2$	0.50	-0.00
$q$	$MLE_\infty$	0.50	-0.00

**Table 53.3 Estimation of average treatment effects using difference-in-means (DIM) and parameter estimation (MLE)**

Estimand	Estimator	Estimand value	Bias
$\tau_2$	$MLE_2$	0.30	-0.00
$\tau_2$	$DIM_2$	0.30	0.00
$\tau_\infty$	$MLE_\infty$	-0.06	-0.00
$\tau_\infty$	$DIM_\infty$	-0.06	-0.00

recover unbiased estimates of average treatment effects.

Why, in this case, are we able to obtain unbiased estimates of the model parameters of interest? To see the intuition, recall that, according to our model (see Table 53.1), the average prices paid by first and second moving customers in a setting with  $n = 2$  are given by the following functions:  $E(\pi_2^1) = q\frac{3}{4} + (1-q)\delta$  and  $E(\pi_2^2) = q\frac{3}{4} + (1-q)(1-\delta)$ . It turns out that, if we knew the values of  $E(\pi_2^1)$  and  $E(\pi_2^2)$ , these two equations could, in most cases, be solved for the unique values of  $q$  and  $\delta$ . For example, if  $E(\pi_2^1) = \frac{1}{2}$  and  $E(\pi_2^2) = \frac{3}{4}$ , then we know that  $q$  must equal  $\frac{1}{2}$  and  $\delta$  must equal  $\frac{1}{4}$ .<sup>15</sup> An experiment that randomly assigns customers to go first or second provides us with unbiased estimates of  $E(\pi_2^1)$  and  $E(\pi_2^2)$ . As a consequence, we are able to recover estimates of  $q$  and  $\delta$ .

Even though this result seems encouraging, one may wonder why we would want to estimate the parameters of our model in the first place. After all, as can be seen in Table 53.3, using a simple difference-in-means estimator yields unbiased estimates of the average treatment effect of moving first irrespective of whether we perform our experiment in a context with  $n = 2$  or  $n = \infty$ . What more can we learn from this exercise about why some taxi customers pay higher prices than others?

In the next four sections, we use this example to demonstrate what we see as some of the potential benefits of combining experimental data and structural estimation. The first section relates to the core argument of this chapter – that stronger theoretical connections can provide (or at a minimum, clarify) the bases for stronger external claims. The other three sections point to ways in which experiments can be strengthened through structural modeling and vice versa.

### **Benefit 1: Theory Allows for Answers to a Wider Set of Questions**

A key benefit of the structural model is that it allows us to answer a more varied array of questions than can typically be addressed by design-based inference, in particular questions regarding different settings, different treatments, and different outcomes.

To illustrate, our causal model suggests that the average treatment effect of moving first varies with the number of rounds for which bargaining can continue. This is confirmed in Table 53.3, where the effect estimate that we obtain in a setting with  $n = 2$  potential bargaining rounds differs from the estimate obtained when bargaining can continue indefinitely. In other words, the effect estimates do not travel across settings.

This is where the structural model may help. Imagine that we conduct our experiment in a setting where bargaining continues for  $n = 2$  rounds and we obtain estimates of  $q$  and  $\delta$ . We can now estimate the treatment effects for the  $n = \infty$  case by consulting the equations in Table 53.1. Thus, provided that our model is correct, we can use an experiment conducted in a single setting to predict effects for other settings where effects may be different.

Table 53.4 shows estimates based on this approach for our model.

Beyond generalization across settings, the model also helps us predict the effects of alternative treatments. The equations in Table 53.1 imply, for example, that the average treatment effect of a change that allows bargaining to continue for  $n = 3$  rounds instead of  $n = 2$  rounds on the average price

**Table 53.4 Extrapolation**

<i>Estimand</i>	<i>Estimator</i>	<i>Estimand value</i>	<i>Bias</i>
$\tau_2$	$MLE_2$	0.30	-0.00
$\tau_2$	$MLE_\infty$	0.30	0.00
$\tau_\infty$	$MLE_2$	-0.06	-0.00
$\tau_\infty$	$MLE_\infty$	-0.06	-0.00

paid by a customer who moves first is  $-(1 - q)\delta^2$ . Based on our estimates of  $\hat{q} = 1/2$  and  $\hat{\delta} = 4/5$ , we would thus predict that such a change reduces the price paid by a customer who makes the first offer by  $\frac{8}{25}$ .

Giving more structure to our model has considerably expanded the set of inferences that we would be able to draw from a single experiment. Of course, these inferences are only warranted if our structural causal model is the correct one. This may well be an unrealistic assumption. Among other things, it entails that the structural parameters  $\delta$  and  $q$  are indeed structural in the sense that they do not vary across settings. If the distribution of behavioral types varies across settings, for example, our predictions will not be correct. We will show below how reliance on the wrong model can lead to biased inferences and, more positively, how randomized experiments can sometimes draw attention to flaws in a model.

### ***Benefit 2: Theory Provides Pointers to Better Design***

Sticking for the moment with the assumption that our stylized model is correct, we can use the model to draw lessons for how to design our hypothetical experiment. This is an example of the use of theory described in the section ‘Strategy 3: Use Theory as a Helper for Design’.

Consider, for example, settings in which only take-it-or-leave-it offers are possible, i.e.  $n = 1$ . We can see from Table 53.1 that neither  $E(\pi_1^1)$  nor  $E(\pi_1^2)$  depends on  $\delta$ .

An experiment in a setting where  $n = 1$  would thus allow us to estimate  $q$  but not  $\delta$ . Without an estimate of  $\delta$ , we will not be able to generalize to other settings or treatments in the manner described above.

Similarly, not all equations for  $E(\pi_n^1)$  and  $E(\pi_n^2)$  can be easily solved for  $q$  and  $\delta$ . In the case of  $n = 3$ , for example, one set of estimates of  $E(\pi_3^1)$  and  $E(\pi_3^2)$  can be consistent

with two different solutions for  $q$  and  $\delta$ . In order to maximize the inferences that can be drawn, the experiment should be conducted in a setting that enables us to uniquely identify both  $q$  and  $\delta$ .

The model also has implications for case selection if we are interested in maximizing power. Suppose, for example, that we believe it likely that  $\delta$  is close to 1 and that the share of norm followers  $q$  is not very large prior to running our experiment. We would then expect  $|\tau_2| > |\tau_\infty|$ , which suggests that we will be better powered to detect a treatment effect if we run our experiment in a setting where bargaining must end after two rounds than in a setting where bargaining can continue indefinitely. While it may generally seem undesirable to let design considerations determine estimands rather than the other way around, greater power here may also imply the ability to obtain more precise estimates of the model’s structural parameters that may be used to generalize towards other estimands of interest.

### ***Benefit 3: Experimental Data Can Make It Possible to Improve Inferences from Theory***

We are used to the idea that randomization helps identify treatment effects (Gerber et al. 2014), but it can also play a key role in parameter identification. Instead of substituting for randomization, model-based inference, here, exploits randomization.

In our example, the assumption of randomization is built into the likelihood function and employing this model in a context without randomization could lead to biased parameter estimates. To illustrate, imagine that the probability of going first is related to a player’s behavioral type. Specifically, we imagine a data generating process according to which norm followers go first with probability  $p_n$  whereas rational players go first with probability  $p_r$ . We thus have a joint probability distribution over  $z$  and  $\pi$  – where  $z_i$

depends on the unknown type and  $\pi_i$  depends on both the unknown type and  $z_i$ .

We now re-do our simulations, changing the data generating process in this way (setting  $p_n = 0.8$  and  $p_r = 0.5$ ), but maintaining the estimation strategy, i.e. we still choose  $q$ ,  $\delta$ , and  $\kappa$  to maximize the likelihood of our observed data according to equation (1). Thus, we (incorrectly) analyze the data *as if* customers were randomly assigned to go first or second.

Table 53.5 contains the resulting estimates of the model parameters and average treatment effects. We also include treatment effect estimates obtained from a difference-in-means estimator. In the absence of random assignment, all our estimates are biased.

Intuitively, without random assignment, we do not achieve unbiased estimates of  $\pi_n^1$  and  $\pi_n^2$ , since the relationship between the treatment (going first) and the outcome (the price that a customer pays) is confounded by an unobserved variable, the customer's type. Without being able to estimate  $\pi_n^1$  and  $\pi_n^2$ , however, we cannot uncover  $\tau_n$  and neither  $q$  nor  $\delta$ . Of course, this problem could be solved by conditioning on the customer's type if we could observe it. Alternatively, one might extend the model in an attempt to incorporate confounding.

**Table 53.5 Diagnosis of design without randomization**

<i>Estimand</i>	<i>Estimator</i>	<i>Estimand value</i>	<i>Bias</i>
$\tau_2$	$DIM_2$	0.30	0.11
$\tau_2$	$MLE_2$	0.30	0.11
$\tau_2$	$MLE_\infty$	0.30	0.12
$\tau_\infty$	$DIM_\infty$	-0.06	0.08
$\tau_\infty$	$MLE_2$	-0.06	-0.03
$\tau_\infty$	$MLE_\infty$	-0.06	0.04
$\delta$	$MLE_2$	0.80	-0.01
$\delta$	$MLE_\infty$	0.80	0.13
$\kappa$	$MLE_2$	6.00	-0.09
$\kappa$	$MLE_\infty$	6.00	-0.04
$q$	$MLE_2$	0.50	-0.22
$q$	$MLE_\infty$	0.50	0.01

In short, randomization can help identify parameters of interest, which can subsequently be used for extrapolation. This point gains importance in more complex models where identification of the parameters of interest becomes more difficult. See DellaVigna (2018) and Card et al. (2011) for more on how additional treatments can help identify parameters of a structural model.

#### ***Benefit 4: Experimental Data Can Help Improve Theory***

So far, we have assumed the model is right. But of course, we know the model is wrong (Box, 1976). The question is how to assess the consequences of relying on a model that is incorrect and how to react if the model is misleading. One way to do so is to take a model seriously, confront it with data, and then step back to see whether the theory did violence to the data. Poor fit can be suggestive of the need to improve a model (Browne and Cudeck, 1993; Gelman et al., 1996).

We illustrate by imagining that we had mistakenly not considered the possibility that there are norm following types and instead assumed that all customers acted rationally, i.e.  $q = 0$ . Essentially, this means ignoring the bottom two panels of Table 53.1 and considering the top panel only. Table 53.6 displays the results of changing our estimation strategy accordingly (we use  $MLE'$  rather than  $MLE$  to denote the new estimators).

The first thing to note is that, because we have returned to the scenario where we randomly assign a customer to make the first offer, the difference-in-means estimator recovers unbiased estimates of the average treatment effects of going first for both cases,  $n = 2$  and  $n = \infty$ . Our estimates of  $\delta$ , however, are biased irrespective of whether we rely on data from an experiment in the  $n = 2$  or  $n = \infty$  context. Moreover, we naturally do not obtain any estimates of  $q$ , since we

**Table 53.6 Diagnosis of design with incorrect model (assume  $q = 0$ )**

<i>Estimand</i>	<i>Estimator</i>	<i>Estimand value</i>	<i>Bias</i>
$\tau_2$	$DIM_2$	0.30	0.00
$\tau_2$	$MLE'_2$	0.30	-0.04
$\tau_2$	$MLE'_\infty$	0.30	0.52
$\tau_\infty$	$DIM_\infty$	-0.06	-0.00
$\tau_\infty$	$MLE'_2$	-0.06	-0.17
$\tau_\infty$	$MLE'_\infty$	-0.06	0.01
$\delta$	$MLE'_2$	0.80	-0.17
$\delta$	$MLE'_\infty$	0.80	0.11
$\kappa$	$MLE'_2$	6.00	-3.83
$\kappa$	$MLE'_\infty$	6.00	-3.05
$q$	$MLE'_2$	0.50	

assume  $q = 0$ . It is thus not surprising that our predictions for treatment effects in other settings based on our estimates of  $\delta$  are severely biased. Yet, we do not only obtain biased estimates of the treatment effect in a *different* context. Our prediction of the treatment effect for the *same* context is also biased. Based on our estimate of  $\delta$  obtained from an experiment run in a place where  $n = 2$ , for example, we would predict a treatment effect of 0.26 for this same place. Yet, the actual treatment effect, which we recover using the difference-in-means estimator, is 0.3.

This pattern shows how random assignment can help us detect problems with our theoretical model. Knowing that we have an unbiased estimate of the average treatment effect allows us to use this estimate to validate the prediction of our theoretical model. The larger the gap between our experimental estimates and our predictions, the weaker our confidence that our theoretical model is correct.

A similar strategy is used by Todd and Wolpin (2006) who evaluate the effects of a randomized school subsidy program in Mexico. They fit a structural model using

households who did not receive the subsidy and validate the model by comparing the predicted effect of the subsidy program to the experimental estimates. Similarly, DellaVigna et al. (2016) use not only new, but also existing, experimental results to validate their model. Specifically, the authors develop a structural model of voting based on the idea that individuals derive pride from telling others that they voted or face costs when lying about whether they voted or not. The authors rely on an experiment with several randomized treatments to estimate the parameters of the model. Subsequently, they compare the effects predicted by their model to the results of one new and various existing get-out-the-vote campaigns.

As encouraging as this strategy is, we note that, in general, there is no guarantee that a model that is wrong will yield observably wrong predictions (though it may still misguide). For example, imagine that the true model is one where a share  $q > 0$  of customers behaves non-rationally and that norm

**Table 53.7 Diagnosis of design with incorrect yet observationally equivalent model**

<i>Estimand</i>	<i>Estimator</i>	<i>Estimand</i>	<i>Bias</i>
$\tau_2$	$DIM_2$	0.30	0.00
$\tau_2$	$MLE'_2$	0.30	0.01
$\tau_2$	$MLE'_\infty$	0.30	0.49
$\tau_\infty$	$DIM_2$	-0.06	0.00
$\tau_\infty$	$MLE'_2$	-0.06	-0.15
$\tau_\infty$	$MLE'_\infty$	-0.06	0.00
$\delta$	$MLE'_2$	0.80	-0.15
$\delta$	$MLE'_\infty$	0.80	0.10
$\kappa$	$MLE'_2$	6.00	-2.62
$\kappa$	$MLE'_\infty$	6.00	-0.09
$q$	$MLE'_2$	0.50	

followers always pay a share of 1/2 of their endowment (instead of 3/4). Further suppose again that we as researchers have in mind the wrong model where  $q = 0$ , i.e. everyone behaves rationally. Table 53.7 contains the results from a simulation based on these assumptions. Note first that our estimates of  $\delta$  are, as one would expect, severely biased. Nonetheless, our prediction of the treatment effect in a context with  $n = 2$  based on experimental data from the same context is only very slightly biased and the prediction of the treatment effect for  $n = \infty$  based on data from this context is not biased at all. Predictions *across* contexts are severely biased, which we would, however, not discover if we conducted only a single experiment in one context.

This example highlights that the ability to use unbiased experimental estimates to validate our model does not guarantee that we will find out if our model is wrong. Our model might yield the correct treatment effect estimates for the wrong reason; it may behave well in sample, but poorly out of sample.

## CONCLUSION

Even though field experiments have become immensely popular in political science, there are ongoing worries about how much we can learn from them. Two interrelated concerns are that experiments enjoy limited external validity and that they are disconnected from theory.

Throughout this chapter, we have highlighted the connection between these critiques and discussed various ways in which theories can help researchers learn more from their experiments. Examples range from selection diagrams that help assess how results can be transported from one setting to another to parametric structural models that allow for the extrapolation of

treatment effects to other settings or even other treatments.

Fundamentally, we think there is scope for researchers to do a lot better on these fronts. Tools already exist and we have illustrated how they can be put to use, albeit for a very simple problem.

We close, however, with a worry. There is nothing new to the idea that theory can be a powerful aid to inference. In fact, in some accounts, social experimentation first came up as a method in economics at a time when the dominant mode of inference was structural estimation. Heckman (1991) describes the vision of early experimentalists who were brought up in the structural tradition as one in which the primary goal of an experiment was not the non-parametric identification of an average treatment effect but the estimation of a structural model that could subsequently be used to assess the welfare consequence of numerous other experiments that had not actually been implemented. The turn towards ‘atheoretical’ experimentation was in many ways motivated by concerns about the over-dependence of results on highly parametric and often unrealistic structural models.

Asking experimentalists to accept more theoretical assumptions in exchange for the ability to make broader claims may thus seem like going in circles. The right response, we think, is use with caution. Like any powerful tool, causal models are easy to misuse and should be handled with care. Such care includes being transparent about robustness of conclusions to alternative assumptions, engaging in routine model validation, and validating extrapolations whenever possible.

## ACKNOWLEDGEMENTS

We would like to thank Donald Green, James Fearon, Alan Jacobs, and Richard Nielsen for their generous comments on earlier versions of this chapter.

## Notes

- 1 We recognize that the same issues can arise for other experimental and also for non-experimental approaches and believe many of the ideas described in this chapter apply more broadly.
- 2 In their review of the role that theory plays in experimental studies published in top economics journals, for example, Card et al. (2011) classify an experimental study as one that draws on theory only if the study explicitly includes mathematical expressions. Other accounts appear to have a less stringent view that encompasses informal statements about causal relationships derived from prior knowledge (Huber, 2017).
- 3 See Pearl and Mackenzie (2018) for other notions of theory that do not involve claims about causality.
- 4 For a discussion of related alternatives, see, for example, Robins (2003).
- 5 The reason is that average effects of one variable can depend upon levels of another variable which depends on the distribution of exogenous variables. Consider the effect of 'going first'. This effect depends on the customer's behavioral type. Since the theory does not specify the distribution of these types in the population, we would not be able to make statements about the average effect of going first based on this model alone.
- 6 See Mesquita and Tyson (2019) for a treatment of 'commensurability' which can be used to assess whether research designs capture quantities that are of theoretical interest.
- 7 Even with an experiment, however, the identification of average causal effects cannot be achieved completely without assumptions. Experiments must invoke some form of the Stable Unit Treatment Value Assumption (SUTVA) (Gerber and Green, 2012).
- 8 The reason is that the taxi fare is a 'collider' on the path from the number of rounds to whether the customer moves first (Pearl, 2009)
- 9 In practice, the models that are invoked vary in their complexity from several informal statements about hypothesized causal relationships (see e.g. Chong et al., 2014; Olken, 2010) to fully

specified decision-theoretic or game-theoretic models from which empirical predictions are derived in the form of comparative statics (see e.g. Avdeenko and Gilligan, 2015; Blattman and Annan, 2016).

- 10 In practice, researchers tend to either test a null hypothesis of no average treatment effect if they rely on the Neyman (1933) tradition of hypothesis testing, or the sharp null hypothesis of no treatment effect for any unit if they follow the Fisherian (Fisher, 1935) approach. See Bowers and Leavitt, Chapter 41, this *Handbook*, for more on the differences between these approaches.
- 11 This logic links to case selection criteria that are used in qualitative research (Van Evera, 1997).
- 12 See also Pritchett and Sandefur (2015), Vivaldi (2019), Dehejia et al. (2015), and Bisbee et al. (2017).
- 13 In the general solution for  $n > 1$  possible rounds, a customer who moves first pays  $\pi_n^1 = \sum_{t=2}^n (-1)^t \delta^{t-1}$ , where  $t$  indexes the bargaining round. The price paid by a customer who moves second  $\pi_n^2$  is just  $1 - \pi_n^1$ .
- 14  $\tau_2 > \tau_\infty \leftrightarrow 2\delta - 1 > 2\delta(1 + \delta) - 1 \leftrightarrow \delta > 0$ .
- 15 In general,  $q = 2(E(\pi_2^1) + E(\pi_2^2) - 1)$  and  $\delta = \frac{E(\pi_2^1) + 3E(\pi_2^2) - 3}{4(E(\pi_2^1) + E(\pi_2^2)) - 6}$ . Note that for the special case of  $E(\pi_2^1) = \frac{3}{4}$  and  $E(\pi_2^2) = \frac{3}{4}$ , the system implies  $q = 1$  and is consistent with any value of  $\delta$ . Moreover, there are values of  $E(\pi_2^1)$  and  $E(\pi_2^2)$  for which this system of equations has no solution. For example, there is no combination of  $0 \leq q \leq 1$  and  $0 \leq \delta \leq 1$  that can produce  $E(\pi_2^1) = 1/2$  and  $E(\pi_2^2) = 1/4$ .

# Survey Experiments and the Quest for Valid Interpretation

Gustavo Diaz, Christopher Grady,  
and James H. Kuklinski

When Diana Mutz wrote *Population-Based Survey Experiments* in 2011, she stressed one theme throughout the book. That theme: the use of large random samples with experiments embedded in them is an ideal means by which to generate causal generalizations. The embedded experiment provides the needed leverage to identify true cause and effect, and the random sample of a national population ensures that the results can be generalized to the population from which the sample was drawn.

Mutz's logic remains as compelling today as it was when she wrote the book. However, two significant changes have occurred. First, the increasing influence of the causal inference movement has changed political scientists' priorities with respect to data collection and analysis. Because causal inference emphasizes making the right comparisons, not generalization, researchers increasingly search for unique, often local, research opportunities, thus avoiding the costs and delays associated with the

collection of random samples of national populations. Their practice resonates with Campbell's long-ago assertion about social scientific practices: 'There was gross overvaluing of, and financial investment in, external validity, in the sense of representative samples at the nationwide level. In contrast, the physical sciences are so provincial that they have established major discoveries like the hydrolysis of water... by a single water sample' (Campbell, 1988, cited in Rosenbaum, 1999).<sup>1</sup> As a result, individual scholars' own research programs have progressed quickly, and, more significantly, these same scholars have been able to respond to and build on others' work in rapid-fire fashion.<sup>2</sup>

Second, measurement has emerged as a distinct and very active area of experimental survey research, with some of the discipline's best methodologists working in it.<sup>3</sup> Much of the effort has focused on the measurement of sensitive attitudes. The ingenuity of the designs that scholars have used to identify 'true' attitudes has been nothing short of

remarkable. We put quotes around true attitudes, since one of the key developments in measurement has been a continuing change in conceptions of what true attitudes are.

In both areas of experimental survey research, inference and measurement, scholars seek to interpret their results correctly (i.e. validly). In the case of causal inference, the goal is to reach proper conclusions about relationships between treatments and outcomes. In the case of measurement, the goal is to construct methodological approaches that increase confidence in the measurement of concepts such as prejudice, given that respondents often seek to hide their true views or do not consciously understand what they truly feel and think.

In both types of survey experimental study, scholars might misinterpret the empirical results. But why expect scholars to misinterpret their results? After all, scholars have been describing well-designed experiments as the gold standard by which to estimate true causal relationships for centuries. And no one would doubt that most political scientists can capably design strong survey experiments these days.

Considering causal inference experiments first, we identify and discuss three potential sources of misinterpretation of results: factors not included in the experiment moderate the basic treatment-outcome relationship; some people enter the experiment already having been treated in the very external world the researcher seeks to understand; and, respondents enter the experiment with different experiences, which are typically unknown to the experimenter and which shape the way respondents interpret the treatments. As part of our discussion, we evaluate some increasingly complex methods that scholars have proposed to overcome the sources of misinterpretation.

With respect to survey experiments designed to uncover true attitudes when social desirability might be coloring the respondent's true beliefs and feelings, we identify and discuss several problems that might undermine the increasingly complex designs that scholars

have brought to bear, thus leading them to misinterpret the results. The biggest obstacle to proper interpretation of results is the lack of full respondent anonymity, as viewed by the respondents themselves. Other problems, such as contamination from earlier questions in the survey, stem from the survey context, not necessarily from features of the experiment.<sup>4</sup> With respect to implicit attitudes, the fundamental problem that can impair interpretations of the results, in addition to some of those discussed in the preceding paragraph, arises when the treatments do not prime the concepts researchers think they have primed.

In both areas of survey experimental research, the designs of the experiments have increased in complexity over time. Two obvious questions, which we keep in mind throughout our discussion: has the increasing complexity of experiments increased scholars' capacities to make right inferences about the outside world? And has this increasing complexity wrought its own set of problems, or at least does the potential exist?

To be clear, we define survey experiments as experiments in which the treatments are delivered through a survey instrument. This excludes field experiments that use surveys to measure outcomes (Broockman et al., 2017). Conversely, if respondents enter a laboratory and are assigned to different treatments via different of a survey item, the study meets the definition of a survey experiment.

We have divided our discussion into three sections. First, we discuss reasons why political scientists can inadvertently misinterpret their results when conducting causal inference studies. Second, we undertake the same task with respect to measurement studies. In both instances, we also discuss designs that scholars have begun to propose to avoid misinterpretation. Finally, we pursue some implications of our earlier discussions. The overall purpose of our discussion is to highlight key areas that require the attention of both experts in the field and junior scholars interested in incorporating survey experiments into their research toolkits.

One of the most difficult aspects of writing this chapter is the knowledge that we will not be able to cite the many meritorious studies that warrant citation. While they originated in American politics, survey experiments are now common across all subfields of political science and international relations, exploring topics as different as immigration (Hainmueller and Hopkins, 2015), vote buying (Gonzalez-Ocantos et al., 2012), corruption (Winters and Weitz-Shapiro, 2013), the democratic peace (Tomz and Weeks, 2013), compliance with international treaties (Findley et al., 2017), and support for extremist groups (Blair et al., 2013). We could dedicate an entire chapter to listing interesting applications. Too keep it simple, we have chosen studies with which we are most familiar and that help us make the points we seek to make. We rely on readers to draw connections with the topics that are salient in their areas of expertise.

## **SURVEY EXPERIMENTS FOR CAUSAL INFERENCE**

Survey experiments for causal inference are experiments that happen to be embedded in a survey instrument. Respondents are randomly assigned to different versions of a treatment, and then they answer one or more outcome questions.<sup>5</sup> Much like in field and laboratory experiments, the researcher can identify an average treatment effect on one or more outcomes of interest (see Bowers and Leavitt, Chapter 41; Morton and Vásquez-Cortés, Chapter 51; Sinclair, Chapter 52; and Wilke and Humphries, Chapter 53, this *Handbook* for details). Because scholars in the discipline use causal inference survey experiments to illuminate real-world social and political phenomena, however, finding a non-zero treatment effect is not enough. Researchers must also convince others that their interpretations of treatment-outcome relationships are valid.

Anyone acquainted with causal inference in the social sciences might respond, ‘of course, how could it be any other way?’ In answer, scholars have identified at least three distinct challenges to valid interpretation, which, in our view, must be taken seriously and addressed head-on.

First, survey experimenters can easily overlook or not be able to incorporate factors that moderate the relationship between treatment and outcome (confounding). Second, some respondents might come to the survey experiment having already been pretreated in the very world to which the researcher is trying to infer (pretreatment contamination). Third, respondents might interpret the same treatment in a survey experiment differently due to differences in life experiences and the nature of the environments in which they live, which can be tantamount to receiving different treatments altogether (lack of information equivalence). Ignoring any of these possible complications can lead to wrong interpretations of estimated treatment-outcome relationships.

### ***Confounding***

The most obvious challenge to interpretation in causal inference survey experiments is confounding, which arises from the omission of one or more factors that moderate the relationship between treatment and outcome. This is akin to the problem of omitted variable bias in observational studies (King et al., 1995). The analogy might sound counterintuitive, as we are taught that experiments balance the distribution of both observed and unobserved covariates across groups. However, survey experiments randomize constructs that are not necessarily independent from each other outside the survey framework. Consequently, a treatment in a simple two-group design might inadvertently activate elements that correlate with the treatment in the real world, so that the researcher cannot disentangle the effect of a manipulated treatment from the confounder that is activated indirectly.

Consider the study of corruption. A recurrent debate in the literature is whether citizens sanction corrupt politicians with their votes. Since scholars cannot manipulate corruption, they use hypothetical situations in survey experiments to understand voters' reactions to corrupt politicians and hope that the findings translate to actual voting behavior.<sup>6</sup>

The simplest design presents respondents with a vignette describing a current officeholder seeking reelection. The control group receives information about the incumbent's profile only, while the treatment includes additional information about the incumbent's illicit activities. The design logic is straightforward: if voters sanction corrupt politicians in the treatment group, then, by inference, all that prevents voters from sanctioning corrupt politicians in the external world is the absence of credible information. More bluntly, when voters do not punish corrupt politicians, it is probably because they are unaware of their bad deeds.

Simple and elegant as this design is, it ignores the possibility that voters also respond to other activities the politician undertakes – and perhaps to the politician's personal characteristics as well. Any of these factors could moderate the original relationship between corruption and vote. In the extreme case, the inclusion of such other factors eliminates any initial effect between corruption and vote, which raises questions about the validity of the original interpretation (i.e. that information is the key). Thus, subsequent studies on corruption manipulate not only corruption, but also the provision of public goods, shared partisanship, and even gender (Anduiza et al., 2013; Winters and Weitz-Shapiro, 2013; Eggers et al., 2018). The accumulated evidence in these studies suggests that other factors moderate the relationship between corruption and vote.<sup>7</sup>

In almost all experimental studies, it is easy to identify several potential confounders. In the preceding example, other possible confounders include coercion, vote-buying, a politician's experience in office, and the credibility of the source (Botero et al., 2015;

Mares and Visconti, 2019; Weitz-Shapiro and Winters, 2017). All of these could simultaneously confound the relationship between corruption and vote – and in different directions. However, traditional survey experimental designs set a low limit on the number of potential confounders that can be included, which invariably raises the annoying and ever-present possibility that the experimenter's conclusion will be wrong, or at least incomplete.

Factorial survey experiments (see Auspurg and Hinz, 2015, and Sniderman, 2018, for overviews) provide one way to address the confounding problem, in that the researcher can manipulate both the explanatory variable of interest and a large number of confounders. However, including many potential confounders comes at the cost of statistical power. The researcher now faces a trade-off between accounting for all potential factors that get in the way of proper interpretation and the capacity to identify a non-zero treatment effect.

Conjoint experiments (Hainmueller et al., 2014) overcome this problem by combining clever design and technological advancements in computer-assisted surveys. In the standard conjoint design, the researcher presents respondents with multiple choice tasks between two or more hypothetical alternatives. The combinations consist of independently randomized attributes. In our earlier example, an experimenter might present respondents with two candidates for office. For each candidate, respondents see information about the candidate's level of public goods provision (low or high), party affiliation (left or right), gender (male or female), and so on. In turn, each one of these attributes is randomly assigned to take one of the values included in parenthesis. Because the exercise is hypothetical, the researcher can repeat this exercise multiple times.

Conjoint experiments, then, can incorporate an unusually large number of factors because respondents answer multiple choice tasks that completely randomize the attributes of each alternative, allowing researchers to explore a wide range of combinations before running

into power limitations. Some tasks, like voting, can be reasonably presented as a choice between two or more alternatives. Others, such as the study of immigration attitudes, where researchers ask respondents to put themselves in the role of an immigration officer to determine which individuals should get priority in the admission process, require more creativity (Hainmueller and Hopkins, 2015).

This increased leverage to address confounding comes with a caution: a seemingly impeccable logic, not empirical reality, drives the methodology. This reality opens the door to possible invalid interpretations of empirical results as they apply to the external world. One potential problem is that the quest for satisfying the logic of the methodology itself can come at the cost of realism, in that some combinations rarely, if ever, exist in the bigger world. For example, if a study randomizes occupation and education levels independently, respondents could potentially encounter a doctor with no post-secondary education (Hainmueller and Hopkins, 2015).<sup>8</sup>

Moreover, scholars can now include virtually as many factors as they can imagine, limited only by statistical power and their own discretion about which factors to include and which to exclude. Which factor has the largest effect size presumably depends heavily on the choices researchers make,<sup>9</sup> and thus misinterpretation of results once again becomes a potential problem. Researchers can be misled into thinking that a given cause is more important than others, although, in fact, any result is the product of choices.

Hainmueller and colleagues offer several valuable examples to emulate. In those examples, the use of well-established theories drives the crucial choices. Unfortunately, we already see a tendency in the work that followed the introduction of conjoint experiments to discard theoretical justification and view every factor in the research design as a treatment. This changes the purpose of the study from proper interpretation centered on one treatment of interest to a horse race to determine which factor has a larger effect size.

### ***Pretreatment Contamination***

As we already mentioned, the goal of causal inference survey experiments is to learn about attitudes and behaviors beyond the survey framework. This presents researchers with an interesting dilemma: a research question worthy of pursuit is also likely to be one where respondents encountered the treatment of interest prior to and outside the experiment. This very pretreatment, if not accounted for, can generate wrong interpretations about the effect of the treatment (Druckman and Leeper, 2012; Gaines et al., 2007).

As one of us noted in earlier work, the effect of pretreatment contamination depends on two factors: when the pretreatment occurs vis-à-vis the survey experiment and the longevity of the pretreatment effect, assuming there is one. We do not repeat the details here, except to say that, depending on the existence and endurance of pretreatments, the same static experiment can generate conclusions ranging from no effect at all to a large effect.

In short, survey experiments and the contexts to which experimenters seek to infer can and often do interact across time in highly complex ways. At the extreme, researchers cannot correctly interpret the experimental results without a thorough understanding of the contextual dynamics. However, if they are intimately familiar with the dynamics that happen in the world to which they are trying to infer, they probably can live without the experiment.

Note that attention to pretreatment moves the focus to dynamics, a shift that should resonate with most scholars. After all, the phenomena in the world that scholars study are dynamic. However, nearly all experimental designs are static, and thus they usually are incapable of addressing the effects of pretreatment. What to do?

One possibility: the researcher could simply include a separate question in the survey asking respondents if they have experienced a version of the treatment recently. This is problematic because the question can trigger different complications depending on

its placement. Including the question before treatment is problematic, in that respondents who did not experience the treatment before might be primed by it and approach the experiment as if they have been pretreated. In other words, the experimenter risks replacing pretreatment contaminations with primacy effects. Conversely, including the question after treatment can trigger a false memory.

Chong and Druckman (2013) propose two possible ways by which to identify and account for pretreatment effects: directly manipulate pretreatment and trace effects over time or find a real-world situation where some respondents have been pretreated and others have not.<sup>10</sup> In a first study, they estimate the effects of two competing frames for and against increased law enforcement. To address pretreatment, they conduct a two-wave panel study in which respondents do or do not receive treatment in the first wave (i.e. they are pretreated or not). In the second wave, they explore whether those not treated in the first wave show greater response to the second-wave treatment than those who had been pretreated. They find a big difference in second wave responses, with those not treated earlier showing greater response to the second-wave treatment. In their second study, they take advantage of a situation where some people have followed a controversy and others have not. Again, the results support the idea that pretreatment affects the experimental results.

Although the Chong-Druckman approach provides leverage on pretreatment contamination, implementing a short panel might be out of reach of many research budgets. Moreover, the field is converging in the opposite way. The norm is to perform increasingly complex one-shot studies, and, when resources permit, the preferred option is to replicate the same experiment with a different sample.

### ***Lack of Information Equivalence<sup>11</sup>***

Suppose that a researcher designs a survey experiment that satisfactorily addresses confounding and pretreatment contamination.

Can that researcher justifiably claim valid interpretation? The answer is a resounding ‘no’. In fact, the final challenge to proper interpretation that we consider, and which only recently has come to the fore, is both the most pervasive and most difficult to resolve. The problem is what Dafoe et al. (2018) call (a lack of) information equivalence. Once expressed, its logic is intuitive, even though solving the problem currently fringes on the impossible.

At the risk of oversimplifying, the idea goes as follows. Respondents routinely interpret and answer survey questions in terms of their life experiences. These experiences will vary greatly, especially when the experiment is embedded in a national survey. To the extent that people’s life experiences are sufficiently strong to influence their interpretations of treatments, the result is that, even though the experimental treatment is the same for everyone, different respondents essentially respond to different treatments. How different depends on how much the contextual considerations vary across respondents, and how much those considerations influence their responses.

To return to one of our previous examples, consider an experiment in which information about corruption primes different thoughts in the minds of a respondent from a rich and highly educated district, and a respondent from a poor district with low education levels. To the former, corruption might mean ‘committed a heinous and inexcusable white-collar crime’. To a respondent from a poor district with low education levels, where constituents depend on their officeholders for assistance, corruption might mean ‘doing a good deed’.

Note that the lack of information equivalence undermines basic tenets of both survey and experimental research. On the survey side, researchers must assume that the same question means the same thing to all respondents (King et al., 2004). On the experimental side, lack of information equivalence violates the Stable Unit Treatment Value Assumption (SUTVA), which states that all units assigned

to receive a treatment experience it in the same way (Cox, 1958).

This lack-of-information-equivalence problem cannot be easily solved without altering the scope of the study. Consider the running example in Dafoe et al. (2018). The democratic peace is a proposition in international relations suggesting that democracies never go to war with other democracies (Russett, 1993). Two alternative explanations underlie this proposition. First, democracies dislike war generally and are less likely than autocracies to go to war with anyone. Alternatively, democracies perceive other democracies as less threatening, so they only go to war less often with fellow democracies. To assess between the two explanations, Tomz and Weeks (2013) used a survey experiment that presented respondents with a hypothetical country in the process of acquiring nuclear weapons. They randomly presented the country as a democracy or dictatorship, and respondents indicate whether they favor or oppose a military intervention from their home countries.

In this study, the treatment is a country's political regime. The study deliberately avoids including explicit country labels to prevent confounding. However, the typical democracy that is suspected of developing nuclear weapons (e.g. Israel) is remarkably different from the typical dictatorship that carries the same suspicion (e.g. North Korea). Note that the limitation here is different from confounding. Even if the researcher manipulates one of the main potential confounders (e.g. economic development), the challenge to interpretation will persist. Rich democracies with nuclear power (e.g. France) still differ from poor democracies with nuclear power (e.g. Pakistan).

Whereas increasingly complex designs help with respect to the first two challenges to valid interpretation (confounding and pretreatment contamination), the verdict on whether they can help with the lack of information equivalence problem remains to be seen. The problem is more encompassing and much more difficult to overcome. The

number of possible interpretations of a treatment are countless. 'Good theory' might convince an audience depending on the application, but we currently do not see plausible solutions to the problem itself. The authors themselves could only hint at possibilities.

The lack-of-information-equivalence problem, we might note in closing, is inherent to surveys and survey responses. It is not a derivative of experiments. To overcome the lack of information equivalence problem would not only bring elation to survey experimentalists, it would bring elation to all researchers who use surveys.

### **Summary**

On the surface, conducting survey experiments is straightforward and deceptively easy. Moreover, the cost is relatively low, which makes them especially attractive to graduate students. In fact, the challenges to valid interpretations of survey experiments are many. These challenges, we emphasize, would not be apparent had earlier generations of survey experiments not existed. Increasingly, these challenges have become apparent, and the next generation of survey experimentalists presumably will be more aware of them as they create their own experimental designs. As a result, if the past is any indication, the demand for increasingly complex and sophisticated survey experiments will continue to grow.

### **SURVEY EXPERIMENTS AS A MEASUREMENT TECHNIQUE**

Scholars who use survey experiments to measure attitudes on sensitive issues, or to measure implicit attitudes that respondents themselves fail to see, also seek to design experiments that facilitate proper interpretations of the results. They, too, have encountered not-easily-identified or remedied problems that complicate the task.

Many, although not all, of the potential challenges in the study of measurement are a function of the survey context, as opposed to, as we saw earlier, the features of the larger context that can influence what respondents bring to the survey. With respect to studies that measure attitudes on sensitive issues, scholars routinely assume that eliminating respondents' perceptions of a lack of anonymity is the key to obtaining honest responses and is thus the key to researchers correctly interpreting the experimental results. Scholars who study implicit attitudes face the same challenge, plus the possibility of a lack of information equivalence, which, as we have already seen, is a potentially big challenge in causal inference studies.

### ***List Experiments and Randomized Response Techniques***

Scholars take for granted that respondents do not always answer survey questions truthfully when they are asked about sensitive issues for which there are 'right', or socially desirable, answers. To overcome this possible social desirability bias,<sup>12</sup> researchers have developed and refined two types of survey experiment: the survey list experiment and the randomized response technique. Both techniques are designed to convince individual respondents that their responses to questions about sensitive issues cannot be traced to them. There is some, albeit limited, evidence that these techniques induce less bias than direct questions (Blair et al., 2015; Lensvelt-Mulders et al., 2005b; Rosenfeld et al., 2016).

In a list experiment, the researcher randomly assigns respondents to one of two (or more) conditions. Individuals in the control condition are presented with a list of items; individuals in the treatment condition see the same list plus an additional item, which is the item of interest and the one on which the experimenter wants to ensure the respondent of anonymity. The average difference

between the treatment and control conditions represents the percentage of respondents who responded to the sensitive item in a 'socially undesirable' way (Blair and Imai, 2012).

The randomized response technique (Boruch, 1971; Warner, 1965) is one of the oldest techniques for asking sensitive survey questions.<sup>13</sup> In the most common version of a randomized response question, the respondent is directly asked a yes or no question about a sensitive topic. The respondent is also given some randomization device, like a coin or die. The respondent is told to answer the direct question when the randomization device takes on a certain value (tails) or to say 'yes' when the randomization device takes a different value (heads).<sup>14</sup> Users of the method assume that respondents will believe their anonymity is protected because the researcher cannot know whether a 'yes' resulted from agreement with the sensitive item or the randomization device. Researchers know the expected distribution of the condition, which allows an estimate of overall agreement with the sensitive item (See Lensvelt-Mulders et al., 2005a and Blair et al., 2015 for summaries).

How likely is it that respondents will perceive their answers to socially-sensitive matters as protected and thus truly anonymous? More specifically, what would it take for them to feel their answers are anonymous, especially if they already harbor suspicions? If they do not perceive the safety of autonomy, they will likely shape their responses to portray themselves in the best light possible, rather than answer honestly (Leary and Kowalski, 1990).

There are conditions under which the basic list experiment will almost surely fail to provide anonymity. Most obviously, if all or none of the items on the list anger respondents, those who seek to hide their true feelings and attitudes must answer dishonestly (Blair, 2015). Respondents might not interpret other response options as fully anonymous, either. If the treatment item is something respondents want to renounce unequivocally, they

might report a very low number to dissociate themselves from that item, on the logic that being associated with ‘three of the four [list items] may be interpreted as a 75% chance’ that the respondent holds the socially undesirable attitude (Zigerell, 2011: 544).

The most widely used randomized response technique also offers only limited anonymity to respondents. If a respondent answers ‘yes’, the answer *could* have been dictated by the randomization device, but it could also signal agreement with the sensitive item (Edgell et al., 1982; Yu et al., 2008). Thus, answering ‘yes’ is not unequivocally protected by the design. This response bias can affect respondents who do not hold the sensitive attitude just as readily as it affects respondents who do hold it. Respondents who hold the sensitive attitude might say ‘no’ when directed to be truthful, and respondents who do not hold the sensitive attitude might say ‘no’ when directed to say ‘yes’ (Edgell et al., 1982).

Knowledge of the various problems has helped researchers sharpen both survey experiments and randomize response techniques as tools for measurement. As researchers have learned more about the ways in which respondents respond to survey experiments designed for measurement, they have developed more complex and penetrating list experiments and randomized response techniques to account for them. In the process, researchers arguably have added some complexity to get closer to the right interpretations.<sup>15</sup>

For list experiments, the added complexity comes from increased attention to preparation and design. In terms of preparation, researchers pay even more attention to piloting to find control items that not only fit with the treatment item, but are negatively correlated with other control items (Glynn, 2013). Negatively correlated control items minimize the number of people who will score very high or very low on the control list, a problem that can compromise anonymity.

Variations on the list experiment have helped to isolate the effect of the treatment

item. One variation is the double list experiment (Droitcour et al., 2004; Glynn, 2013), which attempts to solve the problem of respondent interpretation by using two control lists. The treatment item is randomly selected to appear on either the first or the second control list so that some respondents see it on the first list and some respondents see it on the second. If researchers observe the same treatment effect on both lists, there is less risk that the effect depends on the choice of control items or on how respondents interpret the list. Another modification is a placebo-controlled list experiment, which uses a fourth item as a placebo on the control list to ensure that the difference between the two lists is due to the treatment item, not the presence of an extra item (Riambau and Ostwald, 2019).

Users of survey experiments have come up with variations in the randomized response techniques so as, first, to provide what respondents will view as full anonymity and, second, to keep them from viewing one response as riskier. One such variant is the crosswise model (Jann et al., 2011; Yu et al., 2008).<sup>16</sup> In the crosswise model, respondents are presented with two statements, one sensitive statement and one non-sensitive statement, for which the population mean is known. The respondent is asked to say if neither or both statements are true or if one statement is true. Unlike a typical randomized response question, where individuals who agree with the sensitive statement only occupy the ‘yes’ group, the crosswise model allows people who agree with the sensitive statement to occupy either group.<sup>17</sup>

### ***Beyond Ensuring Anonymity***

The jury is out on the effectiveness of these new techniques. They appear to provide something closer to true anonymity, so they come closer to revealing ‘the truth’ than their predecessors. However, is ensuring anonymity a *sufficient* condition to obtain honest answers

to sensitive questions? It is unlikely to be a *necessary* condition – see coercive measures like the bogus pipeline (Jones and Sigall, 1971) for techniques to obtain honest responses that ignore anonymity altogether – but unspoken in work using list experiments and randomized response techniques is the assumption that respondents will answer honestly if they perceive their answers to be anonymous.

We see several reasons why anonymity is *not* a sufficient condition to obtain honest answers to sensitive questions. First, even with anonymity, respondents have no incentive to answer honestly. If a prejudiced person is presented with a list experiment that uses a treatment item designed to measure prejudice, what incentive does that prejudiced individual have to comply with the instructions of the list experiment? In addition to anonymity, a further assumption must be made: respondents want to express their socially undesirable opinions in a way that eludes social sanctions.

Second, anonymity does not help respondents interpret the question as the researcher intended. When the purpose of a question is unclear, respondents must either increase their own cognitive efforts in order to understand the question or satisfice and provide an answer that seems reasonable, even without understanding the question. All survey questions assume that the respondent interprets the question in the way intended by researchers; techniques to ensure anonymity make that interpretation less likely by obfuscating the question's purpose.

Anonymity does not solve many other pitfalls familiar to survey questions and survey experiments. It does not help researchers to avoid question ordering effects or contamination from earlier questions in the survey; it does not reveal how respondents interpret the sensitive item and thus cannot ensure information equivalence. Who knows what other novel problems it does not address? Future research should further explicate the assumptions necessary to obtain honest answers to sensitive questions. Future research should

also reveal further limitations of techniques to measure sensitive attitudes.

One limitation is clear even without further research: these questions do not uncover implicit attitudes. Many sensitive topics appear so sensitive that individual's conscious, explicit attitudes differ from their implicit attitudes (Greenwald and Banaji, 1995). Even many non-sensitive attitudes seem to be beyond an individual's conscious awareness (Nisbett and Wilson, 1977). Techniques like list experiments and randomized response techniques purport to offer anonymity so that respondents feel comfortable revealing their unsavory conscious attitudes, but these techniques do nothing to draw out attitudes that respondents do not know they have. In the next section, we cover survey experimental techniques to reveal respondents' implicit attitudes.

### ***Priming and Implicit Attitudes***

Whereas techniques to measure explicit attitudes seek to provide respondents with anonymity, techniques to measure implicit attitudes seek to keep the respondent consciously unaware of the implicit attitude being measured. To do so, researchers use priming experiments.<sup>18</sup>

In a priming experiment, researchers expose respondents to a stimulus representing topic X in order to influence their responses to a survey question about topic Y, without the conscious knowledge of the respondents. A control group is not exposed to the stimuli representing topic X, so the difference between the treatment group and control group is due to exposure to the treatment stimuli. Priming experiments work by directing respondents' consciousness away from topic X and towards topic Y so that respondents do not consciously censor their feelings about topic X (Macrae et al., 1994; Schwarz and Clore, 1983).

The earliest priming experiments simply randomized the order in which questions were asked (McFarland, 1981). For example,

Schwarz and Bless (1991) show that a question about someone's marriage *before* a question about their general life satisfaction increases life satisfaction for people with good marriages and decreases it for people with bad marriages. The priming paradigm would later be used to measure sensitive attitudes about social groups by priming the social group and then asking respondents about a related topic. For example, Hurwitz and Peffley (1997) prime race by randomizing whether the target of law enforcement action was white or black. This allows them to determine the effect of race on judgments of crime and punishment.

While these priming experiments are extremely innovative, they are also so simple and straightforward that suspicious respondents might realize a connection between the sensitive item being primed and the non-sensitive item being solicited. And, because they measure implicit attitudes by estimating the relationship between the prime and outcomes, they also suffer from the flaws of information equivalence and confounding we discussed in the previous section.

To prevent subjects from ascertaining the goal of the study, researchers try to hide the prime amid other, ostensibly more important, information. One way to do this is with an endorsement experiment (Cohen, 2003). In an endorsement experiment, respondents are asked how much they support a policy. In the treatment condition, the policy is 'endorsed' by a group that respondents would not consciously admit to influencing their opinion. In the control condition, the policy is not endorsed by any group. The average difference in support between the endorsed and unendorsed policy represents the change in support for the policy because of the endorsement.<sup>19</sup>

Though endorsement experiments help hide the goal of the study by distracting attention away from the group and towards a substantive policy, they still suffer from lack of information equivalence. In endorsement experiments, the problem manifests itself because a group's endorsement may be used

as a heuristic to understand substantive policy details (Lupia, 1994). The basic endorsement experiment cannot differentiate bias towards the endorsing group from use of the endorsing group as an information heuristic. To ensure information equivalence, researchers utilize endorsements as part of factorial experiments that vary substantive details about the policy along with group endorsement. For example, Nicholson (2011) uses this design to show that a group's endorsement of a policy is overwhelmed by information about the social groups who are helped or harmed by the policy.

Priming experiments still suffer from several problems. First, the treatment might not prime the intended concept. Unlike list experiments or randomized response questions, the item of interest is not directly enumerated to the respondent. It is possible that the treatment activates different attitudes than the researcher intends. Second, the mental construct being primed may already be salient in the minds of all respondents (i.e. pretreated), rendering the prime impotent.<sup>20</sup> Unfortunately, methods to validate the estimates of priming experiments do not exist yet.

## Summary

Scholars want to measure concepts validly and reliably. Direct survey questions are often used to measure concepts, but direct questions fail when respondents lie or do not have conscious access to the attitude the researcher is interested in. To address the reasons that direct questions fail, scholars began measuring some concepts with survey experiments in lieu of direct questions. As scholars learned more about measuring concepts with survey experiments, they learned the pitfalls of survey experiments for measurement and further adapted their measures to account for those pitfalls. Thus, the history of measuring sensitive concepts has been to increase complexity of design for the purpose of increasing validity.

One problem plagues all measurement: how do we know that our measure is valid? For some outcomes, such as voter turnout, we can compare our measure with population estimates. But for other outcomes, such as racism or the effect that political parties have on citizens' policy preferences, no population estimate with which to validate our measure exists. We are searching for a truth we cannot know.

Despite an inability to validate most measures, we make progress by fully explicating the assumptions of each measurement strategy and then determining if the strategy fulfills them. When measurement strategies do not satisfy their own assumptions, researchers must create measures that do. For example, researchers assume anonymity is the key to obtaining honest answers about sensitive topics. Yu et al. (2008) noticed that randomized response techniques fail to satisfy this assumption and created the crosswise model to provide respondents with full anonymity.

Part of explicating assumptions is explicating the reasons as to why direct questions will not validly measure a concept of interest. Sometimes scholars will find that people are not as squeamish as scholars expect, and thus direct questions work well. Other times the techniques that provide anonymity do not reveal the attitude of interest because the barrier to measurement is respondents lacking conscious access to that attitude. We think it is important that the theoretical assumptions about the concept we are measuring match the assumptions of our measurement strategy.

## CONCLUSION

Survey experimental research has matured quickly and dramatically. In both areas of endeavor that we reviewed, researchers appear to be functioning in the best tradition of 'normal science' (Kuhn, 1962), which we applaud. The growing complexity and sophistication in research designs has led to new discoveries, and, subsequently, more

challenges, which in turn have generated even more creative and complex designs. The more we learn, it seems, the more complex and sophisticated the next generation of research must be to address the newest, and often unexpected, discoveries. No serious researcher will be surprised to know that a final stopping point is nowhere to be seen.

Increased complexity implies more moving parts, and the more moving parts there are, the less transparent the methods and empirics can become. Recent work on conjoint analysis exemplifies this statement (Hainmueller et al., 2014). The logic of leveraging pair comparisons to isolate independent effects across manipulations fringes on impeccable, and as a result, the potential to remedy some existing challenges is, at least in theory, high. Yet, knowing precisely how respondents respond to and interpret many descriptive pairs remains slightly difficult to ascertain. Likewise, recent measurement advances like the crosswise model (Yu et al., 2008) appear to offer anonymity in a way that is convincing to respondents. Yet, scholars have no way of assessing the validity of this approach on most sensitive attitudes.

We are reminded of the dictum of 'no more than three independent variables', as applied it to the growing complexity of probit and logit models (Achen, 2002). We see no reason to apply it to survey experimental research at this time, although keeping it close at hand as the two areas progress would be wise. Increasing the complexity and sophistication of survey experimental designs has thus far evolved in a logical, progressive, and helpful way. Whether a lack of transparency will begin to obfuscate the power of the designs remains to be seen.

Overall, reviewing the evolution of survey experimental research has been, for us, an eye-opener. Although we have remained conversant with the literature as it has grown, peering into the bowels of the research has increased our understanding of the challenges that await new generations of researchers. It has also increased what was our already-high respect for the work.

## Notes

- 1 We do not address external validity or inferring from an experiment to some (often undefined) world outside it. Suffice it to say that we agree with the contention that the primary purpose of an experiment should be to test theory, not to infer to some outside world (Mook, 1983). However, for the purposes of this chapter, we take the general practice of inferring from experiment to world as given.
- 2 The speed with which researchers can respond to each other underlines the crucial importance of publishing the results of well-designed survey experiments that generate null findings.
- 3 Note that this distinction is primarily a working and admittedly artificial one. The study of causal inference requires good measurement and the study of measurement cannot occur without causal inference. Our distinction echoes what is current practice in the field.
- 4 These problems apply to causal inference studies as well. We bring them up in the discussion of measurement because it is there that the potential consequences of survey contamination are most obvious.
- 5 Depending on the question of interest, the control group may receive no treatment at all, or an innocuous version of the treatment (placebo). Some survey experiments include both pure control and placebo conditions. The conventional advice is to include some form of control group to identify the direction of the treatment effect (Gaines et al., 2007).
- 6 Note that survey experiments are not the only way to study corruption. Occasionally, researchers find direct measures in observational data (Fernández-Vázquez et al., 2016; Ferraz and Finan, 2008; Golden and Picci, 2005; Olken, 2007).
- 7 This example is certainly not the only case of researchers using multiple factors in survey experiments. In the study of American politics, the practice is traceable at least back to the early studies on racial prejudice (Sniderman et al., 1991) and heuristic processing (Mondak, 1993).
- 8 The standard practice is to prevent these combinations from appearing, but that might introduce bias in the average marginal component effect. An alternative is to allow for illogical combinations with a relatively low probability (Hainmueller et al., 2014).
- 9 Although previous work provides guidelines for the number of factors that should be included (Auspurg and Hinz, 2015; Hainmueller et al., 2014), we are not aware of any developments regarding which factors to include.
- 10 Chong and Druckman (2010, 2013) pioneered dynamic studies. Even today, few have followed their footsteps.
- 11 In their original study, Dafoe et al. (2018) use the term information equivalence. We use lack of information equivalence because a lack of equivalence is the problem they address.
- 12 Other instances of response bias are due to demand effects (when the respondent learns what the researcher wants to hear and obliges) and acquiescence bias (the tendency of respondents to agree rather than disagree with statements). Survey experiments help overcome these biases by hiding the intent of the researcher. Other reasons for respondent's lying are when the respondent deliberately provides untrue responses for fun, lack of attention, and desire to get through the survey quickly. Most survey experimental techniques will not overcome these issues.
- 13 While many people do not consider randomized response models as experiments, we view them as experiments in which the researcher does not know the experimental condition of the respondent. Results can still be analyzed in an 'experimental' fashion (and often compared to results from other experiments to reduce bias) because the data-generating process is still known. The same logic applies to non-randomized response models, the close cousins of randomized response models.
- 14 This is known as the 'forced response' model, introduced by Fox and Tracy (1986). Other models use slightly different procedures.
- 15 A full discussion of all recent advances in list experiments and randomized response techniques is beyond our scope. Here we focus on design advances and omit work on statistical analysis of survey experiments and the comparison of responses to direct questions (Ahluquist, 2018; Aronow et al., 2015; Blair and Imai, 2012; Blair et al., 2015; Blair et al., 2018; Chou et al., 2017; Corstange, 2009; Rosenfeld et al., 2016).
- 16 Technically, the crosswise model is a non-randomized response model. Non-randomized response models pair a sensitive question with some nonrandom phenomenon, instead of with random phenomenon like a coin flip. The sensitive question and the non-random phenomenon are paired in such a way that the researcher cannot know if the respondent agrees with the sensitive question or the non-random phenomenon.
- 17 Lensvelt-Mulders et al. (2005a), Azfar and Murrell (2009), and Gingerich (2015) report other randomized response techniques and advances.
- 18 Other techniques are also used, such as implicit associations tests (Greenwald et al., 1998) and physiological measures (Rankin and Campbell, 1955). Survey experiments enjoy one major

advantage: they can easily be administered to respondents outside of the laboratory.

- 19 Endorsement experiments have recently been used to measure explicit attitudes towards groups that may be dangerous to support publicly. Rather than measure implicit attitudes, these 'explicit' endorsement experiments work like list experiments, where individuals can freely express their support for the sensitive group because the researcher cannot differentiate policy support from group support at an individual level. Whereas list experiments hide the respondent's opinion by pairing the sensitive item with non-sensitive control items, endorsement experiments hide the respondent's opinion by pairing the sensitive item with a policy (e.g. Blair, 2015).
- 20 The outcome being measured could also activate the prime, which would accidentally treat the control group. This happens when the outcome is too close mentally to the prime. For example, the term 'welfare' may make racial minorities salient in the minds of white respondents.

# Deep Learning for Political Science

Kakia Chatsiou and Slava Jankin Mikhaylov

## INTRODUCTION

Political science, and social science in general, have traditionally been using computational methods to study areas such as voting behavior, policy making, international conflict, and international development. More recently, increasingly available quantities of data are being combined with improved algorithms and affordable computational resources to predict, learn, and discover new insights from data that is large in volume and variety. New developments in the areas of machine learning, deep learning, natural language processing (NLP), and, more generally, artificial intelligence (AI) are opening up new opportunities for testing theories and evaluating the impact of interventions and programs in a more dynamic and effective way. Applications using large volumes of structured and unstructured data are becoming common in government and industry, and increasingly also in social science research.

This chapter offers an introduction to such methods drawing examples from political science. Focusing on the areas where the strengths of the methods coincide with challenges in these fields, the chapter first presents an introduction to AI and its core technology – machine learning, with its rapidly developing subfield of deep learning. The discussion of deep neural networks is illustrated with the NLP tasks that are relevant to political science. The latest advances in deep learning methods for NLP are also reviewed, together with their potential for improving information extraction and pattern recognition from political science texts.

We conclude by reflecting on issues of algorithmic bias – often overlooked in political science research. We also discuss the issues of fairness, accountability, and transparency in machine learning, which are being addressed at the academic and public policy levels.

## AI: MACHINE LEARNING AND NLP

The European Commission (2019) defines AI as ‘systems that display intelligent behaviour by analysing their environment and taking actions – with some degree of autonomy – to achieve specific goals’. As a scientific discipline, AI includes several techniques like machine learning (with deep learning and reinforcement learning as specific examples), machine reasoning, and robotics (European Commission, 2019). However, much of what is discussed as AI in the public sphere is machine learning, which is an ‘algorithmic field that blends ideas from statistics, computer science and many other disciplines [...] to design algorithms that process data, make predictions, and help make decisions’ (Jordan, 2019).

Machine learning has a history of successful deployment in both industry and academia, going back several decades. Deep learning has more recently made great progress in such applications as speech and language understanding, computer vision, and event and behavior prediction (Goodfellow et al., 2016). These rapid technological advances and the promise of automation and human-intelligence augmentation (Jordan, 2019) reignited debates on AI’s impact on jobs and markets (Brynjolfsson et al., 2018; Samothrakis, 2018; Schlogl and Sumner, 2018) and the need for AI governance (Aletras et al., 2016; Benjamins et al., 2005).

Machine learning (and deep learning as its subfield) is defined as the ‘field of study that gives computers the ability to learn without being explicitly programmed’ (Samuel, 1959). In this context, ‘learning’ can be viewed as the use of statistical techniques to enable computer systems to progressively improve their performance on a specific task using data without being explicitly programmed (Goldberg and Holland, 1988). To be able to learn how to perform a task and become better at it, a machine should:

- be provided with a set of example information (inputs) and the desired outputs. The goal is then to learn a general rule that can take us from

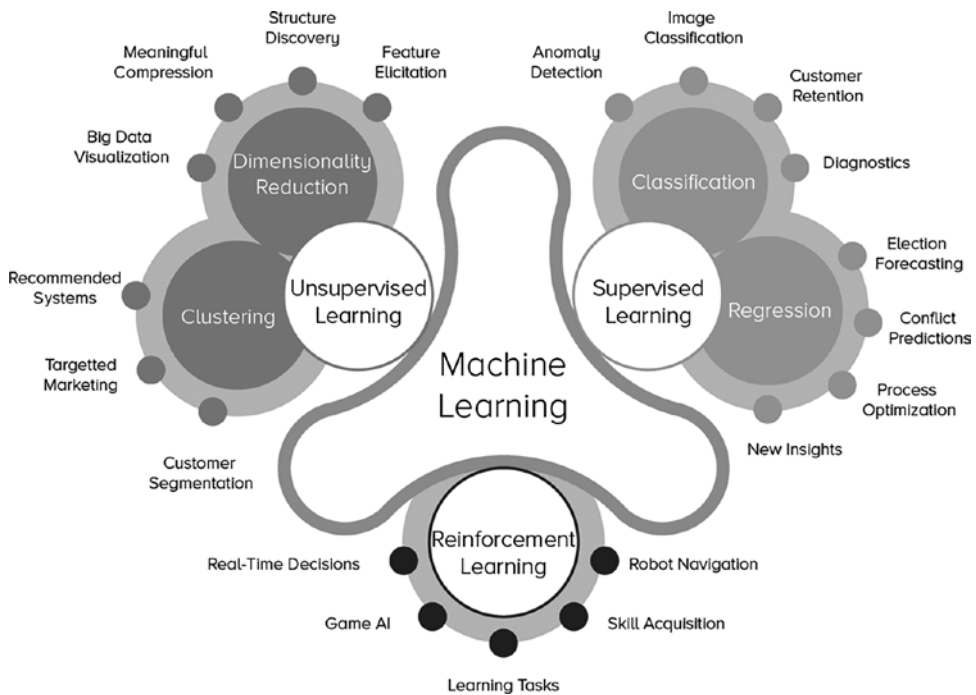

the inputs to the outputs. This type of learning is called *Supervised Learning*. This works well even in cases when the input information is not available in full;

- be provided with an incomplete set of example information to learn from, where some of the target outputs are missing. This type of learning is called *Semi-supervised Learning*. When example information is available in one domain and we want to apply the knowledge to another domain with no available example information, this is called *Transfer Learning*;
- obtain training labels for a small number of instances while at the same time optimize which elements it needs to learn labels for. This is called *Active Learning*, and, in some cases, it can be implemented interactively in order to ask a human user for information on how best to label different elements;
- be asked to find structure in the input without having any labels provided in advance (as input). This type of learning is called *Unsupervised Learning* and can be used both for discovering hidden patterns in the data as well as learning features or parameters from the data; and
- be given information not about the structure of the data itself but rather about whether it has learned something correctly or incorrectly, in the form of rewards and punishments. This is called *Reinforcement Learning* and is the type of learning best performed in dynamic environments such as when driving a vehicle or playing a game against an opponent (Bishop, 2006).

Figure 55.1 summarizes different types of learning and how they relate to their subtasks.

One of the most fruitful areas of machine learning applications in political science relates to work that treats text as data. Such quantitative text analysis could involve tasks such as *classification, clustering, dimensionality reduction, structured prediction or learning*.

Assigning a category to a group of documents or other elements (‘classification’) is useful when, for example, there is a need to understand audience sentiment from social media or customer reviews or sort party manifestos into predefined categories on the ideological spectrum. Spam filtering is an example of classification from our

**Figure 55.1** Machine learning and related tasks

contemporary daily life, where the inputs are email (or other) messages and the classes are ‘spam’ and ‘not spam’. The task involves a dataset containing text documents with labels, which is then used to train a classifier aiming to automatically classify the text documents into one or more predefined categories. Inputs are divided into two or more classes, and the algorithm assigns unseen inputs to one or more (multi-label classification) of these classes. This is typically tackled via supervised learning. In political science work, such models have been used, for example, to understand US Supreme Court decisions (Evans et al., 2007), party affiliation (Yu et al., 2008), and in measuring polarization (Peterson and Spirling, 2018).

Separating elements into groups (‘clustering’) is similar to classification, only the groups are not known beforehand, hence this task usually involves unsupervised learning. Sanders et al. (2017) and Preoțiu-Pietro et al. (2017) are examples of the potential use

of clustering to better understand political ideologies and parliamentary topics.

Reducing the complexity of data (‘Dimensionality Reduction’) involves simplifying inputs by mapping them into a lower-dimensional space. Principal-components analysis and related methods like correspondence analysis have been used to analyze preferences for foreign aid (Baker, 2015) and the ideological mapping of candidates and campaign contributors (Bonica, 2014). Topic modeling is a related problem, where multiple documents are reduced to a smaller set of underlying themes or topics. Feature extraction is a type of dimensionality reduction task and can be accomplished using either semi-supervised or unsupervised learning. Selection and extraction of text features from documents or words is essential for text mining and information retrieval, where learning is done by seeking to reduce the dimension of the learning set into a set of features (Nguyen et al., 2015; Uysal, 2016).

'Structured prediction or structured (output) learning' involves performing structured predictions and is an umbrella term for supervised machine learning techniques that involve predicting structured objects, rather than scalar discrete or real values (BakIr, 2007). In Lafferty et al. (2001), for example, the issue of translating a natural-language sentence into a syntactic representation such as a parse tree can be seen as a structured-prediction problem in which the structured-output domain is the set of all possible parse trees.

Table 55.1 summarizes some of these techniques providing examples from political science.

These political text-as-data applications are related to the broader field of NLP, which is concerned with the interactions between computers and human or natural languages (rather than formal languages). After the 1980s and alongside the developments in machine learning and advances in hardware and technology, NLP has mostly evolved around the use of statistical models to automatically identify patterns and structures in language, through the analysis of large sets of annotated texts or corpora. In addition to document classification and dimensionality-reduction applications in political science, leveraging the latest developments in machine learning and deep learning methods, the NLP field has made significant progress on several additional tasks:

- *Extracting text from an image.* Such a task usually involves a form of *Optical Character Recognition*, which can help with determining the corresponding text characters from an image of printed or handwritten text.
- *Identifying boundaries and segment text into smaller units (for example from documents to characters).* Examples of such tasks include morphological segmentation, word segmentation, and sentence-boundary disambiguation.
- *Morphological segmentation* is the field of separating words into individual morphemes and identifying the class of the morphemes is an essential step of text preprocessing before textual data can be used as an input in some machine learning algorithms. Some such tasks can be quite challenging to perform automatically, sometimes depending on morphological complexity (i.e., the internal structure of words) of the language being considered.
- *Word segmentation or tokenization* makes possible the separation of continuous text into separate words.
- *Sentence-boundary disambiguation* helps identify where a sentence starts and where it ends. This is not as simple as identifying where a period or other punctuation mark is, since not all punctuation signals the end of a sentence (consider abbreviations, for example) and not all sentences have punctuation.
- *Assigning meaning to units. Part-of-speech tagging,* involves automatically determining and assigning a part of speech (e.g., a verb or a noun) to a word is usually the first step to looking at word context and meaning. Of course, many

**Table 55.1 Overview of machine learning methods and examples from political science**

Dimensionality reduction, e.g., topic modeling, feature extraction	Semi-supervised Unsupervised	<ul style="list-style-type: none"> <li>• preferences for foreign aid (Baker, 2015)</li> <li>• ideological mapping of candidates and campaign contributors (Bonica, 2014)</li> <li>• extraction of text features from documents (Uysal, 2016; Nguyen et al., 2015)</li> </ul>

words have more than one meaning or could be assigned different parts of speech, which can prove challenging for NLP, as it needs to select the meaning which makes more sense in the current context. With the emergence of deep learning methods, word embeddings have been used to capture semantic properties of words and their context (see the next section for a more detailed presentation).

- *Extracting information from the text and synthesizing it.* NLP tasks such as *Named Entity Recognition*, *Sentiment Analysis*, *Machine Translation*, and *Automated Text Summarization* build on the above tasks in order to identify and extract specific content from texts and synthesize it to generate new insights or content.
- *Machine Translation* studies ways to automate the translation between languages. Deep learning methods are improving the accuracy of algorithms for this task (Nallapati et al., 2016). This leads to scaling-up opportunities in comparative politics research (de Vries et al., 2018).
- *Named Entity Recognition* helps determine the elements in a text that are proper names (such as people or places) and what type of elements they are (e.g., person, location, organization).
- *Sentiment Analysis* is the automatic extraction of opinions or subjective information from a set of documents or reviews, to determine ‘polarity’ about specific ideas. For example, scholars have used *Sentiment Analysis* to identify trends of public opinion in social media (Ceron et al., 2014; Proksch et al., 2015).
- *Automated Text Summarization* is a common dimensionality-reduction task in machine learning and NLP. It involves producing a readable, coherent, and fluent summary of a longer text, which should include the main points outlined in the document. *Extractive summarization* involves techniques such as identifying key words from the source document and combining them into a continuous text to make a summary. *Abstractive summarization* involves automatically paraphrasing or shortening parts of the original text.

With the deep learning methods being extremely data hungry, we believe that a primary area where the field will benefit from the latest technology is in the text-as-data or broader NLP domain. In what follows, we outline several deep learning models that

have made recent advances in NLP possible and highlight how they can be used in political science research.

## DEEP LEARNING NLP FOR POLITICAL ANALYSIS

### *Understanding ‘Learning’*

To define *deep learning* and understand the difference between deep learning and other machine learning approaches, first we need some idea of what machine learning algorithms *do*. As mentioned above, the field of machine learning is concerned with the question of how to construct computer programs that automatically improve with experience.

But what does *learning* mean in this context?

A computer program is said to learn from experience  $E$  with respect to some class of tasks  $T$  and performance measure  $P$  if its performance at tasks in  $T$ , as measured by  $P$ , improves with experience  $E$ . (Mitchell, 1997; our emphasis)

This type of learning that particularly pertains to NLP regardless of the type of learning (supervised, unsupervised, active, etc.) is very much based on a ‘bag-of-words’ approach that only considers one dimension of the text, without taking onboard any of the contextual information – a rather ‘shallow’ type of learning.

Deep learning, on the other hand, offers the potential to combine multiple *layers* of representation of information, sometimes grouped in a hierarchical way.

### *Understanding ‘Deep’*

Deep learning is a type of machine learning (representation learning) that enables a machine to automatically learn the patterns needed to perform regression or classification when provided with raw data. The approach puts an emphasis on learning

successive *layers* of increasingly meaningful representations. It involves multiple levels of representation. Deng (2014: 199–200) defines deep learning as a class of machine learning algorithms that

- use a cascade of multiple layers of non-linear processing units for feature extraction and transformation, and each successive layer uses the output from the previous layer as input;
- learn in supervised (e.g., classification) and/or unsupervised (e.g., pattern analysis) manners; and
- learn multiple levels of representations that correspond to different levels of abstraction – the levels form a hierarchy of concepts.

In deep learning, each level learns to transform its input data into a slightly more abstract and composite representation. In an image-recognition application, the raw input may be a matrix of pixels, the first representational layer may abstract the pixels and encode edges, the second layer may compose and encode the arrangements of edges, the third layer may encode eyes and a nose, and the fourth layer may recognize that the image contains a face (for more information about

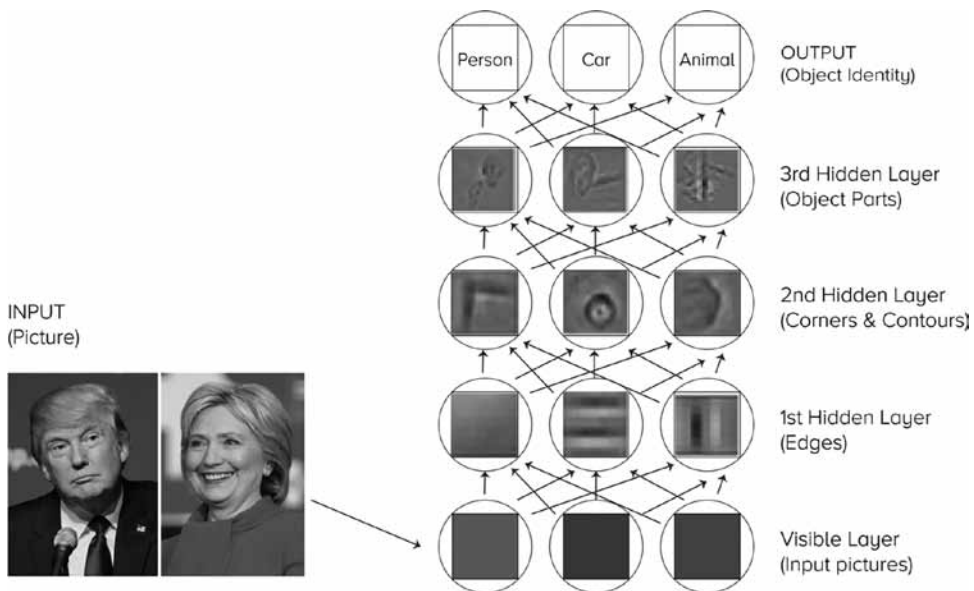

feature visualizations from computer-vision deep neural networks, see Olah et al., 2017 and Zhang and Zhu, 2018). Importantly, a deep learning process can learn which features to optimally place in which level *on its own*. Figure 55.2 shows how a deep learning hierarchy of complex concepts can be built from simpler concepts.

We will next discuss the application of deep learning algorithms in generating insights from images and text data.

### Working with Image Data

Convolutional neural networks (CNNs) are a category of artificial neural networks that have proven very effective when trying to classify or detect features in images. CNNs have been very successful at identifying objects, faces, and traffic signs in images and are currently advancing computer vision in robotics and self-driving vehicles.

CNNs have been trained on satellite imagery to map and estimate poverty, where data on economic livelihoods are scarce and

**Figure 55.2 Building a hierarchy of complex concepts out of simpler concepts**

where outcomes cannot be studied via other data. Jean et al. (2016) combine satellite imagery with survey data from five African countries (Nigeria, Tanzania, Uganda, Malawi, and Rwanda) to train a CNN to identify image features that can explain up to 75% of the variation in the local-level economic outcomes by estimating consumption expenditure. Figure 55.3 shows four different convolutional filters used for extracting these features, which identify (from left to right) features corresponding to urban areas, non-urban areas, water, and roads. Babenko et al. (2017) focus on an urban subsample of satellite images in Mexico (using images from Digital Globe and Planet) identifying rural and urban ‘pockets’ of poverty that are inaccessible and changing frequently – areas that are unlikely to integrate without the support of the necessary policy measures (Figure 55.4).

CNNs have also been used to map informal settlements (‘slums’) in developing countries, using high- and low-resolution satellite imagery (Helber et al., 2018), to help international aid organizations to provide effective social and economic aid.

But how do they work?

Analogous to how children learn to recognize a cat from a dog, we need to ‘show’ an

**Figure 55.3 Visualization of features. Four different convolutional filters (which identify, from left to right, features corresponding to urban areas, non-urban areas, water, and roads) in the convolutional-neural-network model used for extracting**

Source: Jean et al. (2016).

algorithm millions of pictures (‘input’) of a dog before it can reliably make generalizations and predictions for images it has never seen before. However, machines do not ‘see’ in the same way we do – their ‘language’ consists of numbers. One way around this is to represent every image as multi-dimensional arrays of numbers, and CNNs offer a way to move from an image to a set of vectors.

**Figure 55.4 Examples of Digital Globe (left) and Planet (right, Michoacán) imagery**

Source: Babenko et al. (2017).

The main building block of CNN is the *convolutional layer, filter, or kernel*. Convolution is a mathematical operation that allows us to condense information by combining two functions into one. Take the very simple, pixelated representation of a black and white heart in Figure 55.5 element (a) for example. If each cell is a pixel, then we could represent black pixels with value 1 and white pixels with value 0 (see Figure 55.5, element (b)) – this is the ‘input’.

Using a filter, as in Figure 55.5 element (c), with predefined black and white pixels, we can now perform a convolution and create a ‘feature map’ (Figure 55.6, element (d))

by layering the filter on top of the input and sliding it for each row. At every step, we perform element-wise matrix multiplication and sum the result, which goes into the feature map – represented in the black background in Figure 55.6.

We then slide the filter over the next position and perform the same multiplication (see Figure 55.7).

We repeat until the ‘input’ is reduced from a 5x5 matrix to a 3x3 feature map, as in Figure 55.8 element (c). The example above is a two-dimensional convolution using a 3x3 filter – in reality, these convolutions are performed in three dimensions (width, height,

Figure 55.5 Convolution of a black and white image of a heart – the essential elements

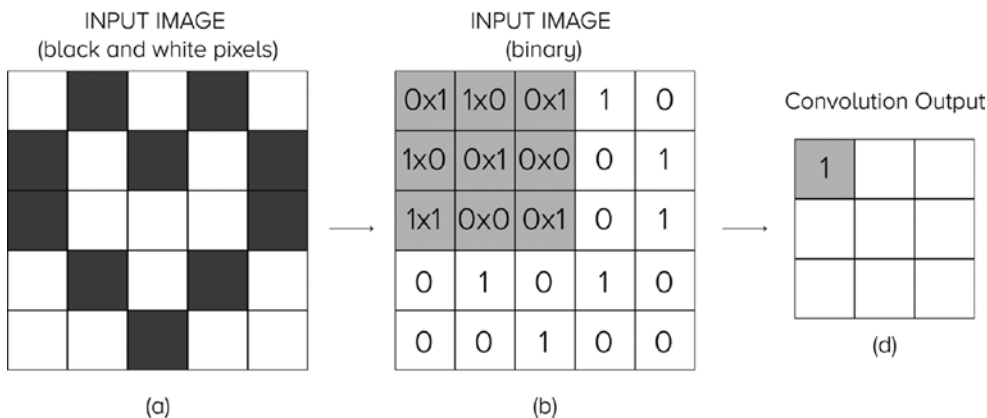

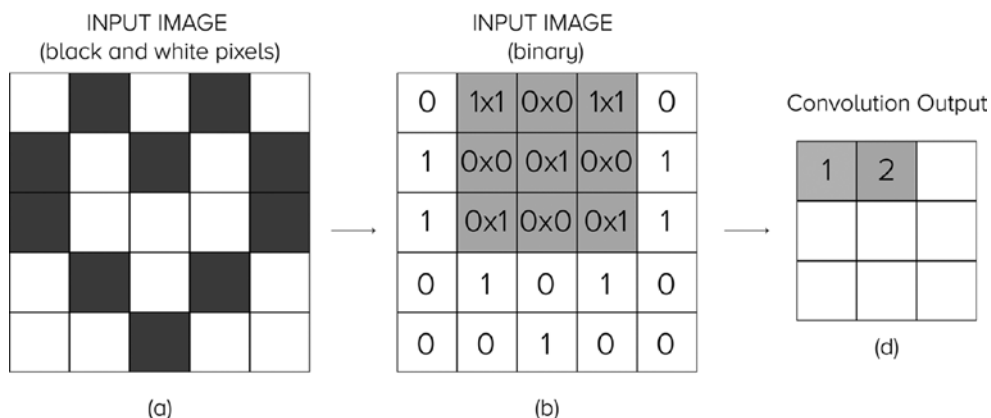

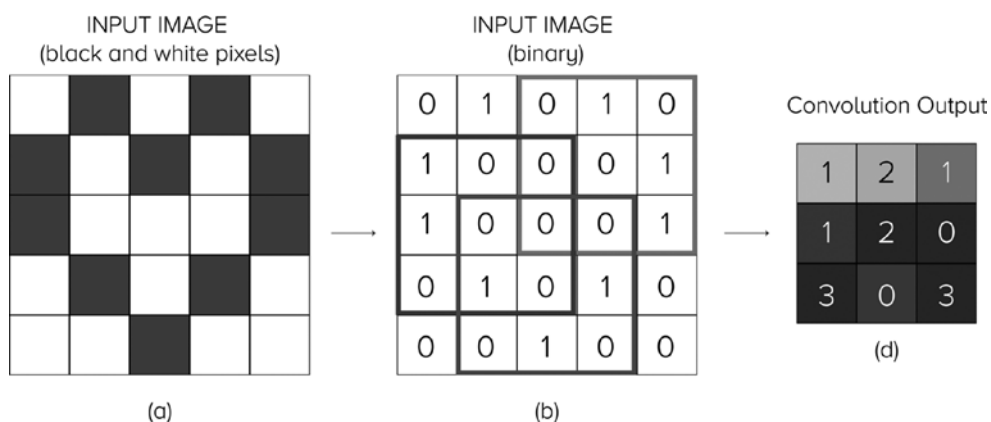

Figure 55.6 Convolution of a black and white image of a heart – step one

**Figure 55.7 Convolution of a black and white image of a heart – step two**

**Figure 55.8 Convolution of a black and white image of a heart – step three**

and RGB color channel) with the filter being 3D as well. Multiple convolutions take place on an input, each using a different filter with a distinct feature map as the output. After a convolution operation, we usually perform *pooling* (usually *max pooling*, i.e., taking the max value in the pooling window) to reduce the dimensionality and reduce the number of parameters (see Figure 55.9).

This is crucial when dealing with the volume of data that is fed to the algorithm, as it both speeds training time and helps avoid overfitting of the algorithm.

CNNs seem to suit the task of image classification, as they can help us predict

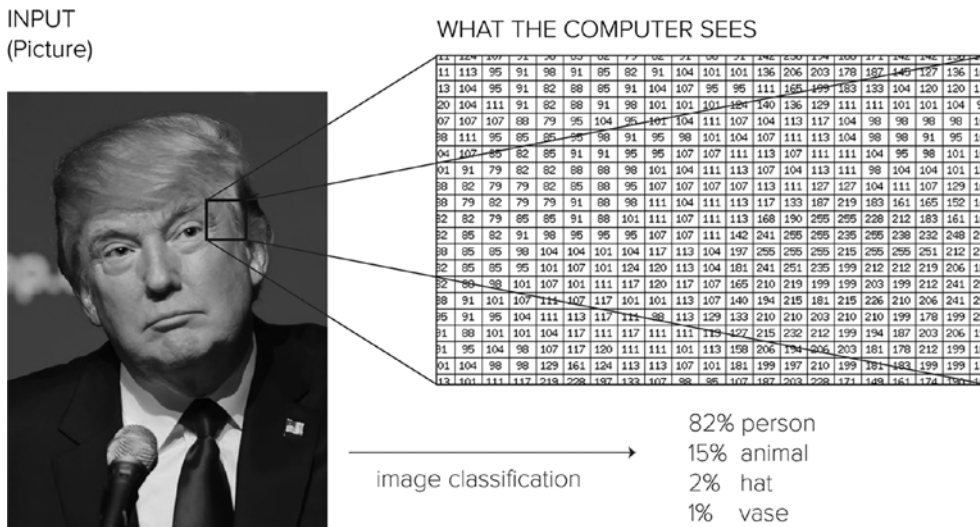

a distribution over specific labels (as in Figure 55.10) to indicate confidence of prediction for a given image. But what about text data?

### **Working with Text Data**

The study of political discourse using text as data has a long tradition in political science. Political texts have long been used as an important form of social practice that contributes to the construction of social identities and relations (Fairclough, 1989, 1992; Laclau and Mouffe, 1985). Text as a representation

**Figure 55.9** Max pooling operation – using a 2x2 input window and stride 2. Each 2x2 outline color maps onto a max-pooling single output on the 2x2 layer

**Figure 55.10** The task in image classification is to predict a single label (or a distribution over labels as shown here – percentages indicating level of confidence) for a given input image. Images are three-dimensional arrays of integers from 0 to 255, of size width x height x 3. The 3 represents the three color channels (red, green, blue)

of discourses has been studied systematically to derive information about actors and combine them with additional resources such as surveys and observations, as well as knowledge and reflective understanding of the context by scholars, yet not in a reproducible and quantifiable way (see Blommaert and Bulcaen, 2000, for a review).

Over the past two decades, scholars have sought to extract information such as

policy and ideology positions and gauge citizen political engagement by treating words as data in a more consistent way. Since some of the earliest implementations of text-scaling methods such as *Wordscores* (Laver et al., 2003) and *Wordfish* (Slapin and Proksch, 2008) to estimate party positions from texts and the increasing availability of annotated political corpora, the availability and complexity of quantitative text-analysis methods

have increased dramatically (Barberá, 2015; Grimmer and Stewart, 2013; Herzog and Benoit, 2015; Lauderdale and Herzog, 2016). Most of these methods tend to involve a ‘bag-of-words’ approach to determine relevance and cluster documents or their parts in groups (see also Laver, 2014). Such approaches assume that each document can be represented by a multiset (‘bag’) of its words, that ignores word order and grammar. Word frequencies in the document are then used to classify the document into a category. Some methods like Wordscores employ a version of the Naive Bayes classifier (Benoit and Nulty, 2013) in a supervised learning setting by leveraging pre-labeled training data, whereas others, like WordFish, are based on a Poisson distribution of word frequencies, with ideological positions estimated using an expectation-maximization algorithm (Proksch and Slapin, 2009; Slapin and Proksch, 2008).

What these approaches do not capture, though, is the linguistic and semiological context, i.e., the information provided by the words around the target elements. Such a context would allow for a better representation of that context and offer a richer understanding of word relationships in a political text. One way to do that is by using *word embeddings*, a set of methods to model language, combining concepts from NLP and graph theory.

### *Representing words in context: word embeddings*

Word embeddings are a set of language modeling and dimensionality-reduction techniques, where words or phrases from a document are mapped to vectors or numbers. They usually involve a mathematical embedding from a space with a single dimension for each word to a continuous vector space with a reduced dimension. The underlying idea is that ‘[y]ou shall know a word by the company it keeps’ (Firth, 1957: 11), and it has evolved from ideas in structuralist linguistics and ordinary language philosophy, as expressed in the work of Zellig Harris, John Firth, Ludwig Wittgenstein, and vector-space models for information

retrieval in the late 1960s to the 1980s. In the 2000s, Bengio et al. (2006) and Holmes and Jain (2006) provided a series of papers on the ‘Neural Probabilistic Language Models’ in order to address the issues of dimensionality of word representations in contexts, by facilitating learning of a ‘distributed representation of words’. The method developed gradually and really took off after 2010, partly due to major advances in the quality of vectors and the training speeds of the models.

There are many variations of word-embedding implementations, and many research groups have created similar but slightly different types of word embeddings that can be used in the deep learning pipelines. Popular implementations include Google’s Word2Vec (Mikolov et al., 2013), Stanford University’s GloVe (Pennington et al., 2014), Facebook’s fastText (Bojanowski et al., 2016) and Allen Institute for AI’s ELMo (Peters et al., 2018). For a recent discussion of word embeddings in a political science context, see Spirling and Rodriguez (2019).

Now that we have a mechanism to turn text into dense vectors (very much like we did with the image of the heart in the previous section), let’s see how CNNs can be applied to NLP tasks for political texts.

### *CNNs for text analysis*

CNNs have recently been applied to various NLP tasks with very good results in accuracy and precision (Johnson and Zhang, 2014; Kalchbrenner et al., 2014; Kim, 2014).

Instead of image pixels, each row of the matrix corresponds to one token (usually a word, but it could also be a character; see Jacovi et al., 2018 and Zhang et al., 2015) or rather a vector that represents a word. These vectors are typically *word embeddings* such as Word2Vec or GloVe (see previous section). Kim (2014) describes the general approach of using CNNs for NLP, assuming a single layer of networks and pretrained static word vectors on very large corpora (Word2Vec vectors from Google, trained on 100 billion tokens from Google News). Sentences are mapped to embedding

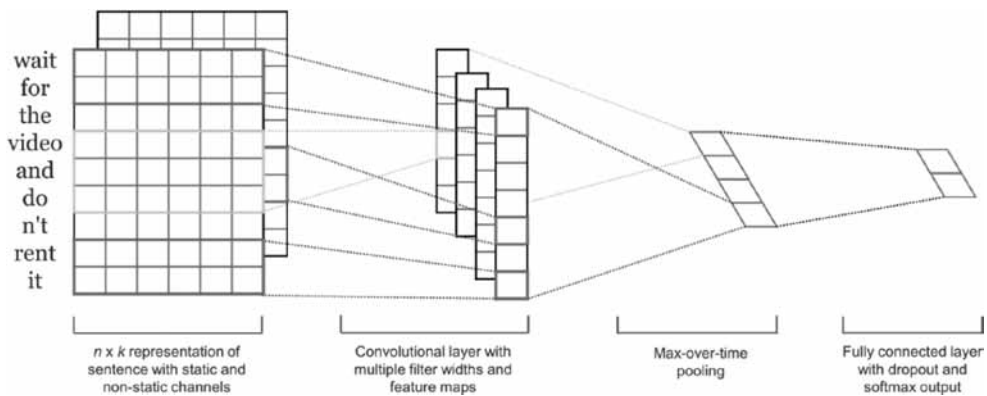

vectors and are available as a matrix input to the model. Convolutions are performed across the input word-wise using differently sized kernels, such as two or three words at a time. The resulting feature maps are then processed using a max pooling layer to condense or summarize the extracted features. Figure 55.11 shows a single-layer CNN architecture for sentence classification from Kim (2014).

Figure 55.12 shows how a CNN would work for a sentence-classification task adapted from Zhang and Wallace (2015). Assuming the sentence we wanted to classify was Michelle Obama’s ‘*When they go low, we go high*’, this would generate a 7×4 sentence matrix, with three filter region sizes: 2, 3, and 4, each of which has two filters for each region size. Every filter performs convolution on the sentence matrix and generates (variable-length) feature maps. Then, 1-max pooling is performed over each map, i.e., the largest number from each feature map is recorded. Thus, a univariate feature vector is generated from all six maps, and these six features are concatenated to form a feature vector for the penultimate layer. The final *softmax* layer then receives this feature vector as input and uses it to classify the sentence; here, we assume binary classification and hence depict two possible output states.

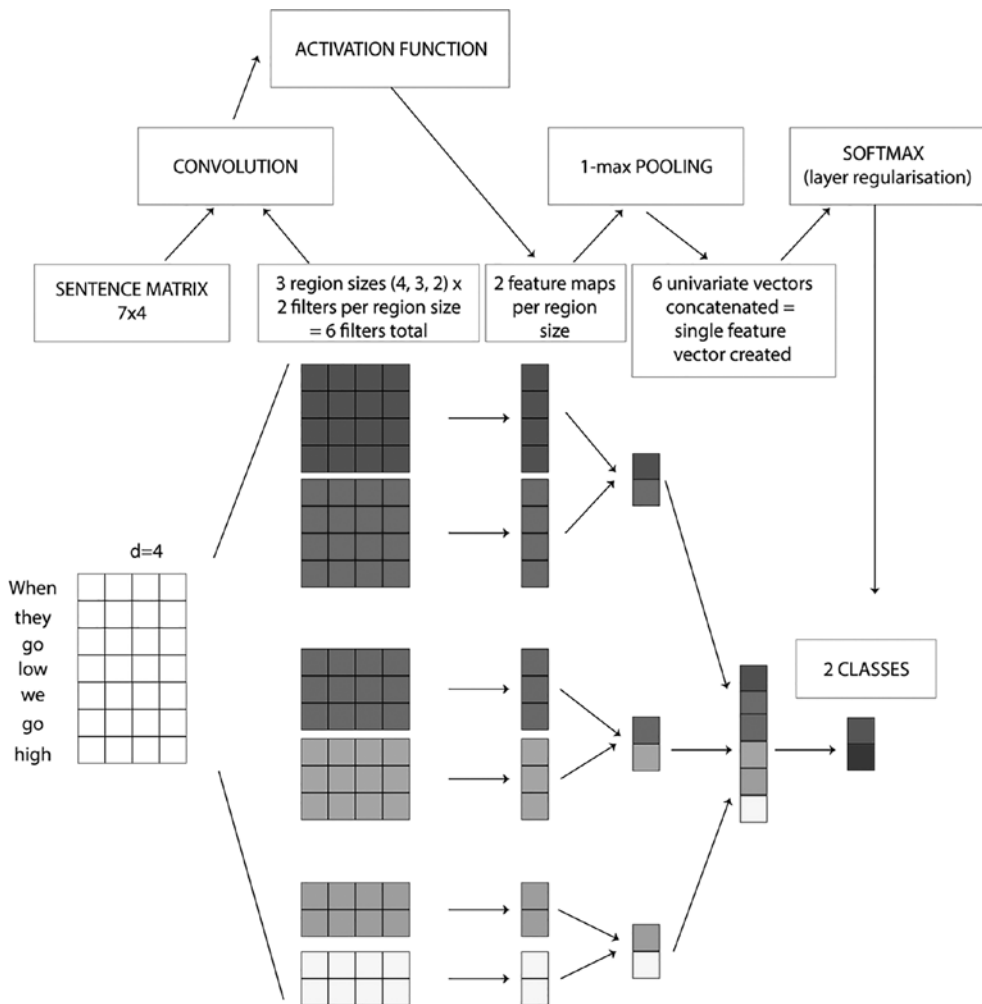

Despite CNNs being a little unintuitive in their language implementation, they perform really well on tasks like text classification. They are very fast, as convolutions are highly parallelizable, form an integral part of computer graphics, and are implemented on graphical processing units (GPUs). They also work much better compared to other ‘bag-of-words’ approaches such as n-grams, as they can learn representations automatically without the need to represent the whole vocabulary (whereas in the case of n-grams, for example, if we had a large vocabulary, computing anything beyond tri-grams would become quite expensive in terms of computational power), with architectures as deep as 29 layers performing sufficiently well (Zhang et al., 2015).

CNNs have been successfully deployed for NLP tasks such as automatic summarization, fake news detection, and text classification. Narayan et al. (2018), for example, apply CNNs to automatically summarize a real-world, large-scale dataset of online articles from the British Broadcasting Corporation (BBC). They demonstrate experimentally that this architecture captures long-range relationships in a document and recognizes related content, outperforming other state-of-the-art abstractive approaches when evaluated automatically and by humans.

Source: Kim (2014).

**Figure 55.12 Illustration of a convolutional neural network for sentence classification. The quote is attributed to Michelle Obama, later used by Hillary Clinton's campaign in the 2016 US presidential election**

Source: adapted from Zhang and Wallace (2015).

Yamshchikov and Rezagholi (2018) develop a model of binary text classifiers based on CNNs, which helps them label statements in the political programs of the Democratic and Republican parties in the United States, whereas Bilbao-Jayo and Almeida (2018) propose a new approach to automate the analysis of texts in the Manifestos Project, to allow for a quicker and more streamlined classification of such types of political texts.

The Manifesto Project (Lehmann et al., 2018) includes data on parties' policy positions, derived from content analysis of parties' electoral manifestos. It covers over 1,000 parties from 1945 until today in over 50 countries on five continents. The corpus includes manually annotated election manifestos using the Manifesto Project coding scheme, which is widely used in comparative politics research. Bilbao-Jayo and Almeida (2018) use

multi-scale CNNs with word embeddings and two types of context data as extra features, like the previous sentence in the manifesto and the political party. Their model achieves reasonably high performance of the classifier across several languages of the Manifesto Project.

Another type of neural network that has shown good performance in NLP tasks are recurrent neural networks (RNNs) and, in particular, a variation of that algorithm, the long short-term memory (LSTM) RNNs.

### *LSTM RNNs for text analysis*

As you read this paragraph, you understand each word based on your understanding of previous words – those right before this word, words expressed in the paragraphs and sections above, as well as words that you might have read in the previous chapters of this *Handbook* (or even words that you have read in other books and articles).

Every time we read a new word, we do not forget what we read before – our understanding has some degree of *persistence*. Unfortunately, CNNs cannot reason about previous steps in the learning process to inform later ones. RNNs overcome this issue because they permit loops, thus allowing for the information in the neural network to persist. A simple RNN is a class of artificial neural networks where connections between nodes form a directed graph along a sequence, incorporating previous knowledge (see Figure 55.13, adapted from Olah, 2015).

**Figure 55.13** A simple RNN network with a feedback loop. A simple RNN, A, looks at some input,  $x_t$ , and outputs a value,  $y_t$

Source: adapted from Olah (2015).

A sequence of RNN blocks can be regarded as multiple copies of the same network, linked to one another like a chain, each passing an input to its future self (Figure 55.14). This enables it to display dynamic temporal behavior for a time sequence and make these networks work really robustly with sequence data such as text, time-series data, videos, and even DNA sequences.

This suits textual data, which for the most part is sequence or list data, and which has been applied with success to NLP tasks such as speech recognition, language modeling, translation, and image captioning (Ba et al., 2014; Gregor et al., 2015). However, simple RNNs are not well suited for remembering information that is not close to the current node they are in (also called long-distance dependencies), a problem detailed in Bengio et al. (1994).

LSTM neural networks (Hochreiter and Schmidhuber, 1997) provide a solution to this issue. LSTMs also have the RNN chain-like structure, but the repeating module has a different structure. Instead of having a single neural network layer, there are four, all interacting in a special way. Figure 55.15 shows the repeating module in a standard RNN with a single layer (A1) and an LSTM with four interacting layers (A2). The LSTM has the advantage of incorporating context from both the input ( $\times$ ) and the previous knowledge (represented with dashed lines in A2) and also feed the augmented knowledge to the next iteration.

Standard LSTMs (like those in Figure 55.15) are *unidirectional* – in other words, they preserve information from the past inputs that have already passed through the different iterations of the hidden layers of the neural network. Let us now consider the following word sequence:

'Let's make ...'

There are a lot of possibilities for what word sequences could follow. All the sentences below are possible:

'Let's make some cake!'

**Figure 55.14** A sequence of simple RNNs

**Figure 55.15** The repeating module in a standard RNN with a single layer (A1) and an LSTM with four interacting layers (A2). The LSTM has the advantage of incorporating context from both the input ( $x$ ) and the previous knowledge (represented with dashed lines in A2), as well as feeding the augmented knowledge to the next iteration

‘Let’s make fun of Bob!’

‘Let’s make my friend see some sense, because I think she is making a huge mistake!’

What if you knew that the words that followed the first word sequence were actually these?

‘Let’s make ... great again!’

Now the range of options is narrower, and it is easy to predict that the next word is probably a noun phrase such as ‘America’ or ‘this business’.

A unidirectional LSTM will only be able to consider past input (‘let’s make’). If you wish to see the future, you would need to use a

*bidirectional* LSTM, which will run the input in two ways: one from the past to the future and one from the future to the past. When running backwards, it preserves information from the future, and by combining this knowledge with the past, it provides improved and more contextualized predictions.

Both types of LSTMs have been used to detect fake news and propaganda discourse in traditional and social media text, where the problem of detecting bots – automated social media accounts governed by software but disguised as human users – has strong societal and political implications.

Kudugunta and Ferrara (2018) propose a deep neural network based on contextual LSTM architecture that exploits both content

and metadata to detect bots at the tweet level. Their proposed technique is based on synthetic minority oversampling to generate a large labeled dataset suitable for deep nets training, from a minimal amount of labeled data (roughly 3,000 examples of sophisticated Twitter bots). The proposed model can, from the first tweet, achieve high classification accuracy (> 96%) in separating bots from humans.

Event detection using neural-network algorithms on tweets describing an event is another area of application of particular interest to media agencies and policy makers. Iyyer et al. (2014) assume that an individual's words often reveal their political ideology, and they use RNNs to identify the political position demonstrated at the sentence level, reporting that their model outperforms 'bag of words' or wordlists models in both the training and a newly annotated dataset. Makino et al. (2018), for example, propose a method to input and concatenate character and word sequences in Japanese tweets by using CNNs and reporting an improved accuracy score, whereas Rao and Spasojevic (2016) apply word embeddings and LSTM to text classification problems, where the classification criteria are decided by the context of the application. They show that using LSTMs with word embeddings vastly outperforms traditional techniques, particularly in the domain of text classification of social media messages' political leaning. The research reports an accuracy of classification of 87.57%, something that has been used in practice to help company agents provide customer support by prioritizing which messages to respond to.

Other scholars have used hybrid neural-network approaches to work with text, by combining aspects of the CNN and RNN algorithms. Ajao et al. (2018), for example, propose a framework that detects and classifies fake news messages from Twitter posts, using such a hybrid of CNNs and LSTM RNNs, an approach that allows them to identify relevant features associated with fake news stories without previous knowledge of

the domain. Singh et al. (2018) use a combination of the CNN, LSTM, and bidirectional LSTM to detect (overt and covert) aggression and hate speech on Facebook and social media comments, where the rise of user-generated content in social media coupled with almost non-existent moderation in many such systems has seen aggressive content rise.

Hybrid neural-network approaches also perform well in the task of automatic identification and verification of political claims. The task assumes that given a debate or political speech, we can produce a ranked list of all of the sentences based on their worthiness for fact checking – potential uses of this would be to predict which claims in a debate should be prioritized for fact-checking. As outlined in Atanasova et al. (2018), of a total of seven models compared, the most successful approaches used by the participants relied on recurrent and multi-layer neural networks, as well as combinations of distributional representations, matching claims' vocabulary against lexicons, and measures of syntactic dependency.

### ***Working with Multimodal Data***

With the resurgence of deep learning for modeling data, the parallel progress in fields of computer vision and NLP, as well as with the increasing availability of text/image datasets, there has been a growing interest in using multimodal data that combines text with images. The popularity of crowd-sourcing tools for generating new, rich datasets combining visual and language content has been another important factor favoring multimodal input approaches.

Ramisa et al. (2018), for example, have compiled a large-scale dataset of news articles with rich metadata. The dataset, *BreakingNews*, consists of approximately 100,000 news articles collected over 2014, illustrated with one to three images and their corresponding captions. Each article is enriched with other data like related images from Google Images, tags,

**Figure 55.16** The BreakingNews dataset. The dataset contains a variety of news-related information including the text of the article, captions, related images, part-of-speech tagging, GPS coordinates, semantic topics list, or results of sentiment analysis for about 100,000 news articles. The figure shows two sample images. Such a volume of heterogeneous data makes BreakingNews a good benchmark for several tasks exploring the relation between text and images

Source: Ramisa et al. (2018).

shallow and deep linguistic features (e.g., parts of speech, semantic topics, or outcomes of a sentiment analyzer), GPS latitude/longitude coordinates, and reader comments. The dataset is an excellent benchmark for taking joint vision and language developments a step further. Figure 55.16 illustrates the different components of the Ramisa et al. (2018) *BreakingNews* corpus, which contains a variety of news-related information for about 100K news articles. The figure shows two sample images. Such a volume of heterogeneous data makes *BreakingNews* a good benchmark for several tasks exploring the relation between text and images.

The paper used CNN for source detection, geolocation prediction, and article illustration, and a mixed LSTM/CNNs model for caption generation. Overall results were very promising, especially for the tasks of source detection, article illustration, and geolocation. The automatic caption-generation task, however, demonstrated sensitivity to loosely related text and images.

Ajao et al. (2018) also fed mixed data inputs (text and images) to CNNs in order to detect fake news in political-debate speech, and they noted that except for the usual patterns in what would be considered misinformation, there

also exists some hidden patterns in the words and images that can be captured with a set of latent features extracted via the multiple convolutional layers in the model. They put forward the TI-CNN (text and image information based convolutional neural network) model, whereby explicit and latent features can be projected into a unified feature space, with the TI-CNN able to be trained with both the text and image information simultaneously.

## Recent Developments

Deep neural networks have revolutionized the field of NLP. Furthermore, deep learning in NLP is undergoing an ‘ImageNet’ moment. In a paradigm shift, instead of using word embeddings as initializations of the first layer of the networks, we are now moving to pretraining the entire models that capture hierarchical representations and bring us closer to solving complex language-understanding tasks. When the ImageNet challenge AlexNet (Krizhevsky et al., 2012) solution showed a dramatically improved performance of deep learning models compared to traditional competitors, it arguably spurred the whole deep learning research wave. Over the last 18 months, pretrained

language models have blown out of the water previous state-of-the-art results across many NLP tasks. These advances can be characterized within the broader framework of transfer learning, where the weights learned in state-of-the-art models can be used to initialize models for different datasets, and this ‘fine-tuning’ achieves superior performance even with as little as one positive example per category (Ruder et al., 2019).

One of the assumptions of standard word embeddings like Word2Vec is that the meaning of the word is relatively stable across sentences. An alternative is to develop contextualized embeddings as part of the language models. Embeddings from language models (ELMo) (Peters et al., 2018), universal language model fine-tuning (ULMFiT) (Howard and Ruder, 2018), and generative pretraining transformer (OpenAI GPT) (Radford et al., 2018) were initial extremely successful pre-trained language models.

More recently GPT2 (Radford et al. 2019) extended the previous GPT model and was used to generate realistic-sounding artificial text. Bullock and Luengo-Oroz (2019) used the pretrained GPT2 model to generate fake but natural-sounding speeches in the United Nations General Debate (see Baturo et al., 2017, for more details about the data and a substantive example). Bidirectional encoder representations from transformers (BERT) (Devlin et al., 2019) extended GPT through bi-directional training and dramatically improved performance on various metrics. While BERT was the reigning champion for several months, it may have recently been overtaken by XLNet (Yang et al., 2019), which outperforms BERT on about 20 NLP tasks.

In parallel with the advances in transfer learning, we are also further understanding what we are learning with the deep neural networks. Liu et al. (2019) show that RNNs (and LSTMs in particular) pick up general linguistic properties, with the lowest layers representing morphology and being the most transferable between tasks, middle layers representing syntax, and the highest layers

representing task-specific semantics. Large pretrained language models do not exhibit the same monotonic increase in task specificity, with the middle layers being the most transferable. Tenney et al. (2019) focus on BERT and show that the model represents the steps of the traditional NLP pipeline, with the parts-of-speech tagging followed by parsing, named-entity recognition, semantic roles, and, finally, coreference. Furthermore, the model adjusts the pipeline dynamically, taking into account complex interactions between different levels of hierarchical information.

Detailed discussion of the above models is beyond the scope of this chapter. Instead, we want to emphasize the pace of development in NLP research, which is leveraging pretrained language models for downstream tasks. Instead of downloading pretrained word embeddings like Word2Vec or GloVe as discussed earlier in the chapter, we are now in a position to download pretrained language models and fine-tune them to a specific task.

## CONCLUSION

It is appealing to think of machine learning algorithms as objective, unbiased actors that are beyond the influence of human prejudices. It is also appealing to think of empirical research in political science that utilizes machine learning algorithms as being sufficiently removed from any potential bias. Unfortunately, this is rarely the case.

Algorithms are designed by humans and learn by observing patterns in the data that very often represent biased human behavior. It is no surprise that algorithms tend to adopt and, in some occasions, perpetuate and reinforce the experiences and predispositions of the humans that have constructed them and those of society as a whole; this is also known as *algorithmic bias*. Although machine learning has been transformative in many fields, it has received criticism in the areas of causal inference, algorithmic bias, and data privacy.

This is forming into a distinct area of social science research, focusing on the lack of (suitable) training data, difficulties of data access and data sharing, data bias and data provenance, privacy preserving data usage, and inadequate tasks, tools, and evaluation settings (Danks and London, 2017).

The quality of insights delivered by algorithms crucially depends on data quality and data provenance. In particular, in each case, we need to effectively query very distinct (heterogeneous) data sources before we can extract and transform them for input into the data models. Common aspects of data quality that may affect the robustness of insights include consistency, integrity, accuracy, and completeness. How image or textual data is preprocessed may affect how data is interpreted and may also lead to biases. For example, dataset biases in computer vision can lead to feature representation flaws where CNNs, despite high accuracy, learn from unreliable co-appearing contexts (Zhang et al., 2018).

The consequences of biased algorithms can be quite real and severe. In 2016, an investigative study by ProPublica (Angwin et al., 2016) provided evidence that a risk-assessment machine learning algorithm used by US courts wrongly flagged non-white defendants at almost twice the rate of white defendants. More recently, Wang and Kosinski (2018) showed how deep neural networks can outperform humans in detecting sexual orientation. Apart from the ethical issues of the study, the ease of deployment of such ‘AI Gaydar’ raises issues of people’s privacy and safety.

The issues of algorithmic bias are also highlighted in the Wellcome Trust Report (Matthew Fenech et al., 2018) with a focus on how AI has been used for health research. The report identifies, among other ethical, social, and political challenges, issues around implications of algorithmic transparency and explainability on health, the difference between an algorithmic decision and a human decision, and what makes algorithms, and the entities that create them, trustworthy. The report highlights the importance of

stakeholders across the public- and private-sector organizations collaborating in the development of AI technology, and it raises awareness of the need for AI to be regulated.

Such algorithmic-bias issues may seem to be removed from everyday political science research. However, various methodological approaches discussed earlier in this chapter are not bias free. Word embeddings have been shown to carry societal biases that are encoded in human language (Garg et al., 2018). These range from biased analogies (Bolukbasi et al., 2016; Manzini et al., 2019; Nissim et al., 2019) to bias in language ID (Blodgett and O’Connor, 2017), natural-language inference (Rudinger et al., 2017), coreference resolution (Rudinger et al., 2018), and automated essay scoring (Amorim et al., 2018).

There are corresponding efforts to reduce algorithmic bias in deep neural-network applications, for example, through postprocessing (Bolukbasi et al., 2016) or directly modeling the problem (Zhao et al., 2018). However, the bias still remains encoded implicitly (Gonen and Goldberg, 2019), and transparency and awareness about the problem may be better as a research and deployment strategy (Caliskan et al., 2017; Dwork et al., 2012; Gonen and Goldberg, 2019).

There are legitimate concerns about algorithmic bias and discrimination, algorithmic accountability and transparency, and general ‘black box’ perception of deep neural-network models (Knight, 2017; Mayernik, 2017). In order to address these issues, scholars (Fiesler and Proferes, 2018; Mittelstadt et al., 2016; Olhede and Wolfe, 2018; Prates et al., 2018), AI technologists, international organizations (European Group on Ethics in Science and New Technologies (EGE), 2018), and national governments (House of Lords Select Committee, 2018) have been recently advocating for a more ‘ethical’ and ‘beneficial’ AI that will be programmed to have humans’ interests at heart and could never hurt anyone.

Kusner et al. (2017), for example, provide an ethical framework for machine

decision-making, whereby a ‘decision is considered fair towards an individual if it is the same in both the actual world and a “counterfactual” world, where the individual would belong to a different demographic group’. In addition, it is vital to think about who is being excluded from AI systems and what is missing from the datasets that drive machine learning algorithms. Often, these blind spots tend to produce disparate impacts on vulnerable and marginalized groups. This leads to the invisibility of these communities and their needs because there are not enough feedback loops for individuals to give their input. While the collection of even more personal data might make algorithmic models better, it would also increase the threats to privacy.

Russell et al. (2015) present relevant questions to be considered: what are the power dynamics between different industry and research groups? Will the interests of the research community change with greater state funding? Will government intervention encourage AI research to become less transparent and accountable? What organizational principles and institutional mechanisms exist to best promote beneficial AI? What would international cooperation look like in the research, regulation, and use of AI? Will transnational efforts to regulate AI fall to the same collective-action problems that have undermined global efforts to address climate change?

To ensure that future iterations of the ethical principles are adopted widely around the world, further research will be needed to investigate long-standing political questions such as collective action, power, and governance, as well as the global governance of AI, to name a few.

# Machine Learning in Political Science: Supervised Learning Models

Santiago Olivella and Kelsey Shoub

## INTRODUCTION

The set of theoretical and computational approaches used under the rubric of ‘machine learning’ (ML) is so diverse that it is easy to think of the field as a kind of catch-all, interdisciplinary exercise at the intersection between statistics, computer science and other affiliated disciplines. Such a perspective, however, would obscure the fact that these seemingly disparate approaches share a common goal: to improve a computer’s performance on a given (typically predictive) task by identifying empirical relationships, patterns, and trends in data that rely on minimal distributional and functional form assumptions on the part of analysts (Hastie et al., 2009; Jordan and Mitchell, 2015). This goal, which is what *learning* is typically taken to mean in this context, happens to be shared by a number of disciplines – including, of course, Political Science and International Relations.

Indeed, our discipline’s approach to the field of ML has resulted not only in careful applications of tools devised in other domains, but also in the development of tools designed to address problems of specific disciplinary interest – such as the fast estimation of ideal points that easily scales to millions of subjects (Imai et al., 2016), the structural analysis of text-as-data with large corpora (Roberts et al., 2014), and the discovery of subgroup causal effects in contexts with relatively few unknown confounders in high-dimensional datasets (Ratkovic and Tingley, 2017).

The goal of this chapter is twofold: to present some of the most commonly used tools in the field of predictive ML, and to illustrate how these tools have been adopted (and often adapted) to answer questions of interest in Political Science. We focus on *supervised models*, whereas other contributions to the *Handbook* (e.g. Chatsiou and Mikhaylov, Chapter 55, this *Handbook* on Deep Learning for Political Science) offer insights into other approaches within ML and computational

social sciences. Supervised models are those where both an outcome of interest *and* relevant predictors are available for a set observations and can be used to learn the patterns of their association, so as to better predict instances in which the outcome is *not* observed.

We begin the chapter with a simple taxonomy of ML tools using the supervised/unsupervised distinction and offer a brief overview of some of the most important concepts in the field. We then discuss the main ideas behind three major supervised learning approaches, namely tree-based methods, kernel-based approaches, and support vector machines. Although we provide enough mathematical detail to understand the formal underpinnings of each approach, we emphasize the intuitions behind these models (rather than their theoretical foundations) to make the materials accessible to a wider audience. Finally, we conclude the chapter with some thoughts on the promise and perils of ML modeling and offer some suggestions for additional readings.

## TYPES OF MACHINE LEARNING MODELS AND RELEVANT CONCEPTS

As is the case in many other social sciences, quantitative data analysis in our disciplines has typically relied on some variant of the linear model. The modal empirical exercise defines a specific functional relationship between the conditional expectation of an outcome of interest and a limited set of predictors suggested by theory, tradition, or a combination of both. Although useful in its parsimony and intelligibility, this common approach has a number of limitations.

For instance, classical regression models require positing a particular specification for the conditional expectation function at the onset of analysis. Even if a few different specifications are considered, choosing among them after estimation results have been observed can at best offer proof that there is

*one* way in which the world is consistent with proposed hypotheses – not a very strong test of a hypothesis. In the absence of real competition from the myriad alternative plausible models, the typical approach offers few meaningful chances for the researcher to be proved wrong (Ho et al., 2007). Similarly, classical regression models are unable to handle situations in which the number of included predictors is far larger than the number of available observations, as is common in text-as-data applications discussed elsewhere in this volume. By increasing modeling flexibility while actively avoiding tracking sample idiosyncrasies too closely, ML models offer viable steps towards resolving these and many other issues raised by classical approaches.

Despite being unified by the same goals and general flexibility, there is a daunting variety of modeling approaches that fall under the purview of ML. Different taxonomies of models exist based on a variety of criteria. For instance, we can distinguish between *generative models* (which define a probability model for the joint distribution of outcomes and predictors) and *discriminative models* (which either define a probability model for the conditional distribution of outcomes given predictors or otherwise propose no distributional assumptions whatsoever) (Bishop, 2016; Ng and Jordan, 2002). Examples of the former include the *latent Dirichlet allocation* and the *hidden Markov model*, while examples of the latter include models like *support vector machines* and *regression trees* (as well as less exotic models, like the logistic regression).

Perhaps the most commonly used dimension along which ML models tend to be classified, however, pertains to the relevance of a target outcome in the learning task. If the goal is to learn structure in a set of inputs (or features) without appealing to a target outcome, then we are said to face an *unsupervised learning* (or descriptive) problem (Murphy and Bach, 2012). Examples of such tasks include problems such as the organization of unstructured text into topics, and the

estimation of latent traits (such as ideology) based on observed behaviors (such as roll-call votes or decisions to follow actors embedded in a social network).

On the other hand, when both features and outcomes are observed for some set of observations – typically called the *training set* – which are then used to infer the outcome values of unlabeled observations, we are said to have a *supervised learning* problem. Examples of such tasks include classical problems such as email spam detection, hand-written digit recognition, and object-detection in images. They also include the problems of learning a response surface defined over an input space or (equivalently) of understanding how an outcome is related to inputs in potentially complex ways (Hastie et al., 2009). Although many interesting ML developments occur in the realm of unsupervised learning (as evidenced, for instance, by the discussions in Egerod and Klemmensen, Chapter 27, and Bouchat, Chapter 28, of this *Handbook*), we focus on supervised learning techniques in this chapter, as they encompass the kinds of predictive tasks most commonly associated with ML.

Within supervised learning models, we can further distinguish between models based on the measurement type of the target outcome. If the outcome is continuous, learning tasks are referred to as *regression problems*. In turn, categorical outcomes (regardless of whether they have two or more categories) give rise to *classification problems* (Bishop, 2016; Murphy and Bach, 2012).<sup>1</sup> Regardless of whether they are regression or classification problems, however, supervised learning models share the same goal: learn the potentially complicated relationships that relate (combinations of) features  $x$  to the outcome of interest  $y$  *in general*, using information available in the set of observations for which the pair  $(x, y)$  is fully observed.

The *in general* qualification is an important one, as it is typically easy to learn even complicated relationships in-sample – that is, relationships that are conditional on the training set. The goal, however, is to learn relationships for which expected *generalization error*

(i.e. the error that can be expected to ensue when learned relationships are evaluated *out-of-sample*, on a random *test set* of observations not involved in the learning process) is low (Hastie et al., 2009). In fact, while it is always possible to reduce *training error* (i.e. error as computed using the training sample) by making models arbitrarily complex, such flexibility typically results in high expected generalization error, as models start to *overfit* their training data (i.e. they start to pick up on idiosyncratic relationships that are conditional on the set of observations used to train the models).<sup>2</sup>

Accordingly, and since the ultimate goal of supervised learning is to find generalizable patterns of association, models are typically subject to some form of *regularization* – typically in the form of a constraint that pushes the model towards parsimony – and are selected based on their ability to generate good out-of-samples predictions. Clearly, it is impossible to evaluate a model's performance on the universe of unsampled test instances, so an approximate measure of performance must be devised. Although several approaches are viable, none is more commonly used than *cross-validation (CV)* – the exercise of further splitting the training data into a training set and a validation set (used to evaluate predictive accuracy, but omitted from the learning phase). To further minimize issues related to bad draws, multiple such splits are typically conducted.

The most popular approach to cross-validation, *k-fold CV*, partitions the training data into  $k$  subsets, estimates the model leaving each subset aside, evaluates predictive accuracy on the held-out set of observations, and approximates the generalization error of the specific model by taking the average of these held-out errors (Hastie et al., 2009). When models require the definition of so-called *tuning parameters* (i.e. ancillary parameters that govern the model's behavior, such as the number of topics in a topic model), multiple values are evaluated using this iterative estimation process, allowing researchers to base their value definitions on a data-driven procedure.

Overall, the typical workflow in ML involves: first (and crucially) representing raw data using quantitative features (e.g. transforming unstructured texts into a document feature matrix); second, choosing an appropriate model for the learning task at hand, tuning the model’s parameters using some form of cross-validation; and third, evaluating the model’s out-of-sample predictive accuracy (i.e. its expected generalization error) using an entirely separate test set.

To give a flavor of what some of these decisions look like, we now turn to a discussion of two of the most commonly used sets of models in supervised learning within Political Science: tree-based approaches and support vector machines.

### EXAMPLES OF SUPERVISED LEARNING MODELS

#### *Tree-Based Approaches: CART, Random Forests, and Tree Boosting*

For a single-tree model, the goal is to partition the space of predictor features (i.e. the set of all unique combinations of predictor

values) into contiguous regions within which prediction is easier, thus improving overall predictive accuracy by sorting observations into their respective bins. Intuitively, this goal is best achieved if the regions are defined by their degree of homogeneity with respect to the outcome of interest, so that region-specific predicted values are as close to the target as possible.

To clarify these abstract ideas, consider the task of predicting turnout based on age and education levels. The left panel of Figure 56.1 shows our feature space (defined by unique values of the two predictor features) as well as a hypothetical target turnout distribution, with darker shades indicating higher turnout rates. In turn, the center panel shows a stratification of all observations into regions for which a simple, constant prediction model (e.g. using the average turnout rate for all observations within the region) offers a good approximation of the underlying turnout distribution. When we restrict regions to form non-overlapping ‘boxes’ that are aligned with the coordinate axes of the feature space (i.e. such that their edges are parallel to said axes), the partition can be represented by a recursive binary tree – hence giving these models their name. The right panel of Figure 56.1 shows

**Figure 56.1** Left panel: feature space comprised of ages and education levels, partitioned into regions that are relatively homogeneous with respect to probability of turnout (indicated with lighter shades of gray for every combination of feature values). Right panel: binary-tree representation of feature-space partition depicted on the left panel. Values at terminal nodes indicate predicted turnout probability in each corresponding region

the recursive binary tree that corresponds to the partition depicted in the left panel and is the result of fitting a *classification and regression tree* (or CART, see Breiman et al., 1984) model to the hypothetical data.

More formally, we can define the predictive task as one in which we need to learn parameters  $\Theta$  in a function

$$f(\mathbf{x}_i | \Theta) = T(\mathbf{x}_i | \Theta) = \sum_{b=1}^B \hat{y}_b \mathbf{1}(x_i \in R_b)$$

where  $R_b$  denotes the  $b_{th}$  region (out of  $B$  total regions) in the partition of the feature space,  $\hat{y}_b$  is the constant prediction for all observations in that region (typically the average or modal category for observations in the region), and  $\mathbf{1}(\cdot)$  is the indicator function. The  $\Theta$  parameters control both the variables for creating each split in the recursive tree, as well as the value at which each split occurs.

Finding the best  $\Theta$  for any given loss function  $L(y_i, f(\mathbf{x}_i))$  is prohibitively costly, as it requires solving an extremely hard discrete optimization problem. Instead, a simple greedy heuristic for finding a local optimum consists of sequentially picking a predictor-value pair  $p, v$  among the set of all predictors  $P$  that minimizes prediction loss among the induced regions. This approach, known as *recursive binary splitting*, forms the tree through a sequence of locally optimal recursive binary splits, starting with the entire feature space at its root<sup>3</sup> and ending when a given stopping criterion is reached (for instance, when fewer than a pre-specified number of observations would fall into a new region).

Although the final model has many advantages (e.g. it is easy to interpret and visualize, it can capture complex interactions between predictors when grown to be deep enough, it performs a kind of automatic feature selection by choosing locally predictive variables, and it can be easily adjusted to accommodate values that are missing<sup>4</sup> or that are measured in different scales), it is also affected by serious limitations. First, growing a single, deep tree using binary recursive splitting can result in a grossly overfit model. In turn, and as an

example of the common bias-variance trade-off, this high level of in-sample predictive accuracy usually comes at the expense of high variability in prediction, as single trees grown recursively can often times yield wildly different predictions as a result of small changes in the training set. Other limitations of common implementations of single-tree models include their practical inability to accommodate additive relationships, the lack of natural measures of prediction uncertainty, and the fact that variable choice in recursive binary splitting is biased towards choosing variables with many potential splitting points.

While there are strategies designed to ameliorate some of these issues,<sup>5</sup> the most common approach consists of building ensembles of trees. Formally, a tree-ensemble with  $M$  trees – grown in a slightly different way to induce variety and learn relationships using a ‘wisdom-of-crowds’ approach – can be defined by

$$f(\mathbf{x}_i | \Theta) = \frac{1}{M} \sum_m^M T(\mathbf{x}_i | \Theta_m)$$

with the goal of learning optimal parameters

$$\tilde{\Theta} = \arg \min_{\Theta} \sum_i L(y_i, f(\mathbf{x}_i | \Theta)) \tag{1}$$

with strategies used to induce differences across trees resulting in a variety of flavors of tree-ensemble methods. Although there is a cost to be paid in terms of interpretability – for example, making a prediction is no longer as easy as ‘dropping’ an observation down the binary tree, and following it until we hit a terminal region with a corresponding predicted value – the gains in predictive accuracy and reduction of generalization error offer substantial advantages. We now present two of the most commonly used ensemble models (viz. random forests and gradient boosting machines).

### *Bagging and Random Forests*

The first approach to building an ensemble of trees consists of bootstrapping samples from the training set, fitting a single tree to each

resampled set, and then aggregating predictions made by each such tree by, for instance, taking their average. Adequately named *bagging* (a portmanteau for *bootstrap aggregating*), this approach can help accommodate non-interactive relationships (by building trees with branches that are functions of a single predictor, for instance) as well as non-additive relationships. However, the approach remains unsuccessful in terms of reducing estimator variance (and thus improving overall generalization error) unless an additional step is taken to de-correlate the trees that form the ensemble.

A simple way to reduce variance by way of reducing correlation among trees is to restrict the choice of each splitting variable to a random subset of predictors  $p \subset P$ , so that each bagged tree provides a different ‘perspective’ on the prediction problem. In fact, it can be shown that correlation  $\rho(x)$  declines as the relative size of  $p$  (i.e. the number of predictors used at any given splitting point) decreases (Hastie et al., 2009). This model, known as a *random forest* (RF) (Breiman, 2001), is one of the most popular ML approaches used in Political Science, with simple to use implementations available through open-source software (e.g. `randomForest` in **R**) that require cross-validation of only a handful of parameters (including the ensemble size  $M$  and the size of the random subset of predictors at each splitting point,  $|p|$ ). And because trees can be grown in parallel, the approach has the potential to scale relatively well in the presence of large ensembles and datasets.

In addition to improving predictive accuracy by reducing variance and maintaining each tree’s low bias properties, RFs increase the set of functional associations the model can represent and performs the same kind of on-the-fly feature selection performed by single-tree approaches. The model is also capable of providing estimates of generalization error by generating *out-of-bag* (i.e. out-of-sample) predictions for observations *not* in the bootstrap sample for each tree. Finally,

measures of uncertainty can be readily produced using bias-corrected versions of the infinitesimal jackknife (Efron and Hastie, 2016; Wager et al., 2014) at no additional computational costs.

### Gradient Tree-Boosting

An alternative approach to building ensembles of trees is known as *boosting* (Freund and Schapire, 1997; Schapire, 1990). Boosting is an example of *forward stagewise additive modeling* – a procedure that tackles a complex optimization problem involving a sum of basis functions (such as Equation 1 *sequentially*, in  $M$  steps. At each step, the parameters involved in each basis function (in this case, trees) fit up until that point are left unchanged, thus reducing the complexity of the optimization problem by solving for the optimal parameters of a single basis function at each stage. As such, the program in Equation 1 becomes

$$\tilde{\Theta}_m = \operatorname{argmin}_{\Theta_m} \sum_i L(y_i, f_{m-1}(\mathbf{x}_i) + \nu T_m(\mathbf{x}_i | \Theta_m)),$$

where  $0 < \nu \leq 1$  is a step size that controls the learning rate, and  $f_{m-1}(\mathbf{x}_i)$  is the prediction of the tree ensemble fit in the first  $m - 1$  stages. What distinguishes boosting from other stagewise approaches is its focus on repeatedly modified versions of the training set, effectively transformed to gradually shift focus, at each stage, to observations that have been poorly fit by the ensemble up until that point.

A general formulation of this approach is given by *gradient boosting machines* (GBMs), which fits a tree  $T_m(\mathbf{x}_i | \Theta_m)$  to the negative gradient of the loss function with respect to  $f(\mathbf{x}_i)$ , evaluated at  $f_{m-1}(\mathbf{x}_i)$  at each stage of the sequential ensemble construction. In doing so, the model progressively concentrates on some measure of difference between the predictions of the  $(m - 1)$ th step and the observed values – which is precisely the information contained in the negative

gradient. For example, with (half) squared error loss, the  $i_{th}$  component of the negative gradient is given by

$$-\frac{\partial}{\partial f(\mathbf{x}_i)} \frac{1}{2} [y_i - f(\mathbf{x}_i)]^2 \Bigg|_{f_{m-1}(\mathbf{x}_i)} = y_i - f_{m-1}(\mathbf{x}_i)$$

which is the model's residual up to the  $(m - 1)_{th}$  step. Other differentiable loss functions make it possible to use gradient tree-boosting for a variety of classification and regression problems. The AdaBoost.M1 algorithm (Freund and Schapire, 1997), for instance, is a commonly used implementation of gradient boosting for binary classification using an exponential loss function and predictions in the set  $\{-1, 1\}$ .

Although not parallelizable like RFs (as they must be learned sequentially), GBMs are typically very fast to estimate. Tuning them requires defining values for the number of trees in the ensemble  $M$ , for the step size  $v$ , and for the tree depth of each ensemble member. In practice, trees are usually grown on training sets to be 'weak' learners (i.e. shallow trees, with depth defined primarily by the theoretical order of anticipated interactions among predictors),  $v$  is set to some small number (e.g.  $v = 0.001$ ), and  $M$  is chosen by  $K$ -fold cross-validation from a fine sequence (e.g.  $M \in \{2, 3, \dots, 5000\}$ ). Overall, gradient tree-boosted models have been found to have excellent predictive performance, prompting some to call them 'the best off-the-shelf classifiers in the world' at one point in time (Breiman, 1998; Hastie et al., 2009). Good implementations in **R** include the `gbm` package (which can be cross-validated using `caret`) and `h2o`. Performance can usually be enhanced even further by incorporating some of the ideas behind RFs, such as using data subsampling at each stage of the ensemble creation, resulting in a variant of GBM called *stochastic gradient boosting* (Friedman, 2002), also implemented in `gbm` in **R**.

### *An Application to Small-Group Preference Estimation*

In addition to their use in forecasting tasks (Muchlinski et al., 2016; Kaufman et al., 2018), tree-based models have commonly been used in the social and political sciences to study interactive effects and other types of conditional associations. In the study of causal relationships, for instance, tree-ensembles have been used to identify heterogeneous treatment effects (Green and Kern, 2012; Imai and Strauss, 2011; Wager and Athey, 2017). Their ability to identify complex functional forms without the need for researcher-defined specifications makes tree-based models ideal for another task: estimating preferences among small target populations using post-stratification of estimates obtained from non-representative samples.

In a survey of potential applications of tree-based models within Political Science, Montgomery and Olivella (2018) are able to reproduce and efficiently scale-up the exercise conducted by Ghitza and Gelman (2013). In their study, Ghitza and Gelman aim to estimate vote intentions of small groups of voters during the 2008 presidential election, as well as their likelihood of turning out to vote. The groups, defined by intersections of geographic and socio-demographic characteristics (e.g. high-school educated Latino women between 18 and 25 who live in North Carolina), were assumed to have preferences that depended on the *combination* of these characteristics, thus requiring models that allowed for 'deep interactions' on their right-hand sides.

The two-step approach they propose – which involves a predictive stage and a post-stratification stage, known as multilevel regression and post-stratification, or MRP – uses a random-intercepts model to model preferences as a function of these interactions and post-stratifies predictions based on this model using highly granular frequency counts (e.g. census tables at the block level)

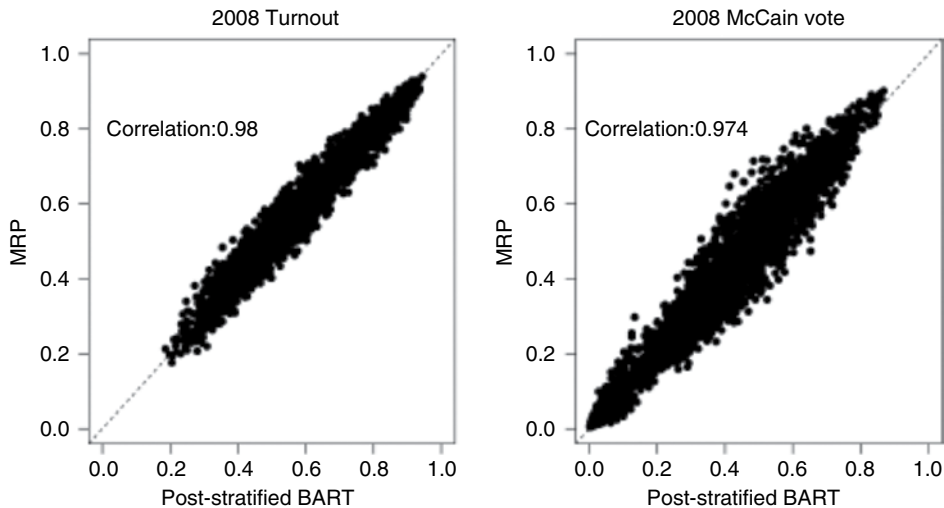

that are then aggregated to whatever level is desired. Although interested in combinations of a large number of socio-demographic characteristics, Ghitza and Gelman's exercise is restricted by the computational limits imposed by the estimation of a large number of random effects involved in fully interactive specification of the first stage model.

To address this, Montgomery and Olivella replace the first stage model with a tree-based ensemble (viz. Bayesian Additive Regression Trees, or BART), which effectively only incorporates interactive effects when the training data support them, thus reducing the computational cost of the estimation without sacrificing potentially relevant model complexity. The results of both exercises are virtually identical when estimated using the same set of four predictors (viz. state, ethnicity, income, and age), as evidenced by Figure 56.2 (which presents the set of post-stratified MRP estimates vs. the post-stratified tree-based estimates).

Contrary to the multilevel model, however, the tree-based approach can easily incorporate the full set of available predictors (a set of eight discrete variables, with a total set of 163,200 fully interacted categories) with very little additional computational overhead.

### **Kernel Methods: Support Vector Machines**

Yet another approach to the supervised learning problem is offered by support vector machines (SVMs), which have been most successfully used to solve classification problems – particularly when the number of predictive features is much larger than the number of observations  $n$ , or  $p \gg n$ . Examples of classes could be party affiliation, vote choice, sentiment, or whether or not a respondent received the experimental treatment. Like many tree-based models,

**Figure 56.2** Left panel: post-stratified predictions of turnout during the 2008 presidential election in the United States at low levels of demographic aggregation. Predictions produced by a multilevel model along the y-axis, and predictions along the x-axis produced by a Bayesian additive regression tree model. Right panel: post-stratified predictions of vote intention for McCain during the 2008 presidential election in the United States at low levels of demographic aggregation. Predictions produced by a multilevel model along the y-axis and predictions along the x-axis produced by a Bayesian additive regression tree model

SVMs are ‘one of the “must-have” tools in any machine learning toolbox’ (Efron and Hastie, 2016: 387).

Intuitively, an SVM finds a hyperplane that maximizes the distance between it and the nearest instances of each class (the support vectors), thus producing the ‘cleanest’ possible sorting of observations. This distance to the nearest instances, called the margin, generates a kind of buffer between types of observations; the optimization objective behind SVMs is to maximize the width of this buffer. To make these ideas more concrete, take an example where a researcher wants to predict whether instances are members of class A or class B. To do so, the researcher has two variables:  $X_1$  and  $X_2$ . When fitting an SVM to predict which class each observation belongs to, the SVM finds the maximum-margin (hyper-)plane that separates these two classes while maximizing the distance between the (hyper-)plane and the nearest class instances.

Graphically, this is depicted on the left panel of Figure 56.3. In the figure, instances belonging to class A are shown as light-gray circles, and instances belonging to class B are shown as dark-gray triangles. The

maximum-margin hyperplane is the solid line separating the two groups, and the margin (which touches the support vectors) is depicted using dashed lines equidistant from the hyperplane. As can be seen, all of the circles lie below the hyperplane (a line, in this case), while all of the triangles lie above the hyperplane: classes are perfectly linearly separable. Fitting an SVM (or, in this simple case, a *maximum margin classifier*) amounts to finding this separating line. Note that an important implication of this goal is that only those instances near the class boundary play a big role its definition, while those that remain far away from the boundary have little effect on its location and direction.

More formally, assume that a given data set consists of  $N$  instances represented by a set of features. In Figure 56.3, there are 40 instances, and the features used are the variables  $X_1$  and  $X_2$ , where  $x_{1i} \in \mathbb{R}$  and  $x_{2i} \in \mathbb{R}$ . Additionally, the target classes can be either  $-1$ , or  $y_i \in \{-1, 1\}$ . A hyperplane is defined by:

$$x : f(x) = x^T \beta + \beta_0 = 0 \tag{2}$$

where  $\beta$  is a unit-length vector. Such a plane is separating if all instances of a class lie

**Figure 56.3** Left panel: classifying by a Maximum-Margin Hyperplane: a linearly separable problem, with the corresponding separating line (solid line) and classification margins (dashed lines). Right panel: non-linearly separable classification problem of Class A (outer light gray triangles) and Class B (inner dark gray circles) instances

above it, and all instances of the other class lie below it (or, equivalently, if  $y_i \times f(x_i)$  for all training instances). Thus, a classification rule based on the separating plane would be  $G(x) = \text{sign}[f(x)]$ . Finally, note that (given  $\|\beta\| = 1$ ) the distance between any observation  $i$  and the separating plane is given by  $y_i(x_i^T \beta + \beta_0)$ . Thus, and for a margin  $M$  and set of support vectors  $\mathcal{S}$ , finding the maximum margin classifier amounts to finding

$$\underset{\beta, \beta_0}{\text{argmax}} M \text{ subject to } y_i(x_i^T \beta + \beta_0) \geq M \quad \forall i$$

To do so, the relevant Lagrangian dual objective function is maximized, and the solution for  $\beta$  is found to be:

$$\hat{\beta} = \sum_{i=1}^N \alpha_i y_i x_i = \sum_{i \in \mathcal{S}} \alpha_i y_i x_i, \quad (3)$$

where  $\alpha_i$  are the Lagrange multipliers, and the second summation highlights the fact that only those observations in the support set affect the separating hyperplane.

### The Soft-Margin Classifier

So far, we have assumed that a hyperplane can perfectly separate instances across classes. When this is not the case, we must relax the constraint imposed on the distances between points and the hyperplane, and allow for a certain amount of slack. This slack will allow for instances to be within the margin, or even to cross the (quasi-)separating hyperplane.

Thus, although the objective of the optimization stays the same (i.e. maximize the margin), the *soft-margin* constraint is given by  $y_i(x_i^T \beta + \beta_0) \geq M(1 - \epsilon_i)$ , where the  $\epsilon_i$  are the slack terms, themselves constrained so that  $\sum_i \epsilon_i \leq C$ . The dual objective is now maximized subject to  $0 \leq \alpha_i \leq C$  and  $\sum_{i=1}^N \alpha_i y_i = 0$ . As a result,  $C$  becomes a tuning parameter.

Specifically, the margin around the identified hyperplane(s) is larger for smaller values of  $C$  (e.g.  $C = 0.01$ ) and is smaller for larger values of  $C$  (e.g.  $C = 1000$ ). Larger values of  $C$  thus result in greater focus of attention on the points located very close to the decision boundary, while smaller values involve

data points farther away. It is these points (which effectively have Lagrange multipliers greater than zero) that now become the support vectors.<sup>6</sup>

Typically, the value for  $C$  is defined through cross-validation. When identifying *linear* boundaries, however, the results tend not to be too sensitive to the specification of  $C$  (Hastie et al., 2009). The choice matters considerably more when linear boundaries no longer generate optimal classifiers, as smaller values of  $C$  can result in severe over-fitting. The generalization of these ideas to non-linear decision boundaries is what is typically called a *support vector machine*.

### Support Vector Machines and Kernels

It is often the case that a non-linear classification boundary is needed in order to correctly classify instances. For instance, consider the right panel of Figure 56.3. Although the two classes are easily recognized as occupying different regions of feature space, no hyperplane across it would result in a good separation. The optimal decision boundary, which in this case corresponds to a circle, is not linear.

In the classical regression context, dealing with non-linear associations involved incorporating non-linear functions of predictors (e.g. higher order polynomials, log-transformations) into the specification of the conditional expectation of the outcome. SVMs adopt a similar strategy: instead of operating on the space defined by the original set of predictors (where no linear boundary can correctly separate classes of the target outcome), they operate on a transformed space of higher dimensions *in which linear separability becomes possible*.

Consider, once again, the classification problem illustrated on the right panel of Figure 56.3 (now reproduced as a tilted projection at the bottom of Figure 56.4). Suppose we add a third feature equal to the negative sum of squares of the original predictors. This results in the 3D scatterplot depicted

**Figure 56.4** Illustration of kernel trick: tilted projection of instances depicted in right panel of Figure 56.3 onto space with an additional dimension  $z = -(X_1^2 + X_2^2)$  (original two-dimensional representation can be seen at the bottom). Observations of Class B (in dark gray) now cluster at the top of a conical surface. SVM learns the gray plane that cuts across this conical surface, resulting in perfect separation of Class A instances (light gray, below plane) and Class B instances (dark gray, above plane)

on Figure 56.4, slightly tilted to improve visibility. In this new, three-dimensional feature space, observations are now arrayed on a conical surface, with instances of class B rising to its apex. It is now easy to define a plane, depicted in gray in Figure 56.4, that cuts the top of this cone and separates instances of the two classes. The projection of this separating plane back onto the original two-dimensional

space generates the circular decision boundary we needed. Once again, the SVM’s goal is to learn this separating plane.

What is remarkable about actual implementations of SVMs is that there is no need to explicitly define what these additional dimensions are, provided they can be expressed as functions of the pair-wise dot products  $\langle x_i, x_j \rangle$  of the original features. Specifically, SVMs rely on kernels  $K(x_i, x_j)$  – bivariate, symmetric, and positive-definite functions that define measures of proximity or similarity between observations, and which operate on the space of original features. In practice, different kernels support different kinds of implicit added features. This approach, called the *kernel trick*, avoids explicit re-mapping onto higher-dimensional spaces. Like boosting, kernelization can be applied to many different types of learners (including GLMs; see, for instance, Hainmueller and Hazlett, 2014).

In the SVM literature, popular kernels include the polynomial kernel, the radial basis function (RBF) kernel, and the sigmoid kernel. Table 56.1 provides a summary of the kernels. All of these (and many others) are implemented in the `svm` function included in `R` package `e1071`. The use of different kernels may result in different predictions and different weights being placed on the features. Additionally, values taken by different (hyper)parameters (such  $d$  in the Polynomial kernel,  $c$  in the RBF, or  $\kappa_1$  and  $\kappa_2$  in the Sigmoid kernel) must be defined by the researcher. Once again, in practice, cross-validation is a good strategy for choosing these values.

One interesting aspect of both the RBF kernel and the sigmoid kernel is that each is

**Table 56.1** Popular SVM kernels

Kernel	Form
Linear	$K(x, x') = \langle x, x' \rangle$
$d$ th degree polynomial	$K(x, x') = (1 + \langle x, x' \rangle)^d$
Radial basis function	$K(x, x') = \exp(-\ x - x'\ ^2/c)$
Sigmoid (neural network)	$K(x, x') = \tanh(\kappa_1 \langle x, x' \rangle + \kappa_2)$

essentially a type of neural network. In fact, earlier editions of Hastie et al. (2009) refer to the sigmoid kernel as the *neural network kernel*. The first is a type of neural network actually called an RBF network. The second is a standard neural network fit with a multi-layer perceptron and one hidden layer.

Incorporating the kernel-transformed features into the SVM optimization problem is not difficult. In general, Equation 2 can be reformulated using kernels. Specifically, the function used to define the hyperplane can be rewritten as:

$$f(x) = \sum_{i \in S} \alpha_i y_i K(x, x_i) + \beta_0. \quad (4)$$

with everything else (including soft constraints and prediction rules) staying as before.

Although we have discussed SVMs in the context of binary classification, there are extensions to multinomial classification problems and even regression-like tasks, where they are typically called *support vector regressions* (Cortes and Vapnik, 1995; Grundler and Krieger, 2015; Hastie, Tibshirani and Friedman, 2009; Witten et al., 2016).

It is also worth noting that while SVM's are typically very fast and accurate (and scale particularly well in terms of the dimensionality of the original feature space), they have been shown to be very closely related to regularized logistic regression models (the so called *Loss + Penalty* representation of SVMs) (Hastie et al., 2009), and they tend to provide similar results – particularly when classes are well separated.

### *An Application in the Study of Criticism in Congress*

One common application of support vector machines is to learn characteristics of interest, effectively using the SVM as a measurement model. Examples of this are scattered throughout computer science and are becoming more common within political science. A good example is the recent study by the Pew Research Center's Data Labs team on partisan conflict and Congressional outreach

(Messing, VanKessel, Hughes, Blum, and Judd 2017).

In light of heightened political hostility within and outside the walls of Congress, they questioned who actively criticizes the other party, who 'goes negative', and how the public responds to both of these strategies. To answer these questions, they looked at 108,235 Facebook posts and 94,521 press releases made by members of Congress between January 1, 2015 and April 30, 2016 (during the 114th Congress). Within the posts and releases, they needed to identify three characteristics of the text: whether the member of Congress in that document criticized someone or some group, whether they expressed disagreement, and whether they discussed bipartisanship.

To code every post by hand for each of these characteristics would have been prohibitively time intensive. As an alternative approach, the authors resorted to a *semi-supervised* approach. Specifically, they trained SVMs to identify the concepts of interest on a small hand-coded subset of the data, and then used the trained model to classify the unlabeled documents. First, they randomly sampled a subset of both the press releases and Facebook posts to code by hand.<sup>7</sup> The team at Pew then used Mechanical Turk to garner human-coded labels. Using these codes, they then re-trained an SVM for each concept of interest. To ensure that the final SVM used to classify the remaining data performed as well as possible, they compared penalty levels<sup>8</sup> and different kernels<sup>9</sup> with five-fold cross validation to identify which combination resulted in the best performing algorithm out-of-sample. Finally, using the best performing model for each characteristic, they then applied labels to the remaining documents.<sup>10</sup>

The authors find that the party leadership and ideological extremists on both sides of the aisle are more likely to be critical of the other party and vocally disagree. Conversely, moderates in competitive districts are more likely to talk about bipartisanship. Additionally, they find that the public tends

to like, share, and comment on critical posts more than other posts on Facebook.

## CONCLUSION: PROMISE AND PERILS OF MACHINE LEARNING

ML approaches and methods provide a wide variety of new and exciting tools to political scientists that are especially useful in the face of high-dimensional data sets. As political scientists seek answers to increasingly complex questions and using increasingly complex data (e.g. text or images), such techniques and methods will be increasingly relevant. However, such a promise does not come without challenges and pitfalls. Political scientists face three general challenges when seeking to adopt and use ML techniques and other methods developed by computer scientists.

The first is derived from the fact that, for a long time, those developing ML approaches sought only to *predict* outcomes rather than *understand* the phenomena of interest. This is problematic for at least two reasons. First, many ML algorithms, methods, and models rely on black box techniques. As a result, interpreting the learned relationship between inputs and outcomes becomes much more difficult than with classic techniques used within Political Science. For example, while SVMs are fantastic tools for accurate classification, they offer few ways of determining which features are most predictive. This implies that their use for theory evaluation is extremely limited. Moreover, while *partial dependence plots* (i.e. plots of marginal predicted outcomes as a function of features of interest) (Friedman, 2001) and *variable importance* measures (e.g. weighted averages of error reduction induced by variable selection; Breiman, 1984) can provide a sense of how the target changes as a function of given predictors and which features are most relevant, they remain underutilized and misunderstood.

Second, and partly as a result of the complex problems they tackle, ML approaches tend not to be robust to technical decisions made by researchers. While ML models take away researcher degrees of freedom and can help prevent common issues related to *p*-hacking or specification-related forking-paths (Gelman and Loken, 2013), these models come with their own set of potentially consequential decisions: how is data pre-processed to extract relevant features; how are initial values of parameters chosen; and what set of criteria are used to evaluate goodness-of-fit? While cross-validation techniques can help justify and evaluate some of these choices, the added computational costs of these safe-guards can make this process prohibitively time-intensive, which results in many researchers choosing to use defaults as a path of least resistance. Indeed, recent work has shown that these kinds of technical decisions can have important substantive consequences – consequences that may be hard for the discipline to identify (Alvarez, 2016; Denny and Spirling, 2018).

A byproduct of this second major challenge is a false sense of complacency induced by seemingly technical choices. It is naïve to think that data can ‘speak for itself’ in a way that is untarnished by human biases. All data has a history – a distinctly *human* one at that. Contemporary sources of the massive online data-sets typically studied using the tools of ML, for instance, may reflect the commercial intents of those designing social platforms, rather than the actual preferences and typical behaviors of their users (Ruths and Pfeffer, 2014). Similarly, implicit and explicit human biases are embedded in data that exist already, and predictive models designed to learn patterns and trends will reproduce (and magnify) biases that went into the generation of data to begin with (Dressel and Farid, 2018).

Finally, it is important to remember that no amount of modeling sophistication or data size can, in its own right, correct the issues that plague observational studies. Selection on unobservables, interference, treatment

heterogeneity – all of these issues will continue to pose threats to valid causal inferences. Unless description is the only goal of the learning exercise, researchers will need to justify the kinds of inferential jumps needed to move from prediction to explanation (Grimmer, 2015). Of course, this challenge is perhaps the discipline's greatest opportunity to continue offering meaningful contributions to the field of ML: given our history and scholarly interests, we are uniquely positioned to generate analytic strategies at the intersection of sophisticated computation and careful attention to issues of causal identification with observational data.

## Notes

- 1 Unsupervised models can be similarly classified based on the nature of the learning output: tasks that result in continuous outputs are typically called *dimensionality reduction* problems (and typically involve some variant of the factor-analytic model), whereas tasks that result in discrete outputs are typically called *clustering* problems.
- 2 This is also an example of the so-called *bias-variance trade-off*, which suggests that there is an optimal level of bias that can be achieved such that only a small price is paid in terms of variance of the predictor. Generalization error, which can be thought of as a function of both bias *and* variance (in addition to fundamental uncertainty) of the estimator implied by the model, is therefore at a minimum when this balance is achieved (Hastie et al., 2009).
- 3 Non-binary splits can always be represented as a sequence of binary splits, and, as a result, most tree-based algorithms rely on the latter.
- 4 Typically, missing predictors in the test-set are handled using *surrogate splits* – splits based on non-missing variables that result in similar reductions in loss as the original splitting feature.
- 5 Cost-complexity pruning, for instance, was originally proposed by Breiman et al. (1984) to reduce the likelihood of overfitting and consists of going over the internal nodes of a deeply grown tree and sequentially collapsing those that reduce loss the least. It has been shown that this is equivalent to finding a sub-tree that minimizes a penalized loss-term, where the penalty term  $\lambda B$  is linear on the number of terminal nodes  $B$ , and the choice of the strength of penalization  $\lambda$  is typically chosen via cross-validation. Yet another alternative is given by *conditional inference trees*, proposed by Hothorn et al. (2006), which choose splitting variables and values using a non-parametric significance test of association between predictors and the outcome of interest, thus reducing feature selection bias and focusing on statistically predictive variables.
- 6 Incidentally, this is yet another manifestation of the bias-variance tradeoff: larger  $C$  values result in a low-bias/high-variance estimator, whereas smaller  $C$  values (and consequently a higher number of support vectors) results in low-variance/high bias estimators.
- 7 Because a sample of documents from every member of Congress would be needed and the use of each type of speech occurs in a small proportion of the text (approximately 10% or less of the time for each), random sampling would likely miss much of the picture. Instead, they drew a weighted random sample of documents.
- 8 They tested  $\gamma$  at 1, 10, 100, 1,000, and 10,000.
- 9 They tested the linear and RBF kernels.
- 10 For a longer description of the process, see the methods note in the original report.

PART VI

# Qualitative and 'Mixed' Methods

*This page intentionally left blank*

# Set Theoretic Methods

Adrian Duşa

## INTRODUCTION

There are various ways to analyze social phenomena. The traditional, qualitative, and quantitative approaches involve specialized languages and seemingly incompatible methods – but such phenomena can also be framed in terms of set relations, as it is often the case in common, everyday language. For instance, poverty research can either employ quantitative, nationally representative samples, or they can use case studies to unfold particular, exemplar life stories that are usually obscured by numbers, or it can be framed in a set theoretical perspective, as recently demonstrated by Ragin and Fiss (2017).

Ragin and Fiss studied the relation between poverty and various configurational patterns that include race, class, and test scores and found that white people are mainly characterized by multiple advantages that protect them from poverty, while there are configurations of disadvantages that are mainly prevalent in black people. These disadvantages do not necessarily

lead to poverty, with an important exception: when they combine with black women.

Being black, being a woman, and having children, along with a configuration of disadvantages, are factors that are more than sufficient to explain poverty. This approach is less concerned about the relative effects of each independent variable included in the model, but rather about identifying membership in a particular set (in the current example, of disadvantaged black women). It is a set relational perspective, more precisely with a focus on set intersections to explain social phenomena.

This chapter begins with a short background of set theory and the different types of sets that are used in the social sciences. It presents the most important set operations that are commonly used in the mathematical framework behind a set theoretical methodology, and it shows how to formulate hypotheses using sets and exemplifies how to calculate set membership scores via the different calibration methods. Finally, it presents important concepts related to necessity

and sufficiency and ends with a discussion about how to apply set theory in Qualitative Comparative Analysis (QCA).

### SHORT BACKGROUND OF SET THEORY

Formally initiated by philosopher and mathematician Georg Cantor at the end of the 19th century (Dauben, 1979), classical set theory became part of the standard foundation of modern mathematics, well suited for the treatment of numbers (Pinter, 2014). Elementary mathematics is embedded with notions such as the set of real numbers, or the set of natural numbers, and formal demonstrations almost always employ sets and their elements as inherent, prerequisite properties of a mathematical problem.

It is nowadays called the naive set theory (Halmos, 1974), and was later extended to other versions, but the basic properties prevailed. A set can be defined as a collection of objects that share a common property. If an element  $x$  is a member of a set  $A$ , it is written as  $x \in A$ , and if it is not a member of that set, it is written as  $x \notin A$ . This is the very essence of what is called binary crisp sets, where objects are either in or out of a set.

For any object, it can be answered with ‘yes’ if it is inside the set and ‘no’ if it is not. There are only two possible truth values in this version: 1 (true) and 0 (false) – a country is either in, or outside the EU, a law is either passed or not passed, an event either happens or does not happen, etc. It has certain roots into Leibniz’s binary mathematics from the beginning of the 18th century (Aiton, 1985), later formalized into a special system of logics and mathematics called Boolean algebra, to honor George Boole’s work in the mid 19th century.

In formal notation, a membership function can be defined to attribute these two values:

$$\mu_A(x) = \begin{cases} 0 & \text{if } x \notin A \\ 1 & \text{if } x \in A \end{cases}$$

It is perhaps worth mentioning that the work of all these people was influenced by the Aristotelian logic, a bivalent system based on three principles (laws of thought): the principle of identity, the principle of non-contradiction, and the principle of excluded middle. A single truth value could be assigned for any proposition (either true, or false), but this was only possible for past events. No truth value could be assigned to a proposition referring to the future, since a future event has not yet happened. Future events can be treated deterministically (what is going to be, is going to be) or influenced by peoples’ free will (we decide what is going to be), leading to a paradox formulated by Aristotle himself.

A solution to this problem was proposed by the Polish mathematician Łukasiewicz (1970), who created a system of logic at the beginning of the 20th century that extends the classical bivalent philosophy. His system (denoted by  $\mathbb{L}_3$ ) presents not just two but three truth values:

$$\mu_A(x) = \begin{cases} 0 & \text{false} \\ \frac{1}{2} & \text{undetermined (neither} \\ & \text{false nor true, or partially true)} \\ 1 & \text{true} \end{cases}$$

Łukasiewicz’s system (using a finite number of values) was eventually generalized to multivalent systems with  $n = v - 1$  values, obtained through a uniform division of the interval  $[0, 1]$ :

$$\left\{ 0 = \frac{0}{n}, \frac{1}{n}, \frac{2}{n}, \dots, \frac{n}{n} = 1 \right\}$$

While some phenomena are inherently bivalent (an element is either in, or out of a set), there are situations where two values are unable to describe the whole picture. A social problem is not necessarily solved or unsolved but can be more or less dealt with. A country is not simply rich or poor, but it can be more or less included in the set of rich countries. There is a certain degree of uncertainty regarding the truth value, which was modeled in the middle of the 20th

century by another great mathematician who laid out the foundations of the fuzzy sets (Zadeh, 1965). These types of sets have a continuous (infinite) number of membership values, in the interval bounded by 0 (completely out of the set) to 1 (completely in the set).

**SET OPERATIONS**

Set operations are mathematical transformations that reflect the logical relations between sets to reflect various configurations that involve intersections, unions, and/or negations. The simplest way to think about these operations is an analogy using basic mathematical algebra: addition, subtraction, multiplication, and division are all very simple – but they are essential operations to build upon. In set theory, there are essentially three main operations that are used extensively in the set theoretical research and comparative analysis: set intersection, set union, and set negation.

These operations perform differently for crisp and fuzzy sets, but the fuzzy version is more general and can be applied to crisp situations as well.

**Set Intersection (Logical AND)**

In the crisp version, the goal of this operation is to find the common elements of two sets. A truth value is involved, that is, it is assigned a ‘true’ value if the element is common and a ‘false’ if otherwise. Out of the four possible combinations of true/false values in Table 57.1 for the membership in the two sets, only one is assigned a ‘true’ value for the intersection, where both individual values are true.

This is called a ‘conjunction’, meaning the logical AND expression is true only when both sets are (conjunctively) true. It is usually denoted using the ‘∩’ or multiplication ‘.’ signs.

The fuzzy version of the set intersection formula is obtained by calculating the minimum between two (or more) values:

$$A \cap B = \min(A, B) \tag{1}$$

As the minimum between 0 (false) and any other truth value is always 0, this formula holds for the data from Table 57.1, where a minimum equal to 1 (true) is obtained only when both values are equal to 1.

**Set Union (Logical OR)**

The counterpart of the set intersection is the set union, used to form larger and larger sets by pulling together all elements from all sets. In the crisp sets version, the result of the union operation is true if the element is part of at least one of the sets. Contrary to set intersection, the only possible way to have a false truth value is the situation where an object is not an element of any of the (two) sets:

The union of two sets is called a ‘disjunction’ and it is usually denoted with the ‘∪’ or ‘+’ signs, and the later should not be confused with the arithmetic addition.

The fuzzy version of this operation is exactly the opposite of the set intersection, by calculating the maximum between two (or more) values:

$$A \cup B = \max(A, B) \tag{2}$$

**Table 57.1 Set intersection for crisp sets**

A		B		
0	AND	0	=	0
0	AND	1	=	0
1	AND	0	=	0
1	AND	1	=	1

**Table 57.2 Set union for crisp sets**

A		B		
0	OR	0	=	0
0	OR	1	=	1
1	OR	0	=	1
1	OR	1	=	1

**Table 57.3 Set negation for crisp sets**

		A	
NOT	0	=	1
NOT	1	=	0

### Set Negation

Set negation is a fundamental operation in set theory, consisting of finding the complement of a set,  $A$ , from a universe,  $U$  (which is a different set of its own, formed by the elements of  $U$  that are not in  $A$ ). It is many times denoted with the ' $\sim$ ' or ' $\neg$ ' signs, and sometimes (especially in programming) with the exclamation sign '!'.

Negating multivalued crisp sets involves taking all elements that are not equal to a specific value. It is still a binary crisp operation, first by coercing the multivalued set into a binary crisp one and then by negating the resulting values.

Negation is a unary operation, and its fuzzy version is a simple subtraction from 1:

$$\sim A = 1 - A \quad (3)$$

The importance of set negation will be revealed later, especially when comparing the quantitative methods with the set theoretical ones, to reveal a certain asymmetry that is specific to sets, with a methodological effort to explain both the presence and the negation (its absence) of a certain phenomenon.

## FORMULATING HYPOTHESES USING SETS

There are multiple ways to conceptualize, measure, and hypothesize social and political phenomena. Previous chapters from this book present several such approaches, from the quantitative types centered on variables to qualitative methods focused on cases. The quantitative approach relies on very precise statistical properties stemming from large samples, and it describes the net effect of

each independent variable on the outcome (the dependent variable), controlling for all other variables in the model. It is a relatively straightforward, albeit with specialized statistical language that is extensively used in quantitative research, however, it is not the most common language to formulate scientific hypotheses.

Hsieh (1980), Novák (1991), Arfi (2010), and even Zadeh (1983) himself have shown how the set theory, and especially the fuzzy sets, can be related to the natural language. Moreover, and contrary to most common expectations, scientific hypotheses do not usually mention the specific net effects of various independent variables, instead they seem very compatible with the language of sets, much like the natural language.

For instance, hypothesizing that democratic countries do not go to war with each other (Babst, 1964) can be naturally translated into sets. The elements are countries, and there are two sets involved: the set of democratic countries, and the set of countries that do not go to war with each other. It is the type of hypothesis that can be best expressed in terms of sufficiency and subset relation, but for the moment, it should suffice to state that it is a concomitant membership of the two sets: those countries that are included in the set of democratic countries are also included in the set of countries that do not go to war with each other.

The same type of language can be applied to another common type of hypothesis in an if-then statement, for instance: 'if a student passes the final exam, then he or she graduates'. Here, too, it is about two sets: the set of students who pass the final exam, and the set of students who graduate, membership in the first guarantees membership in the second.

It seems natural to specify such hypotheses in terms of set language, both in fuzzy sets form (more or less democratic countries) and even binary crisp form (either graduate, or not). Scientific thinking, at least in the social and political sciences, is a constant interplay between abstractization and exact

measurement: we first start by specifying the (pre)conditions that make a certain outcome possible, and only then do we measure the exact values for each such condition or variable.

A statement such as: ‘welfare is education and health’ does not mention any specific values of the education, or of the health, that produce the welfare. This is but one among many possible causal recipes (in the vein of the welfare typologies contributed by Esping-Andersen, 1990) where only the ingredients (education and health) are mentioned without specifying the exact net effects that are needed to produce welfare. It is entirely possible to assign precise mathematical numbers to sets (more exactly, to set membership scores), which is the topic of the next section, but formulating hypotheses is more a matter of specifying abstract concepts (similar to sets) and less about exact values for each.

Using a different perspective on the relation between fuzzy sets and natural language, George Lakoff rejects the notion that natural language can be perfectly mapped over the set theory (Ramzipoor, 2014). He also criticizes Charles Ragin’s approach that assigns membership scores (presented in the next section about set calibration), based on his expertise combining linguistics and cognitive science. More recently, Mendel and Korjani (2018) propose a new method using the Type-2 fuzzy sets.

The whole debate is extremely interesting, for social science concepts have a dual nature stemming from both linguistics and theoretical corpus, but it is by now evident that set theory is well established in social and political research. Conceptual thinking has a long tradition in sociology, with Max Weber’s ideal types being similar to set theoretic concepts that play a central role in comparative analysis. In fact, the whole process of concept formation is embedded with the language of set theory (Mahoney, 1980; Goertz, 2006b; Schneider and Wagemann, 2012).

Despite the predominance of the quantitative methods in the social and political

sciences, there are situations where statistical analyses are impossible (mainly due to a very small number of cases) and, most importantly, where the use of set theory is actually more appropriate, for both formulating and testing theories.

## SET CALIBRATION

In the natural sciences, assigning membership scores to sets is a straightforward procedure. Objects have physical properties that can be measured and transformed into such membership scores. In the social and political sciences, the situation is much more complex. These sciences deal with highly complex phenomena that can only be conceptualized at a very abstract level. They do not exist in the physical reality and do not have visible properties to measure directly.

Concepts are very abstract things, and their measurement is even more complex: it depends on theory, which determines their definition which, in turn, has a direct effect over their operationalization which has an influence on constructing the research instrument – only then can some measurements be collected.

Each of these stages require highly specialized training involving years (sometimes a lifetime) of practice before mastering the activity. Theoreticians are rare, or at least those who have a real impact over the research praxis of the entire academic community. Most researchers follow a handful of theories that attempt to explain the social and political reality. Each such theory should be ideally reflected into a clear definition of the abstract concept.

Based on the definition, the process of operationalization is yet another very complex step towards obtaining some kind of numerical measurements about the concept. It is based on the idea that, given the impossibility of directly measuring the concept, researchers can only resort to measuring its effect over the observable reality. For instance, we cannot tell

how altruistic a person is unless we observe how the person behaves in certain situations related to altruism. There are multiple ways for a person to manifest this abstract concept, and the operationalization is a process that transforms a definition into measurable indicators, usually via some other abstract dimensions and subdimensions of the concept.

Finally, obtaining numerical scores based on the indicators from the operationalization phase is yet another complex activity. There are multiple ways to measure (counting only the traditional four levels of measurement: nominal, ordinal, interval, and ratio, but there are many others), and the process of constructing the research instrument, based on the chosen level of measurement for each indicator, is an art. It is especially complex as the concepts should also be equivalent in different cultures, and huge efforts are being spent to ensure the compatibility between the research instruments from different languages (translation being a very sensitive activity).

The entire process ends up with some numerical measurements for each indicator, and a final task to aggregate all these numbers to a single composite measure that should be large if the concept is strong, and small if the concept is weak. In the above example, highly altruistic people should be allocated large numbers, while unconcerned people should be allocated low numbers, both on a certain numerical scale.

In set theory, calibration is the process of transforming these (raw) numbers into set membership scores, such that a completely altruistic person should receive a value of 1, while a non-altruistic person should receive a value of 0. This process is far from straightforward, even for the natural sciences.

Describing the procedure, Ragin (2008) makes a distinction between 'calibration' and 'measurement' processes and exemplifies with temperature as it is a directly measurable physical property. While exact temperatures can be obtained from absolute zero to millions of degrees, no such procedure would

even be able to automatically determine what is 'hot' and what is 'cold'. These are human interpreted concepts and need to be associated with some subjective numerical anchors (thresholds). On the Celsius scale, 0 degrees is usually associated with cold, while 100 degrees is usually associated with very hot, and these numbers are not picked at random. They correspond to the points where the water changes states: to ice at 0 degrees and to steam at 100 degrees, when the water boils.

The choice of thresholds is very important, for it determines the point where something is completely out of a set (for instance at 0 degrees, the ice is completely out of the set of hot matter) and the point where something is completely inside the set (at 100 degrees, steam is completely inside the set of hot matter). A third threshold is also employed called the 'crossover': the point of maximum ambiguity where it is impossible to determine whether something is more in than out of a set, corresponding to the set membership score of 0.5.

The set of thresholds (exclusion, crossover, and inclusion) is not universal, even for the same concept. A 'tall' person means one thing in countries like Norway and Netherlands, where the average male height is more than 1.8 m, and another thing in countries like Indonesia and Bolivia, where the average is about 1.6 m. It is the concept that matters – not its exact measurement – therefore, different thresholds need to be used in different cultural contexts, depending on the local perception.

Traditionally, there are two types of calibrations for each type of sets, crisp and fuzzy. Calibrating to crisp sets is essentially a matter of recoding the raw data and establishing a certain number of thresholds for each value of the calibrated set. When binary crisp sets are intended to be obtained, a single threshold is needed to divide the raw values in two categories: those below the threshold will be allocated a value of 0 (out of the set) and for those above the threshold, a value of 1 (in the

set). When multivalued crisp sets are intended, there will be two thresholds to divide into three categories, and so on. The general formula for the number of thresholds is the number of values minus 1.

Even for this (crude) type of recoding, the values of the thresholds should not be mechanically determined. A statistician will likely divide the values using the median, which would, in many cases, be a mistake. It is not the number of cases that should determine the value of the threshold, but rather the meaning of the concept and the expert's intimate knowledge about which cases belong to which category.

For instance, there will be a certain value of the threshold to divide countries' GDP in the set of 'developed countries' and a different value of the threshold for the set of 'very developed countries'. The exact value should be determined only after an inspection of the distribution of GDP values, especially if they are not clearly clustered. In such a situation, the researcher's experience should act as a guide in establishing the best threshold value that would correctly separate different countries in different categories, even if the difference is small. The whole of this process should be thoroughly described in a dedicated methodological section, with strong theoretical justifications for the chosen value of the threshold.

Calibrating to fuzzy sets is more challenging and, at the same time, more interesting because there are multiple ways to obtain fuzzy membership scores from the same raw numerical data. The most widely used is called the 'direct method', first described by Ragin (2000). It uses the logistical function to allocate membership scores, using the exclusion, cross-over, and inclusion thresholds.

Table 57.4 below displays the two relevant columns extracted from Ragin's book, the first showing the national income in US dollars and the second showing the degree of membership (the calibrated counterparts of the national income) into the set of developed countries.

**Table 57.4 Per capita income (INC), calibrated to fuzzy sets membership scores (fsMS)**

	<i>INC</i>	<i>fsMS</i>
Switzerland	40,110	1.00
United States	34,400	1.00
Netherlands	25,200	0.98
Finland	24,920	0.98
Australia	20,060	0.95
Israel	17,090	0.92
Spain	15,320	0.89
New Zealand	13,680	0.85
Cyprus	11,720	0.79
Greece	11,290	0.78
Portugal	10,940	0.77
Korea, Rep.	9,800	0.72
Argentina	7,470	0.62
Hungary	4,670	0.40
Venezuela	4,100	0.25
Estonia	4,070	0.25
Panama	3,740	0.18
Mauritius	3,690	0.17
Brazil	3,590	0.16
Turkey	2,980	0.08
Bolivia	1,000	0.01
Cote d'Ivoire	650	0.01
Senegal	450	0.00
Burundi	110	0.00

At the top of the list, Switzerland and the United States are highly developed countries, which explains their full membership score of 1, while Senegal and Burundi, with national incomes of 450 USD and 110 USD respectively, are too poor to have any membership whatsoever in the set of developed countries.

What threshold values best describe this set, and how are the membership values calculated? A quick quantitative solution would be to calculate the ratio of every other country from the income of Switzerland, the richest country in that data.

Aside from the fact such a method is mechanical and data driven, it would immediately become obvious that, for instance, the Netherlands (which currently has an almost full inclusion of 0.98 in the set of developed

**Figure 57.1 Calibration in the set of developed countries**

countries) would have a ratio equal to 0.628, which does not seem to accurately reflect our knowledge. Likewise, a median value of 8,635 USD would leave Argentina more out of the set than more in, and the average of 11,294 USD is even more misleading, leaving Greece more out than in.

Ragin started by first deciding the crossover threshold at a value of 5,000 USD, which is the point of maximum ambiguity about a country being in more in than more out of the set of developed countries. He then applied some mathematical calculations based on the logistic function and the associated log odds, arriving at a full inclusion score of 20,000 USD (corresponding to a membership score of at least 0.95 and a log odds of membership of at least +3) and a full exclusion score of 2,500 USD (corresponding to a membership score of at most 0.05 and a log odds of membership lower than -3).

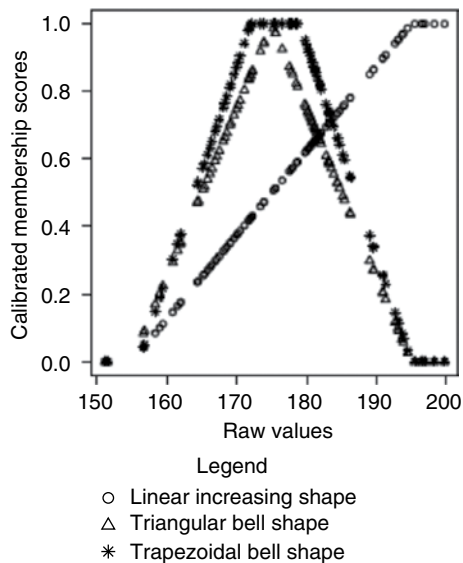

Employing the logistic function, the generated set membership scores follow the familiar increasing S shape displayed in Figure 57.1, but this function is only one among many other possible ones to perform calibration. Linear mathematical transformations are also possible, such as the one from the Equation (4), as extracted from Duşa (2019: 84):

$$dm_x = \begin{cases} 0 & \text{if } x \leq e, \\ \frac{1}{2} \left( \frac{e-x}{e-c} \right)^b & \text{if } e < x \leq c, \\ 1 - \frac{1}{2} \left( \frac{i-x}{i-c} \right)^a & \text{if } c < x \leq i, \\ 1 & \text{if } x > i. \end{cases} \quad (4)$$

where:

- *e* is the threshold for full exclusion
- *c* is the crossover
- *i* is the threshold for full inclusion
- *x* is the raw value to be calibrated
- *b* determines the shape below the crossover (linear when *b* = 1 and curved when *b* > 1)
- *a* determines the shape above the crossover (linear when *a* = 1 and curved when *a* > 1)

The calibration functions in Figure 57.2 refer to the calibration of 100 randomly selected heights ranging from 150 cm to 200 cm. These values are calibrated in the set of ‘tall people’ (the linear increasing function that could act as a replacement for the logistical S shape) as well as in the set of ‘average height

**Figure 57.2 Other possible calibration functions**

people’ (with a triangular shape, and also with a trapezoidal shape). This is an example that shows how the calibrated values depend on the conceptual meaning of the calibrated set. All shapes refer to people’s heights and all use the exact same raw values, but the meaning is different for ‘average height’ and for ‘tall’ people.

The set of three threshold values (155 cm for full exclusion, 175 cm for the crossover, and 195 cm for full inclusion) can be used only for the increasing linear that approximates an S shape for the set of ‘tall’ people. The other linear functions that approximate a bell shape (for the set of ‘average height’ people) are more challenging, and need a set of six values for the thresholds (three for the first part that increases towards the middle, and the other three for the second part that decreases from the middle towards the higher heights). There are two full exclusion thresholds, two crossover values, and, finally, two full inclusion thresholds (that coincide for the triangular shape), with the calibrated values being obtained via the mathematical transformations from Equation (5):

$$dm_x = \begin{cases} 0 & \text{if } x \leq e_1, \\ \frac{1}{2} \left( \frac{e_1 - x}{e_1 - c_1} \right)^b & \text{if } e_1 < x \leq c_1, \\ 1 - \frac{1}{2} \left( \frac{i_1 - x}{i_1 - c_1} \right)^a & \text{if } c_1 < x \leq i_1, \\ 1 & \text{if } i_1 < x \leq i_2, \\ 1 - \frac{1}{2} \left( \frac{i_2 - x}{i_2 - c_2} \right)^a & \text{if } i_2 < x \leq c_2, \\ \frac{1}{2} \left( \frac{e_2 - x}{e_2 - c_2} \right)^b & \text{if } c_2 < x \leq e_2, \\ 0 & \text{if } x > e_2. \end{cases} \quad (5)$$

Apart from the direct method, Ragin also presented an ‘indirect’ one in order to obtain fuzzy membership scores from interval level raw data. In this method, no qualitative anchors (thresholds) need to be specified in advance, but, rather, it involves creating an

artificial dependent variable where each case is allocated a certain fuzzy membership category from 0 to 1 (usually six, an even number to avoid the point of maximum ambiguity 0.5), then performs a (quasi)binomial logistic regression using a fractional polynomial equation with the raw values as an independent variable against the newly formed dependent variable containing the fuzzy membership categories (for more details, see Duşa, 2019: 92).

A different type of calibration is applied for categorical causal conditions (for instance, containing values from a response Likert type scale). It is not possible to determine any thresholds because the variation is extremely small and data can sometimes be severely skewed, which limits the variation even more. For the same reasons, no regression equation can be applied with the indirect method, since it assumes at least the independent variable to be metric.

A possible solution to this problem is to manually allocate fuzzy membership scores for each category (the so-called ‘direct assignment’ method), introduced by Verkuilen (2005) who also criticized it for containing bias due to researcher’s subjectivity. Verkuilen mentions a possibly better solution, by employing the Totally Fuzzy and Relative (TFR) method (Cheli and Lemmi, 1995), making use of the empirical cumulative distribution function of the observed data  $E$ , then calculating the fraction between the distance from each CDF value  $E(x)$  to the CDF of the first value from the Likert scale  $E(1)$ , and the distance from 1 (the maximum possible fuzzy score) to the same  $E(1)$ :

$$TFR = \max \left( 0, \frac{E(x) - E(1)}{1 - E(1)} \right) \quad (6)$$

Calibration is a very important topic in set theoretical methods, as many of the subsequent results depend on this operation. It should not be a mechanical process, but rather an informed activity where the researcher should present the methodological reasons that led to one method or another.

## SET MEMBERSHIP SCORES VS. PROBABILITIES

Despite this topic being discussed numerous times before (Dubois and Prade, 1989; Kosko, 1990; Zadeh, 1995; Ragin, 2008; Schneider and Wagemann, 2012), and despite attempts to combine set theory and statistics (Heylen and Nachtegael, 2013), set membership scores and probabilities can still be confused as both range from 0 to 1 and, at a first glance, seem very similar.

Before delving into the formal difference, consider the following example involving a potentially hot stove. If the stove has a 1% probability of being very hot, there is still a small (but real) chance to get severely burned when touching it. However, if we say the stove has a 1% inclusion in the set of hot objects, the stove can be safely touched without any risk of getting burned.

Ragin's example with the glass of water has the same interpretation. If there is a 1% probability the glass will contain a deadly poison, there is a small but definite chance of dying after drinking that water. But if the glass has a 1% inclusion in the set of poisonous drinks, there is absolutely no risk of dying.

Intuitive as they may seem, these two examples still don't explain the fundamental difference. At the formal level, the probability has to obey the Kolmogorov axioms:

- the probability of an event that is certain is equal to 1:  $P(C) = 1$
- the probability of an impossible event is equal to 0:  $P(\emptyset) = 0$
- if two events do not overlap ( $A \cap B = \emptyset$ ), then  $P(A + B) = P(A) + P(B)$

The probability can essentially be interpreted as a relative frequency obtained from an infinite repetition of an experiment. It is a frequentist statistic (based on what is called a frequentist approach), where the conclusions are drawn from the relative proportions in the data.

However, frequencies can only be computed for categorical variables, in this situation: for events either happening or not. To calculate probabilities (relative frequencies) there are only two possible values for the event: 1 (true, happening) or 0 (false, not happening). The first section already presented the different types of sets, and this corresponds to the definition of a binary crisp set.

Therefore, the meaning of probability is necessarily related to crisp sets, while membership scores are related to fuzzy sets. They simply refer to different things, given that crisp sets are only particular cases of fuzzy sets. Set membership scores refer to various degrees of membership to a set, they are related to the uncertainty about set membership that cannot be computed the same as a probability because the set itself is not crisp, but fuzzy.

When flipping a coin, there are only two possible outcomes (heads or tails) and an exact probability of occurrence for each can be computed by flipping the coin numerous times. These are clear-cut categories (either heads or tails), but not all concepts are so clear. Whether a person is 'young' is a matter of uncertainty, and every person can be included (more, or less) in the set of young people. Same with 'smart', 'healthy', etc., all of which cannot be determined unequivocally.

There are situations where probabilities and fuzzy sets can be combined (Singpurwalla and Booker, 2004; Demey et al., 2017), especially with Bayesian probabilities (Mahoney, 2016; Barrenechea and Mahoney, 2017; Fairfield and Charman, 2017) in conjunction with process tracing, but these two concepts do not completely overlap. In the words of Zadeh (1995) himself, they are 'complementary rather than competitive'.

## POLARITY AND ASYMMETRY

There is an even deeper layer of understanding that needs to be uncovered with respect to

probabilities and fuzzy sets. Describing probability, Kosko (1994: 32) shows that it works with bivalent sets only (an event either happens or it does not happen), and another important difference refers to how a set relates to its negation.

In probability theory,  $A \cap \sim A = \emptyset$ , and  $A \cup \sim A = 1$ . For fuzzy sets, it turns out that  $A \cap \sim A \neq \emptyset$ , and  $A \cup \sim A \neq 1$ . These inequalities (especially the first one) essentially entail that objects can be part of both a set and its negation, and the union of the two sets might not always be equal to the universe.

This has deep implications over how we relate to events, their negation, and the common misperception of bipolarity. Sets are unipolar, therefore a bipolar measurement scale (for instance, a Likert type response scale) cannot be easily accommodated with a single set.

In a bipolar space, ‘good’ is the opposite of ‘bad’; but a ‘not bad’ thing is not precisely the same as a ‘good’ thing: it is just not bad. Same with ‘ugly’ vs. ‘beautiful’: if a thing is not ugly, that does not mean it is necessarily beautiful, or, the other way around, something that is not beautiful is not necessarily ugly. Bauer et al. (2014) encountered similar difficulties in evaluating a bipolar scale with left-right political attitudes, analyzing the vagueness of the social science concepts in applied survey research.

Things, or people, can have membership scores of more than 0.5 in both a set and its negation. A person can be both happy and unhappy at the same time, therefore translating a bipolar scale into a single set is difficult, if not impossible. There should be two sets, first for the happy persons and the second for the unhappy ones, and a person can be allocated membership scores in both, such that the sum of the two scores can exceed 1 (something impossible with probabilities).

The set negation leads to another point of misunderstanding between quantitative statistics (especially the correlation-based techniques, for instance the regression analysis) and set theoretic methods. Numerous

articles have been written comparing empirical results (Katz et al., 2005; Grendstad, 2007; Fujita, 2009; Grofman and Schneider, 2009; Woodside, 2014), pointing to the deficiencies of regression techniques (Pennings, 2003; Marx and Soares, 2015), criticizing fuzzy sets (Seawright, 2005; Paine, 2015; Munck, 2016), and revealing the advantages of fuzzy sets (Cooper and Glaesser, 2010), or, more recently, focusing on the integration and complementarity between the two methods (Skaaning, 2007; Mahoney, 2010; Fiss et al., 2013; Radaelli and Wagemann, 2019).

The sheer amount of written publications suggest at least a couple of things. First, that set theoretic methods are increasingly used in a field traditionally dominated by the quantitative analysis, and second, there is a lot of potential for these methods to be confused (despite the obvious differences) as they both refer to explanatory causal models for a given phenomenon.

Correlation-based techniques assume an ideal linear relation between the independent and dependent variables. When high values of the dependent variable (that can be interpreted as the ‘presence’ of the outcome, in set theory) are explained by high values of the independent variable(s), then low values of the dependent (‘absence’ of the outcome) are necessarily explained by low values of the independent variable(s).

By contrast, set theoretical methods do not assume this kind of linearity. While the presence of the outcome can be explained by a certain configuration of causal conditions, the absence of the outcome can have a very different explanation, involving different causal combinations. If welfare can be explained by the combination of education and health, it is perfectly possible for the absence of welfare to be explained by different causes.

While the correlation-based analyses are symmetric with respect to the dependent variable, the set theoretic methods are characterized by an asymmetric relation between a set of causes and a certain outcome. This is a fundamental ontological difference that

separates the two analysis systems, which should explain both why they are sometimes confused, as well as why their results are seemingly different.

**NECESSITY AND SUFFICIENCY**

Natural language abounds with expressions containing the words ‘necessary’ and ‘sufficient’. In trying to identify the most relevant conditions that are associated with an outcome, theorists often ask: what are the necessary conditions for the outcome? (without which the outcome cannot happen), or what conditions are sufficient to trigger an event? (that, when present, the event is guaranteed to happen).

The contrast between the correlational perspective and the set theoretic methods can be further revealed by analyzing Figure 57.3. The crosstable on the left side is a typical, minimal representation of the quantitative statistical perspective, focused on the perfect correlation from the main diagonal. Everything off the main diagonal is problematic and decreases the coefficient of correlation.

The crosstable on the right side, however, tells a different story. In the language of statistics, the 45 cases in the upper left quadrant potentially ruin the correlation, but they make perfect sense from a set theoretical point of view: since there are no cases in the lower right quadrant, this crosstable tells the story of X being a perfect subset of Y. The ‘problematic’ upper left quadrant simply says there are cases where Y is present and X is

absent – in other words, X does not cover (does not ‘explain’) all of Y.

The zero cases in the lower right quadrant – combined with the 14 cases in the upper right quadrant – say there is no instance of X where Y is absent, which means that X is completely included in Y (it is a subset of Y). Whenever X happens, Y happens as well, that is to say X is ‘sufficient’ for Y (‘if X, then Y’).

This is a different type of language, a set theoretical one, that is foreign to the traditional quantitative analysis. Regression analysis and the sufficiency analysis have the very same purpose, to seek the relevant causal conditions for a given phenomenon. However, when inspecting for sufficiency, the focus is not the main diagonal (correlation style) but rather on the right side of the crosstable where X happens (where X is equal to 1).

This is naturally a very simplified example using just two values for both X and Y. Quantitative researchers would be right to argue that, when the dependent variable is binary, a logistic regression model is more appropriate than a linear regression model. However, set theoretical data need not necessarily be crisp, they can also be fuzzy with a larger variation between 0 and 1 – a crosstable is not enough to represent the data.

At a closer inspection on Figure 57.4, the situation is identical for fuzzy sets. The left plot displays the characteristic ellipse shape of the cloud, with a very positive correlation between the independent and the dependent variables. It does not really matter whether the points are located above or below the diagonal, as long as they are close.

The cloud of points from the right plot would be considered problematic. Not only are the points located far from the main diagonal (ideally, the regression line), but they also display inconstant variance (a phenomenon called heteroskedasticity). However, this is not problematic for set theory: as long as the points are located above the main diagonal (values of X are always smaller than corresponding values of Y), it is a perfect representation of a fuzzy subset relation. In set theoretical language,

**Figure 57.3 Correlation (left) and subset sufficiency (right)**

**Figure 57.4 Fuzzy correlation (left) and fuzzy subset sufficiency (right)**

such a subset relation, it is also described as perfectly ‘consistent’.

Not all subset relations are that perfect. In fact, there can be situations where X can happen and Y is absent, without affecting the sufficiency relation (too much). Just as there are no countries with perfect democracies (they are ‘more or less’ democratic), situations with perfect sufficiency are also extremely rare. When perfect sufficiency happens, it is mainly the result of our calibration choice: it can happen in crisp sets, but this is almost never observed with fuzzy sets.

The concept of fuzziness teaches us that conditions can be ‘more or less’ sufficient, just as two sets can be more or less included one into the other. The causal set should be ‘consistent enough’ with (or ‘included enough’ in) the outcome set, to be accepted as sufficient.

The big question is how much of outcome set Y is explained by causal set X, a very common question in traditional statistics that is usually answered with the  $R^2$  coefficient in the regression analysis. In set theory, this is a matter of coverage. There can be situations with imperfect consistency but large coverage, and perfect consistency but low coverage.

Out of the two situations in Figure 57.5, the relation from the left plot is the most relevant. Despite the imperfect consistency (inclusion),

**Figure 57.5 Incomplete inclusion/large coverage (left) and complete inclusion/low coverage (right)**

the causal condition X covers a lot of the cases in the outcome Y, qualifying as a highly relevant (albeit imperfect) sufficient condition for Y.

In the plot from the right side, X is perfectly consistent with Y but it covers only a very small area, which means there are very many cases in Y that are not explained by X, suggesting we should search for more causal conditions that explain the entire diversity of the outcome’s presence. In such situations, X is called sufficient but not necessary, an expression which is also described by the concept of ‘equifinality’: the very same outcome can be produced via multiple causal paths, just as there are many roads that lead to the same city.

Inclusion and coverage can be precisely measured, with the same formula being valid

for both crisp and fuzzy sets. Equation (7) calculates the consistency for sufficiency (*inclS*), while Equation (8) calculates the coverage for sufficiency (*covS*), where the sufficiency relation is denoted by the forward arrow sign  $X \Rightarrow Y$ :

$$inclS_{X \Rightarrow Y} = \frac{\sum \min(X, Y)}{\sum X} \quad (7)$$

$$covS_{X \Rightarrow Y} = \frac{\sum \min(X, Y)}{\sum Y} \quad (8)$$

In the regression analysis, independent variables may be collinear, meaning they explain the same part of the dependent variable’s variation. This is usually detected with the contribution of each independent variable to the model’s  $R^2$  coefficient: only those variables that contribute a significant increase of the  $R^2$  are preferred.

Similarly, in set theory, the causal conditions have a so called ‘raw’ coverage and also a ‘unique’ coverage. Their unique coverage (*covU*) is the area from the outcome Y which is solely covered by a certain causal condition, as shown in Equation (9) and Figure 57.6.

$$covU_{A \Rightarrow Y} = \frac{\sum \min(Y, A)}{\sum Y} - \frac{\sum \min(Y, A, \max(B, C, \dots))}{\sum Y} \quad (9)$$

In Figure 57.6, the unique coverage of condition A can be computed as the area of Y covered by A, minus the intersection of A and B (its area jointly covered by condition B). More generally, minus the intersection between A and the union of all other causal conditions that cover the same area of Y covered by A.

Necessity and sufficiency are mirrored concepts. While sufficiency is about the subset relation of the causal condition within the outcome set, necessity is the other way around: the superset relation of the causal condition over the outcome set. A causal

**Figure 57.6 Unique coverage of A (hashed area)**

condition is necessary *iff* it is a superset of the outcome: when Y happens, X is always present. When the outcome Y does not occur in the absence of X, it means that X is necessary.

The upper left quadrant in a  $2 \times 2$  crosstable should be empty (where  $Y = 1$  and  $X = 0$ ), and, correspondingly, the area above the main diagonal in a fuzzy XY plot should also be empty in order to determine necessity.

Mirrored scores for the consistency of necessity (*inclN*, how much of Y is included in X), as well as for the coverage of necessity (*covN*, how much of X is covered by Y) can be calculated, as shown in Equations (10) and (11):

$$inclN_{X \Leftarrow Y} = \frac{\sum \min(X, Y)}{\sum Y} \quad (10)$$

$$covN_{X \Leftarrow Y} = \frac{\sum \min(X, Y)}{\sum X} \quad (11)$$

When analyzing necessity, the most important thing is to determine how relevant a necessary condition is. Oxygen is a necessary condition for a fire, but it is an irrelevant necessary condition as oxygen can be found everywhere, and in most situations where oxygen is present, a fire is not observed. A more important necessary condition would be heat, and another necessary condition may be a spark. Both of these are truly necessary (hence relevant) to start a fire.

The relevance of a necessary condition is revealed by the coverage score. If the outcome Y covers only a very small area of the

**Figure 57.7** X as a trivial necessary condition for Y

causal condition, it is a sign that X might be irrelevant.

Goertz (2006a) is a leading scholar in the analysis of necessity, further differentiating between irrelevant and trivial necessary conditions. Irrelevance and triviality are somewhat similar, and they are frequently used as synonyms, but there is a subtle difference between them. Triviality is a maximum of irrelevance, to the point that not only the subset outcome Y covers a very small area of the causal condition X, but the superset condition X becomes so large that it fills the entire universe. When trivial, the causal condition is omnipresent, with no empirical evidence of its absence.

In the previous example, oxygen is an irrelevant, but not exactly a trivial, necessary condition for a fire, as there are many (in fact, most) places in the Universe where oxygen is absent. In the Euler/Venn diagram from Figure 56.7, Y is completely consistent with X but it covers a very small area. Moreover, it can be noticed that X occupies the entire universe represented by the rectangle: it is an omnipresent necessary condition.

The same line of reasoning can be applied on the XY plot from the right side, where the focus on necessity is the area below the main diagonal, and X is trivial since all of its points are

located on the extreme right where X is always equal to 1, and most of the points are located in the lower half of the plot where Y is more or less absent (below the crossover 0.5 point).

A condition becomes less and less trivial (hence more and more relevant) when the points move away from the extreme right, where X is always equal to 1, towards the main diagonal. Goertz proposed a measure of triviality by simply measuring the distance between the fuzzy values and 1. Later, Schneider and Wagemann (2012) advanced Goertz’s work and proposed a measure called Relevance of Necessity (*RoN*), that is the current standard to complement the coverage score for necessity:

$$RoN = \frac{\sum (1 - X)}{\sum (1 - \min(X, Y))} \quad (12)$$

The XY plots and Venn/Euler diagrams have a couple of more interesting properties to discuss. If points are located all over the plot, there is no clear relationship between the cause and the outcome. We expect the points to be positioned either above the main diagonal (for sufficiency) or below (for necessity). If that happens, it means that if a cause is perfectly sufficient, it is usually not necessary

and, conversely, if it is perfectly necessary, it is usually not sufficient.

Ideally, we would like to find a causal condition that is both necessary and sufficient for an outcome, thus having the greatest explanatory power. At a first sight, that would seem impossible since a causal set  $X$  cannot be a subset and a superset of the outcome  $Y$  at the same time. It may in fact happen when the two sets coincide: the subset  $X$  covers 100% of the set  $Y$ .

In terms of  $XY$  plots, the points are located neither above nor below the main diagonal. When the two sets coincide, the points are located exactly along the main diagonal, which would also correspond to a (close to) perfect correlation in the statistical tradition, similar to the left plot from Figure 57.4.

However, such a perfect correlation is difficult to obtain in practice, and it would usually mean we are not dealing with two different concepts (for the cause and for the effect) but with one and the same concept under two different measurements. No causal set is perfectly correlated with the outcome, and, perhaps more importantly, a single causal set is neither necessary nor sufficient by itself. It is very rare to obtain an explanatory model with a single causal condition, a typical outcome being produced by various combinations of causes.

Causal factors combine in conjunction, which in set theory is set intersections. Where a single cause might not be (sufficiently) included into an outcome set, an intersection with other condition(s) might be small enough to fit.

The same thing happens for necessity, but in reverse. If a single causal condition is not big enough to qualify as a necessary superset of the outcome, disjunctions (set unions) of two or more causal conditions might eventually form a big enough superset to cover the outcome. However, if conjunctions are easy to interpret (the simultaneous presence of two causal sets), disjunctions need to have theoretically valid interpretations, much like the quantitative researchers having to find a meaningful interpretation for the latent constructs resulted from the principal component analysis.

More recent and interesting developments in the analysis of necessity include the Necessary Condition Analysis (NCA) by Dul (2016), while on sufficiency, Schneider and Rohlfing (2016) bring important insights in the cutting edge, so called Set Theoretic Multi-Method Research (STMMR) which is an entire topic on its own and deserves a separate and more extended presentation.

## SET THEORY AND THE QUALITATIVE COMPARATIVE ANALYSIS

Having presented the background of set theory, the stage is set to introduce a (third) way to tackle research problems traditionally approached through the qualitative and quantitative methods.

The trouble with quantitative research is that it needs many cases (a large  $N$ ) to make the Central Limit Theorem work, and a typical political science research compares only a handful of countries or events and does not have that many cases. There are only 28 countries in the EU, and a comparative study on the eastern European countries will have even less cases. When studying very rare events such as revolutions, Skocpol (1979) had only three cases to work upon: France, Russia, and China.

It is difficult to argue that there is an underlying, potentially infinite population of 'possible' such events to draw large samples from, in order to justify the use of the quantitative analysis, even with Monte Carlo simulations for small samples. On the other side, the qualitative analysis is very much case oriented and produces perfect explanations for all individual cases. This is often useful for theory formation, but it is usually regarded as too specific to have generalizable value.

With both sides having strong arguments to defend one method or another in different situations, Ragin (1987) employed set theory and Boolean algebra to import a methodology created for electrical engineering (Quine, 1955; McCluskey, 1956) into the social and political sciences. He showed how, through a systematic

**Table 57.5 Boolean minimization example**

A	B	Y
1	1	1
1	0	1
1	-	1

comparative analysis of all possible pairs of cases, the relevant causal factors can be identified and the irrelevant ones eliminated. More importantly, he showed how to identify the patterns, or the combinations of causal conditions, that are sufficient to produce an outcome.

The essence of the entire procedure can be reduced to a process called Boolean minimization, which was itself imported into the electrical engineering from the canons of logical induction formulated by J.S. Mill (1843).

The two expressions in Table 57.5 are equivalent to  $AB + A\sim B$ , which can be simplified to A alone since the condition B is redundant, present in the first, and absent in the second:  $A(B + \sim B) = A$ . In such an example, B is said to be ‘minimized’ (or eliminated), hence the name of the Boolean minimization procedure.

Each case that is added to the analysis displays a certain combination (of presence or absence) of causal conditions, and the algorithm exhaustively compares all possible pairs cases to first identify if they differ by only one literal, then iteratively and progressively minimize until nothing else can be further simplified. The final product of this procedure is the set of so-called ‘prime implicants’, which are simpler (more parsimonious) but equivalent expressions to the initial, empirically observed cases.

Since pairs of cases are compared, the process is more qualitative than quantitative, therefore the ‘Q’ in QCA stands for the ‘Qualitative’ Comparative Analysis. It has absolutely nothing to do with traditional statistics, yet it employs a systematical and solid mathematical algorithm such as the Boolean minimization to identify the minimal configurations of (relevant) causal conditions which are sufficient to produce an outcome.

Crisp sets are very attractive as they allow one to map the empirically observed configurations over a finite number of combinations of presence/absence for the causal conditions (equal to  $\prod l_c$ , where  $l$  is the number of levels for each causal condition  $c = 1 \dots n$ ). This finite space is called a truth table, and it contains all positive and negative observed configurations, as well as those for which there is no empirical information (called ‘remainders’).

However, it is precisely the ‘Boolean’ nature of the algorithm that attracted a lot of criticism (Goldstone, 1997; Goldthorpe, 1997), since it suggests a very deterministic view of reality (Liebersson, 1991) and, as pointed many times before, most social phenomena are not simply present or absent, but somewhere in between.

The debate led to an upgrade of QCA from Boolean to fuzzy sets (Ragin, 2000, 2008). Instead of crisp values, each case has a membership score for each of the causal condition sets. The challenge, that was also solved by Ragin (2004), was to translate fuzzy membership scores to truth table crisp scores, because the minimization process is Boolean.

In the fuzzy version, the truth table configurations act as the corners of a multidimensional vector space where the set membership scores play the role of fuzzy coordinates for the position of each case. Figure 57.8 presents the simplest possible vector space with two dimensions, and a case having two fuzzy membership scores of 0.85 on the horizontal and 0.18 on the vertical. For only two

**Figure 57.8 Bidimensional vector space (left) and the corresponding truth table (right)**

causal conditions, the truth table contains  $2 \cdot 2 = 4$  rows, represented by the corners of the square, and the case is located close to the lower right corner 10 (that is, presence of the first condition and absence of the second).

It is rather clear to which truth table configuration does the case belong to in this example, but it would be more difficult to assess if the case were located close to the middle of the vector space. Ragin's procedure uses the fuzzy coordinates of each case to calculate consistency scores for each of the corners and determines which corners are the cases more consistent with (or closest to).

The consistency score of this case is the set intersection between the first membership score (0.85) and the negation of the second ( $1 - 0.18 = 0.82$ ), which is the fuzzy minimum between 0.85 and 0.82, equal to 0.82. Provided there is no fuzzy membership score of exactly 0.5 (the point of maximum ambiguity), there is only one corner to which cases have a higher than 0.5 consistency.

The corners of the vector space can be interpreted as genuine ideal types in the Weberian tradition, which an imperfect fuzzy configuration is most similar to. Upon determining where each case is ideally positioned in the truth table configurations, the algorithm proceeds with the same Boolean minimization procedure as in the crisp version in order to identify minimally sufficient configurations that are related to the presence (or absence) of an outcome.

It is beyond the purpose of this chapter to offer a complete presentation of the QCA procedure with all its details. There are entire books written for this purpose (Ragin, 2000, 2008; Rihoux and Ragin, 2009; Schneider and Wagemann, 2012; Duşa, 2019), and the interested reader is invited to consult the relevant literature. The main purpose was to reveal how the language of sets and the Boolean algebra can be employed for social and political research.

To conclude, set theoretic methods are rather young compared with the long-established quantitative tradition, but they

already compensate through a sound and precise mathematical procedure that uses set relations (subsets and supersets) to identify multiple conjunctural causation, where the outcome can be produced via several (sufficient) combinations of causal conditions.

Different to the strict statistical assumptions in the quantitative analysis, the causal conditions in QCA are not assumed to be independent of each other. What matters is how they conjunctively combine to form sufficient subsets of the outcome, and their relevance in terms of both coverage of the outcome and how well they explain the empirically observed configurations.

# Mixed-Methods Designs

Imke Harbers and Matthew C. Ingram

## INTRODUCTION

Mixed-methods (MM) research designs are those that combine more than one methodological approach within the same study. MM designs are also commonly called multimethod (Seawright, 2016), hybrid (Palinkas et al., 2015; Schoonenboom and Johnson, 2017), or simply mixed designs (Johnson et al., 2007: 118). MM research has exploded in popularity and prestige since the mid-1990s. This explosion was driven in part by methodological debates in the social and behavioral sciences. Initially, these debates focused on the relative merit of different methodological traditions (e.g., quantitative versus qualitative), but a productive debate eventually emerged about the complementary and synergistic strengths of different traditions, and therefore on the value of leveraging different approaches in MM designs. Thus, the appeal of MM to researchers, funding bodies, and publishers is rooted in the belief that combining methods adds value by

enhancing the validity of conclusions in ways that would be impossible using any one method in isolation. The basic intuition is that studying complex social processes requires researchers to be prepared to use diverse elements from the full breadth of the methodological toolbox of the social sciences. From a practical perspective, MM designs also tend to provide realistic, pragmatic, and feasible approaches even for some of the most compelling and probing research questions, making MM designs attractive to a wide range of researchers, including graduate students and junior scholars.

In this chapter, we proceed as follows. First, we clarify what we understand as mixed-methods research (MMR). We focus on designs that combine quantitative and qualitative methods, though we recognize that it is possible to combine a wide variety of methods. Second, we document the rise in (and still rising) popularity of MMR. Third, we disaggregate different types of MMR designs. We do so by differentiating types of

research designs according to (1) the manner in which methods are combined, or the degree of integration, (2) the sequence in which they are combined, and (3) the analytic motivations for such combinations. We also discuss some of the challenges inherent in MMR and identify innovations and future directions for overcoming them.

## WHAT IS MIXED-METHODS RESEARCH?

There is a lively debate about what does and does not constitute MMR. The popularity of the term, and its appeal to a broad range of audiences, has contributed to a situation where many seek to claim the label. We take as our starting point the broad definition offered by the founding editors of the *Journal of Mixed Methods Research*, who define MMR as ‘research in which the investigator collects and analyzes data, integrates the findings, and draws inferences using both qualitative and quantitative approaches or methods in a single study or a program of inquiry’ (Tashakkori and Creswell, 2007: 4).<sup>1</sup> Such research stands in contrast to ‘mono-method’ or ‘purist’ designs that rely on a single methodological approach (Johnson and Onwuegbuzie, 2004). While MMR potentially spans the full epistemological spectrum from positivism to interpretivism, our emphasis throughout this chapter is on the more positivist expressions of MMR. That is, we focus on designs where the analytic goal is inference, either causal or descriptive, and where the purpose of the design is to ensure that methods are employed in a way that is rigorous, systematic, and replicable (see also Gerring, 2017: xxi). Following Brady and Collier (2004: 291), we use the term ‘inference’ here to mean ‘the process of using data to draw broader conclusions about concepts and hypotheses that are the focus of research’. Especially relevant to MMR is Brady and Collier’s notion

of ‘nested inference’, where researchers seek to explain social phenomena by drawing ‘on both data-set observations and causal-process observations, sometimes at different levels of analysis’ (Brady and Collier, 2004: 298). This is the kind of research that has been most visible in mainstream political science journals. Moreover, by limiting ourselves to studies where the goal is inference, we are able to circumvent debates about the compatibility of qualitative and quantitative research on ontological and epistemological grounds (see Howe, 1988, on this debate). Our point of departure is that quantitative and qualitative methods can be combined fruitfully, and that doing so offers researchers additional opportunities for answering their respective research questions. While our definition of MMR is broad, it is worth pointing out what it does not cover. Research designs that combine two different quantitative methods, or two different qualitative methods, are not considered instances of MMR under our definition, even though these are also sometimes labeled as such in the literature.<sup>2</sup>

At its best, MM designs allow researchers to ‘draw from the strengths and minimize the weaknesses’ of different methods in a single study (Johnson and Onwuegbuzie, 2004: 14–15). The relationship between quantitative and qualitative methods is then one of ‘mutual illumination’ (Sammons, 2010: 699–700). This speaks to two methodological commitments that are sometimes seen as the defining core of the broad tent that is MMR. The first is a high degree of methodological eclecticism, where researchers ‘are constantly looking for other methods to explore a research problem or answer a research question through a synergistic process’ (Teddlie and Tashakkori, 2010: 16). The underlying motivation is the belief that through the successful integration of methods, the whole becomes greater than the sum of its parts.<sup>3</sup> The second principle is the subscription to an ‘iterative, cyclical approach to research’ (Teddlie and Tashakkori, 2010:

17; also, Yom, 2015). Conceptualizing the research process as an iterative cycle allows MM researchers to alternate between inductive and deductive phases, and between exploratory and confirmatory phases, during the course of a research project. Rather than thinking about inquiry as a process with discrete starting and ending points, the iterative understanding is motivated by the belief that each phase should inform the next, and that there is not a single, unique point of departure for investigations, but rather there are multiple possible points of departure.

That said, it is worth noting that even the most enthusiastic proponents of MMR will readily accept that MMR is not a silver bullet for every research problem. From an analytic perspective, the integration of methods offers opportunities, but it also creates challenges that do not arise in monomethod work (Rohlfing and Starke 2013). For instance, Rohlfing (2008) examines MMR designs where cases are selected for in-depth study on the basis of a quantitative model and notes that if the statistical model in the quantitative stage is misspecified, then the contribution of the qualitative phase is unclear because the basis for case selection was flawed. Rather than each phase of the research cycle guiding and improving the next one, problems that arise in one phase may then carry forward and undercut subsequent phases. In such cases, subsequent phases add little value to the understanding of the phenomenon under study, and researchers may draw incorrect inferences. We return to some of the challenges inherent in MMR below.

While MMR researchers share a commitment to methodological eclecticism, it is important not to equate this with an ‘anything goes’ attitude. There is a lively debate among MMR scholars about methodology that acknowledges not only the analytic benefits of MMR but also potential pitfalls. As with monomethod designs, the value of MMR depends on the quality of execution. All else being equal, a strong monomethod study is better than a weak multimethod one.

That said, if both designs are strong and well-executed, then MM scholars would argue that the findings of the multimethod one are likely to be more informative and valid, since they are able to incorporate a broader range of evidence. They may also be able to speak to a broader audience if they succeed in engaging quantitative as well as qualitative scholars. Overall, our purpose in this chapter is not to argue that MMR is always better, but to provide an overview of the menu of options that exists for researchers interested in pursuing MMR and to highlight some of the choices researchers will have to make. Throughout, we aim to provide citations to the different strands of methodological scholarship we discuss to facilitate further reading.

## THE RISE OF MIXED-METHODS RESEARCH

MMR has exploded in popularity and prestige since the mid-1990s, driven in part by broader methodological debates in the social and behavioral sciences. Initially, these debates focused on the relative merit of the quantitative and qualitative traditions. For instance, a major driver in the social sciences was *Designing Social Inquiry* (King et al., 1994) – advocating that quantitative and qualitative designs share a single logic of inference – and the responses to it, including a prominent set of review articles (and a rejoinder) in the *American Political Science Review* (Caporaso, 1995; Collier, 1995; King et al., 1995; Laitin, 1995; Rogowski, 1995; Tarrow, 1995), a response that culminated with *Rethinking Social Inquiry* (Brady and Collier, 2004/2010) – advocating for different logics of inference for quantitative and qualitative research, though with rigorous standards in either approach for reaching those inferences. Beyond this quantitative/qualitative divide in the social sciences, a productive debate eventually focused on the complementary nature of different traditions,

and therefore on the value of leveraging the strengths of different approaches in MMR. Social and behavioral scientists advanced full, book-length treatments on mixing methods. Major efforts in this regard include textbooks by Tashakkori and Teddlie (2003, 2010) and Creswell and Plano Clark (2007, 2011). Both of these volumes are intended for audiences from across the social and behavioral sciences. In political science, books by Seawright (2016), Gerring (2017), Goertz (2017), and Weller and Barnes (2014) offer guidance for the design and implementation of MMR, and many other methodological texts incorporate at least a brief discussion of MMR (e.g., Cyr, 2019: 25–32; Neumayer and Plümper, 2017: 73–5). Handbooks focusing on subfields such as comparative policy studies (Biesenbender and Héritier, 2014) and violence studies (Thaler, 2019) now frequently include chapters specifically discussing MM designs and their role in the study of the respective field. Such publications clearly responded to the

demand among political scientists for methodological advice on mixing methods. Indeed, the use of MM designs has continued to increase over time, suggesting they are more than a passing fad and are here to stay.

We can document this rise with citations to individual publications, interest in related topics in online searches, the emergence of new specialized journals, organized communities of scholars, and in awards by major funding sources. Regarding citations, as of January 2019, the handbook by Abbas Tashakkori and Charles Teddlie (2003, 2010) had more than 11,000 citations, and together with two additional books by these authors on the topic (1998, and Teddlie and Tashakkori 2009) combined more than 22,000 citations.<sup>4</sup> A single book by Creswell and Plano Clark (2007/2011) tallied more than 25,000 citations – that is, this book alone (both the 1st and 2nd editions) is being cited more than 2,000 times a year over a span of more than 10 years. A single article that is prominent

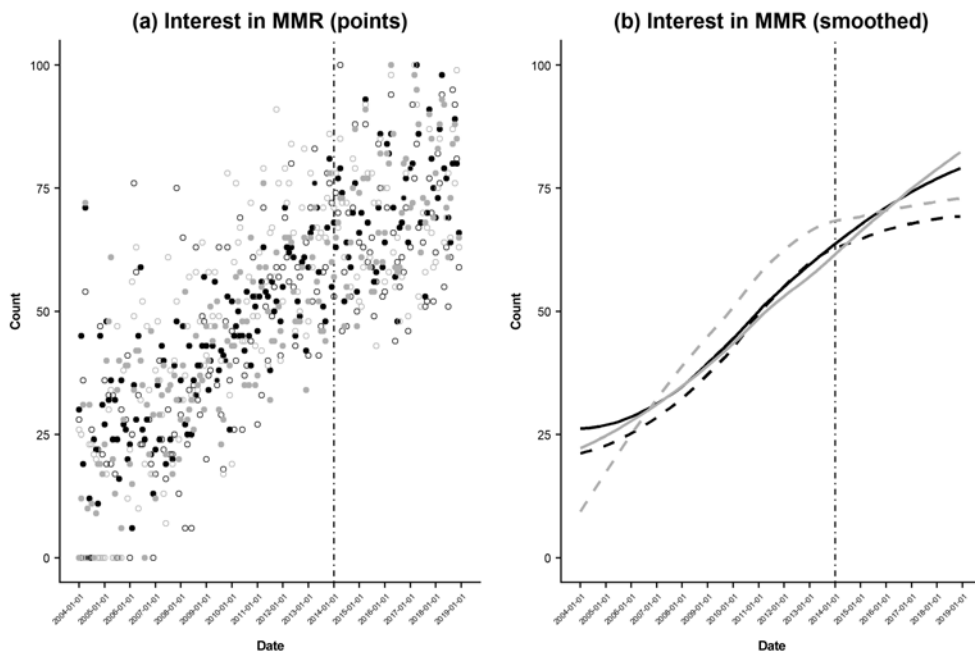

Figure 58.1

among political scientists (Lieberman, 2005), had more than 1,100 citations.

Interest in related topics in online searches also demonstrates the rise in MMR. Relying on Google Trends data (2019), we searched for two related terms: ‘mixed methods’ and ‘multimethodology’. Figure 58.1 shows the results of this search. In the monthly data from January 2004 to December 2018, each point represents the number of online searches for each term.

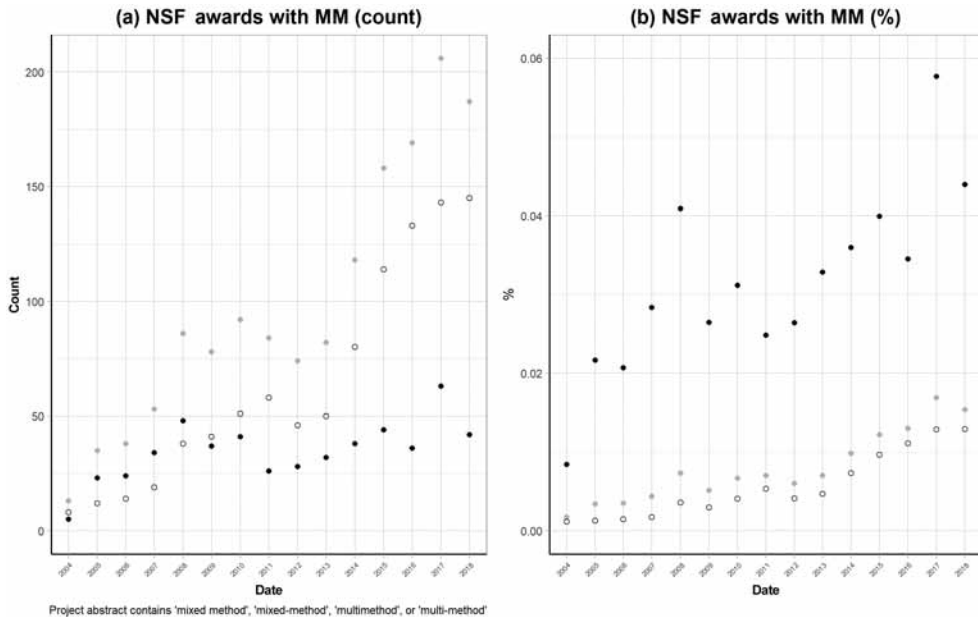

Panel (a) shows the raw data points, with filled circles representing worldwide data and empty circles representing the United States. Panel (b) shows smoothed trend lines: solid lines represent worldwide data and dashed lines represent the United States. In both panels, black represents the term ‘mixed methods’ and grey represents the term ‘multimethodology’; dates are on the x-axis and the number of searches is on the y-axis. Google Trends normalizes the variable on the y-axis so that 100 represents the maximum value in the time span examined for each search. The dashed vertical line in both panels represents January 2014.

Two major patterns emerge from Figure 58.1. First, interest in MMR has been increasing steadily over the last 15 years. This is evident in the upward, left-to-right sweep of the cloud of points in panel (a) and the trend lines in panel (b). Further, focusing on the vertical dashed line that marks January 2014 and looking at the upper-right corner of panel (a), all of the maximum values for each of the four measures appear in 2014 or later, that is, within the last few years. Second, interest in MMR appears to have risen faster in the United States and slowed in the last few years, starting around 2013–14, as shown by the flattening of the two dashed trend lines near the vertical dashed line. In contrast, interest in MMR worldwide keeps climbing; the solid trend lines retain a fairly steep slope, especially the gray one representing ‘multimethodology’.

Beyond individual publications or general interest, several journals now focus on,

or foreground, MMR (Creswell 2010: 61), including the *Journal of Mixed Methods Research* (JMMR). JMMR, founded in 2007, has had an impact factor of around 2.00 from 2010–16, and its impact factor rose to 3.27 in 2017 and 3.54 in 2018, with a 5-year impact factor of 3.28 in 2018 (Clarivate Analytics, 2018). This record made JMMR the top-ranked journal in both 2017 and 2018 among around 100 journals (98 in 2017 and 104 in 2018) in the category ‘Social Science – Interdisciplinary (SSCI)’. In the field of political science, the rising interest in MMR lead to the creation of a new section on ‘Qualitative and Multi-Method Research’ within the American Political Science Association. The section newsletter, which has been published since 2003, provides a platform for section members to showcase and discuss developments in MMR, and it enjoys a wide readership. In sum, both the number of outlets and the prominence of these outlets in their respective areas support concluding that both the popularity and prestige of MMR are increasing.

Lastly, data from the US National Science Foundation (NSF) strongly indicate that funding interest in MMR has been increasing over time. Specifically, Figure 58.2 reports data based on a search of 180,639 proposals that were funded by the NSF between 2004 and 2018. This time span is the same as the one for data from Google Trends above, facilitating a comparison of trends across Figure 58.1 and Figure 58.2. In the NSF data, we searched the abstract narrative of each award for key terms that showed the project included a mixed methods component. Specifically, we searched for any one of four terms (‘mixed methods’, ‘mixed-methods’, ‘multimethod’, or ‘multi-method’). Based on these criteria, we identified 1,479 projects that included a mixed methods component. We also distinguished projects in the social sciences from other programs. We did so by searching for the term ‘social’ in the ‘organization’ field of the data, which is the field that identifies the main NSF

**Figure 58.2**

unit in charge of reviewing and funding the proposal. For instance, this process identified all awards issued by the Directorate for Social, Behavioral, and Economic Sciences (SBE). Thus, we were able to classify MMR research across social and other sciences. Out of the 180,639 projects, 16,284 (9%) were in the social sciences. In Figure 58.2, panel (a) graphs the total count of projects by year within each disciplinary category, and panel (b) graphs the percentage of MMR projects within each disciplinary category. In both panels, gray dots identify projects across all disciplines, filled black dots identify projects in social sciences, and hollow black circles identify projects in disciplines other than social sciences.

Panel (a) shows that overall, the number of awards for MM projects in disciplines other than social sciences has been steadily trending upwards, and, since 2014–15, it has been two or three times as high as the number for the social sciences. However, prior to 2009, the number of awards for MMR projects in the social sciences was higher than

the number for MMR projects in other disciplines (except for 2004). This is somewhat striking because awards in the social sciences constitute only about 9% of all awards (see the earlier discussion of NSF data), so the number of awards in SBE relative to all other awards is proportionately small. Thus, the pattern in panel (a) is strong evidence that MMR designs were well-regarded in the social sciences before they began to grow in popularity in other disciplines.

This conclusion is supported by panel (b), which shows that the proportion of all awards that include an MMR component – a metric that is comparable across disciplines – is much higher for the social sciences than for other sciences. Specifically, the black filled dots show that about 2% to 4% of all NSF awards in the social sciences included an MM component from 2005 to 2016, and this increased to above 4% in the last two years of data (2017 and 2018). In contrast, the percentage in other disciplines was below 1% through 2015; the proportion of MMR projects in other disciplines has been rising,

but it has never risen above 1.5%. To sum up, MMR projects are increasingly successful in obtaining highly competitive NSF funding, and NSF awards in the social sciences are two to three times more likely to include an MM component than awards in other disciplines.

## TYPES OF MIXED-METHODS DESIGNS

MMR, as outlined above, is a broad church. In light of the range of designs labeled as MMR, it is helpful to highlight the nature of methodological choices different types of designs involve. There has been a lively debate about possible ways to classify MMR designs, and a number of scholars have offered typologies (Biesenbender and Héritier, 2014; Morse, 2010; Teddlie and Tashakkori, 2009). Gerring (2017: chapter 7) distinguished different types of MM designs based on whether the quantitative phase precedes the qualitative phase or vice versa. He also offers a range of research examples for each type (also Seawright and Gerring 2008). Even though the debate about various ways to classify MM designs and the respective advantages and drawbacks of different designs has been fruitful, the utility of such efforts for applied researchers and for teaching remains limited. Given the diversity of MM designs, it is impossible to provide a comprehensive and exhaustive menu of options from which researchers may simply select the appropriate one for their research problem based on a pre-defined set of criteria. Instead, ‘researchers using mixed methods are encouraged to continuously reexamine the results from one strand of the study compared to the results from another and to make changes both in the design and data collection procedures accordingly’ (Teddlie and Tashakkori, 2010: 23).

While proponents of MMR stress this ‘inclusive, pluralistic, and complementary’ approach to method selection as its core

selling point (Johnson and Onwuegbuzie, 2004: 17), it is also somewhat unsatisfying to researchers seeking to implement MM in their own work. If there is no authoritative overview of designs from which the right one may be selected, how are researchers supposed to know where to start? Rather than proposing an additional typology of MM designs, or discussing previous efforts to classify MM designs, we aim to highlight the nature of key methodological choices and the analytic tradeoffs involved in these choices. In this section, we identify three of the key dimensions along which MM designs can vary. These are: (1) the manner in which the methods are combined, that is, the degree of integration; (2) the sequence in which they are combined; and (3) the analytic motivations for such combinations.

First, by degree of integration, or the *manner* in which quantitative and qualitative methods are combined, we refer to the extent to which one method is embedded within the other, that is, the extent to which each method is analyzing the same data or information. At one extreme, there might be no integration at all. Following Domínguez and Hollstein (2014), we refer to these designs as ‘parallel’. Parallel designs execute each individual method separately and could even examine separate data or samples of data. The basic idea of parallel designs is to check whether different methods yield the same substantive conclusions, that is, whether they corroborate each other. If the results from a quantitative analysis are in line with those of a qualitative study of the same relationship or vice versa, then researchers can be more confident in their results.<sup>5</sup> At the other extreme, the combined methods might be highly integrated. Integrated designs – also called nested (Lieberman, 2005) or embedded (Hollstein, 2014) designs – ensure that each method is examining observations from the same sample of data, or that one method examines a subset of observations from the sample examined by the other method (Seawright, 2016).

Second, the *sequence* of methods refers to the temporal ordering of the methods. Some authors advocate starting with a qualitative study and then complementing that study with a quantitative one (Rohlfing, 2008), and others advocate reversing that sequence of methods (Lieberman, 2005). Note that the issue of sequencing is particularly relevant to integrated designs, where the quantitative and qualitative phase are supposed to build on each other. Sequence is less important for parallel designs. Parallel designs, where quantitative and qualitative phases are conducted independently of one another, are therefore also called ‘concurrent’ or ‘simultaneous’ designs (Morse, 1991; Teddlie and Tashakkori, 2010: 11). Within political science, the sequence from quantitative to qualitative has been particularly prominent, and there is a broad literature on how diagnostics from regression models can be leveraged for case selection. Indeed, a recent special issue on case selection emphasized that quantitative tools ‘should be enlisted, wherever possible, as the procedure is transparent and replicable, it limits opportunities for cherry-picking, and it enhances claims for representativeness’ (Elman et al., 2016: 383). Arguably, however, regression-based case selection is only possible where the state-of-the-art in the field allows researchers to build a robust model. Where less is known about the phenomenon, or where data availability restricts opportunities for quantitative analysis, it may be better to start with a case study. Ultimately, given the emphasis MMR places on an iterative conceptualization of the research cycle, the discussion about sequence should be seen in the context of a broader commitment to going back and forth between quantitative and qualitative phases. The exact starting point is therefore somewhat arbitrary and depends on previous knowledge – conceptual, theoretical, and empirical – and data availability.

The third dimension along which MM designs may vary are the *analytic motivations* of the project as a whole, and of mixing

methods in particular. As outlined above, we restrict the discussion in this chapter to projects where the overarching goal is inference. This includes descriptive inference, which ‘employs data to reach conclusions about what happened’, and causal inference, which ‘employs data to reach conclusions about why it happened’ (Brady and Collier 2004: 291). Under the broad label of inference, scholars pursue a broad range of analytic goals. The most obvious distinction might be the one between theory-testing and theory-building (George and Bennett, 2005; Lieberman, 2005). Equally important, however, and prominent among MM researchers, are concerns about concept formation and measurement (Adcock and Collier, 2001; Ahram, 2013). Moreover, MM designs are increasingly leveraged for policy evaluation (Bamberger et al., 2010).

The pre-eminent example of an MM design in political science is the nested design as introduced by Lieberman (2005). Nested designs combine quantitative and qualitative methods for the purpose of inference. The manner in which qualitative and quantitative methods are combined is integrated, and the design sequences the methods from quantitative to qualitative. In nested analysis, the combination of methods is highly systematic, explicitly conducting diagnostics on the quantitative phase of analysis in order to integrate the cases analyzed qualitatively within the same sample of observations that was examined quantitatively. The analytic motivation for this kind of design can be either theory-testing or theory-building. In nested analysis, the MM component is explicit, and the methods section of the eventual article or book would outline how the case selection was informed by the initial quantitative phase and post-estimation diagnostics.

Yet, the MM component of a broader research project may also be more implicit. Jensenius (2014) offers an insightful discussion about the fieldwork of quantitative data collection. While the goal of spending time

in the field is to collect data that will be analyzed with quantitative techniques, the quantitative phase of the research is then informed and refined by case knowledge. Qualitative techniques like (informal) interviews and participant observation may be indispensable to appreciate how large datasets were collected, and to evaluate data quality. Especially for data originally collected by public or private institutions, rather than professional survey organizations, understanding the origins of the data can be crucial to know how to spot irregularities, and to appreciate which inferences are and are not possible on the basis of the data. We believe that such ‘implicit’ MMR, where the eventual article or book only reports the results of the quantitative phase without discussing how the qualitative techniques contributed to the development of this analysis, are prominent across the social sciences. Note that the reverse sequence (i.e., from quantitative to qualitative) is probably also prominent. Researchers building their statistical model are encouraged not only to examine the overall model-fit, but also to examine outliers. Puzzling patterns of outliers may lead researchers to take a closer look at these cases, and to uncover what might be missing from the model. While such ‘lightweight case studies’ might not rise to the level of extensive, in-depth analysis that many associate with case study research, we would still argue that this constitutes an instance of MMR, even though this may remain implicit in the eventual presentation of results.

We illustrate the dimensions of MMR based on two examples of empirical research in political science: one book and one article. Both come from scholarship on violence in Latin America.

In her book on displacement in civil wars, Steele (2017) leverages subnational variation in patterns of displacement in Colombia. To understand when and where armed groups engage in ‘political cleansing’, that is, the strategic targeting of certain civilian groups for displacement by armed actors, she first

conducted in-depth fieldwork in a region affected by the violence. An initial round of archival research allowed her to link electoral results with locations of violence and thus to connect partisan preferences and patterns of displacement. The integration of different types of data from local archives constituted the basis for a test of the argument that armed groups target civilians when they are trying to conquer territory and have reason to believe that the local population supports a rival group. To test the argument beyond the region where it was developed, Steele then collected quantitative data on election results and displacement in other parts of the country. In terms of our dimensions, this constitutes an instance of an integrated design, where different phases of the research build on each other. The sequence is from qualitative to quantitative, though this is also an excellent example of the iterative nature of MMR. Quantitative data on key variables of interest informed case selection during the initial phase of the project, and insights gleaned there then informed further quantitative analysis. The analytic goal of the project was to explain patterns of displacement.

An article by Trejo and Ley (2018) on the origins of large-scale criminal violence in Mexico offers an illustration of how even an ambitious MMR design can be communicated within the space constraints of a journal article. The authors argue that political alternation in gubernatorial power eroded the informal networks of protection that organized crime groups relied on. To defend their turf, these groups invested in private militias, which they subsequently deployed to expand their territory and to fight rivals. The authors drew on spatial data of cartel murders to map the development of spatial patterns of violence. This reveals that violence is more pronounced in states that experienced alternation in gubernatorial power. To better understand networks of protection, the authors then conducted in-depth interviews with former governors of the states affected by the violence.

They submitted the implications of their argument about the timing and location of violence to quantitative tests and probed the mechanisms with case studies. Their project again provides an illustration of an integrated design, where quantitative and qualitative phases directly speak to each other. The primary sequence in the article is from quantitative to qualitative, but the hypothesized mechanisms are elaborated on the basis of interview data about informal networks. This, again, indicates how researchers may draw on quantitative and qualitative data to build more robust and convincing causal arguments.

### **OVERCOMING CHALLENGES INHERENT IN MMR: INNOVATIONS AND FUTURE DIRECTIONS**

As highlighted above, despite the promises and advantages of MMR, mixing methods also creates challenges for researchers beyond those inherent in monomethod work. In this section, we discuss some of these challenges, as well as ways in which researchers are addressing them methodologically and practically. The challenges we focus on here arise primarily from the increasing sophistication of methods, which place additional burdens on researchers aiming to make use of the full breadth of methodological innovation. The variety of chapters in this *Handbook* illustrates the wealth of methodological literature available to empirical scholars in political science and international relations, and a substantial share of this work is relevant to scholars seeking to conduct high-quality MMR.

New, more advanced, and specialized techniques are continuously emerging in the quantitative and qualitative traditions. In quantitative research, development has moved away from OLS, which has long been the workhorse of statistical analysis, to more complex types of modeling that can

take into consideration different types of dependent data structures (e.g., panel data, networks, spatial data, or complex systems) or that are geared towards causal identification with observational data (Angrist and Pischke, 2009; Dunning, 2012), as well as moving away from frequentist assumptions and towards Bayesian approaches. In qualitative research, new work has been particularly rich in the area of within-case analysis, including Bayesian process tracing (Bennett 2008; Bennett and Checkel, 2015; Fairfield and Charman, 2017; Rohlfing, 2012). There is also a lively debate about transparency in qualitative research, which raises the bar for communicating methodological choices and procedures inherent in qualitative research. The challenge for MM research is to keep up by offering guidance on how to build research designs that integrate the strengths of new (and old) techniques from each tradition.

First, from a practical perspective, given the complexity and sophistication of methodological approaches, individual researchers may find it challenging to be proficient in state-of-the-art approaches from more than one tradition. MMR compounds the challenge of keeping up with relevant methodological developments by asking scholars to stay on top of methods from different traditions. This requires effort and time, which necessarily involves compromises and opportunity costs and, depending on the availability of additional training, may also require funding, travel, and other investments and commitments, as well as integrating into new research communities. There are clear barriers for individual scholars who want to build expertise in quantitative and qualitative methods.

This has prompted researchers to work in teams, and to divide tasks according to methodological expertise. Collaboration can help resolve the challenge of becoming expert in two or more methods. Yet, collaboration also poses its own challenges. A good collaboration requires complementary interests and skills, but it also requires complementary

personal attributes, including mutual respect, balance of effort, communication, and a larger sense of partnership. Costs of collaboration can include ‘heightened transaction costs, shirking by a coauthor, monitoring differing levels of individual commitment and effort, duplication of effort, difficulty in coordinating tasks, and not receiving credit for individual performance’ (McDermott and Hatemi, 2010: 52–3). Moreover, if the collaboration is interdisciplinary, then there might be additional costs, including publishing in outlets valued in one discipline but not another, and the added effort of communicating ideas across different disciplinary vocabularies, norms, and audiences. Undoubtedly, these costs are also distributed unevenly among scholars based on several factors, including career stage, institutional profile, subfield, and global region. In addition, reporting findings and justifying methodological choices from multiple traditions is difficult within the space constraints of a journal article. Researchers may therefore struggle to explain methodological choices sufficiently while also leaving enough space to discuss the substantive importance of their findings. These practical challenges of conducting research and publishing results are generally more pronounced in MMR than in monomethod work.

Beyond such practical challenges, in this section we illustrate some of the methodological issues that arise for MMR from the increasing sophistication of methods. We do this by focusing on dependent data structures. This is a field of quantitative analysis that has expanded considerably, and the substantive importance of dependent data structures for understanding phenomena of interest to the social sciences is widely recognized. The standard regression assumption that units of analysis constitute independent observations that do not interact with each other is often hard to sustain and may even be antithetical to the ‘social’ part of social science research (Darmofal 2015). Yet, especially for integrated designs, ensuring that

dependencies are conceptualized and modeled consistently throughout the quantitative and qualitative phase of the research is often more challenging than it may appear at first glance. Even though qualitative research has long emphasized path dependence and how causal processes unfold over time, as well as issues like cross-unit interactions in processes of diffusion or contagion, integrating insights from both traditions systematically is often challenging.

Panel data, where dependencies may be temporal as well as cross-sectional, are one prominent example of an area where the field has advanced substantially. Case selection strategies based on the diagnostics of a quantitative model (Elman et al., 2016) may then not adequately identify promising cases in which to conduct in-depth analysis. For instance, if one were to follow Lieberman’s nested analysis, it is not clear that identifying a single well-predicted observation for model-testing analysis, or one poorly predicted observation for model-building analysis, makes sense when units are contributing multiple observations over time. Rather, researchers may want to identify the properties of observations over time from different units and select units for in-depth analysis based on the overall pattern or totality of properties (e.g., well-predicted, poorly predicted, influential) exhibited by all observations contributed over time by any one cross-sectional unit. There is limited methodological guidance for MM designs employing panel data during the quantitative analysis. Similar challenges confront MM designs with multi-level or hierarchical data. For illustrations of how researchers attempt to work through these challenges, see Giraudy (2015) and Ingram (2016a).

Furthermore, spatial data and the greater prominence of Geographic Information Systems (GIS) have prompted scholars to explicitly examine spatial dependence (Darmofal 2015). Especially in IR and conflict studies, there is widespread evidence that the processes underpinning phenomena

of interest often have a distinctly spatial component (Gleditsch and Weidmann, 2012). If a spatial process is at work, then selecting and studying one unit without examining its interactions with neighbors is insufficient. Spatial dependence therefore challenges MM researchers to examine their conceptualization of what constitutes a ‘case’. It may well be that, rather than a single unit, the in-depth analysis needs to consider the unit along with its neighbors to better understand the causal process. As we have argued elsewhere (Harbers and Ingram, 2017, Ingram and Harbers, Forthcoming), MMR has tremendous potential to enhance our understanding of spatial processes in political science. Nevertheless, the systematic integration of insights from the quantitative and qualitative phase is challenging, regardless of whether the quantitative phase precedes the qualitative phase or vice versa. For interdisciplinary perspectives and illustrations of how quantitative and qualitative approaches to spatial processes may be combined, see Matthews et al. (2005), Kwan and Ding (2008), Fielding and Cisneros-Puebla (2009), and Yeager and Steiger (2013).

Separately, there are novel approaches in MM network analysis (Domínguez and Hollstein 2014; Ingram 2016b). Given the analytic emphasis on the relational ties among units in network analysis, MM designs in network research include those that investigate how units themselves perceive or attach meaning to those ties. For instance, does the structure of relational ties exert an influence on units regardless of how units perceive those ties? Or, alternately, if a quantitative, structural analysis concludes that relational ties exert some influence, then how can units be selected to investigate the causal channels or mechanisms undergirding that influence? For example, in research examining the spread of legal ideas among a network of judges in Mexico, Ingram (2016c) identifies a network influence in a quantitative phase and then follows up by selecting individual judges based on their centrality in

the network. He conducts personal interviews with these judges to assess what influence or meaning they attribute to their network ties in understanding how these judges came to hold specific legal ideas.

There are also innovative multi-method approaches with Bayesian approaches. Humphreys and Jacobs (2015) provide one prominent and pioneering example. Specifically, they identify a key problem in MM research, namely, that in combining two or more methodological techniques, it is difficult to determine how much weight to attribute to inferences from one approach relative to the weight attributed to inferences from another approach. Their solution is a unified, Bayesian approach that ‘allows qualitative evidence to update the assumptions underlying quantitative analysis, and vice versa’ (Humphreys and Jacobs 2015: 654). They illustrate their approach with two examples from major research areas – origins of electoral systems and the causes of armed conflict. Further, they also provide guidance on how to use their approach to determine the optimal balance between quantitative and qualitative techniques in an MM design by estimating relative benefits expected from: (1) adding more cases (i.e., emphasizing the cross-sectional, correlational logic underlying the quantitative component); or (2) focusing more deeply on one or a small number of cases (i.e., emphasizing the within-case, process-based logic of the qualitative component).

Lastly, there are promising new developments in MM research that employ the growing toolkit of techniques associated with causal identification. For instance, Nielsen (2016) advocates using matching methods – which are increasingly used in quantitative analysis – as a novel tool for case selection in order to design ‘most similar’ systems for subsequent, in-depth qualitative analysis. These types of research designs are not new, but the use of matching software (and its many variations) and other tools to generate these designs is novel.

## CONCLUSION

As noted, MMR means different things to different people. We have clarified what MMR means – both in general and to us specifically, for the purposes of this chapter. We also documented the rise of MMR – including data on citations and interest from general internet audiences and funders. Further, we identified analytic goals that motivate MMR. Perhaps most importantly, we categorized major types of MM approaches according to the key decisions that researchers need to consider: (1) the manner in which methods will be combined (parallel or integrated); (2) the ways in which methods will be sequenced; and (3) the analytic motivations for such combinations. Lastly, we identified challenges researchers are likely to encounter in pursuing MMR, as well as some new, innovative approaches and promising future directions for additional work in this area.

We close by re-iterating two methodological commitments at the core of MMR: methodological eclecticism, and an iterative, cyclical understanding of the research process. As we emphasized earlier, these commitments do not mean that ‘anything goes’. Rather, good MMR research needs to be structured according to how diverse methods will be integrated, in what sequence, and for what analytic purpose. Good MMR is hard to do but, done well, the MMR whole promises insights larger than the sum of its parts.

## Notes

- 1 This is similar to the definition proposed by Johnson et al. (2007: 123): ‘Mixed methods research is the type of research in which a researcher or team of researchers combines elements of qualitative and quantitative research approaches (e.g., use of qualitative and quantitative viewpoints, data collection, analysis, inference techniques) for the broad purposes of breadth and depth of understanding and corroboration’.
- 2 This kind of data triangulation, where all methods employed come from the qualitative methodological tradition (e.g., interviews, archival analysis,

observation), is discussed by Tarrow (1995) and King et al. (1995: 479–80), and the latter express the possibility of a mixed-methods design that is purely qualitative and would meet the standards of inference they espouse. In addition to qualitative and quantitative methods, scholars may also mix methods by including components based on formal (e.g., Chapters 3, 7, 8, this *Handbook*), experimental, or design-based (e.g., Bowers and Leavitt, Chapter 41 and Sinclair, Chapter 52, this *Handbook*), as well as computational or machine-learning, approaches (see Olivella and Shoub, Chapter 56, this *Handbook*). For instance, the Empirical Implications of Theoretical Models (EITM; Chapters 3, 7, 8, this *Handbook*) tradition emphasizes a sequence from formal modeling to quantitative analysis. While we readily acknowledge the analytic value of such combinations, they are beyond the scope of our discussion in this chapter.

- 3 Creswell phrases a similar idea as the ‘sum of quantitative and qualitative is greater than either approach alone’ (Creswell, 2009: 104; citing Hall and Howard, 2008).
- 4 All citation counts are based on a Google Scholar search of these authors and titles on January 11, 2019.
- 5 For a critical discussion of this notion see Seawright (2016: 4–10). He argues that it is unlikely that the quantitative and qualitative study in fact address the same question. Rather, both methods ask and answer slightly different questions, so that reconciling the results of the two studies may be difficult, if not impossible.

# Case Study Methods: Case Selection and Case Analysis

Chiara Ruffa

Case study methods are a group of approaches in political science and international relations that aim at testing and developing theory.<sup>1</sup> The key characteristic of case study methods is their focus on one or few cases but with the ambition to understand and capture broader and more general underlying dynamics. This implies two core inter-related functions: the first is describing an observed phenomenon in all its depth and complexity; the second is attempting to generalize to a broader universe of cases. A research project using case study methods can rarely attempt to do both at the same time and to the same extent: the attempt to go deep usually has to compromise with trying to describe and study several cases in breadth. Either way, case study methods imply a more or less explicit positivist assumption in terms of the objective of research: in different ways case studies aim at generalizing beyond the case or the set of cases at hand and they acknowledge an attempt to identify and describe patterns of behavior. Notwithstanding the positivist

assumption, the spectrum of positions can vary greatly: it ranges from explicit positivist approaches to interpretivist ones, in which the ability to observe causality is somewhat challenged (della Porta, 2008: 32; Vennesson, 2008). Case study methods' opportunities and challenges partly derive from being tools that can be used by scholars with different understandings of causality and different assumptions about what a researcher wants and can ostensibly know about the world.

Case study methods are a very well established set of methods in political science and international relations. In a 2011 TRIP (Teaching, Research and International Policy) survey, most scholars in international relations declared that their main chosen methods were qualitative.<sup>2</sup> As Bennett and Elman (2010: 499) have noted on several occasions, 'qualitative research methods are currently enjoying an almost unprecedented popularity and vitality in both the international relations and comparative politics subfields'. Notwithstanding their persistent popularity

and traction, the relevance of case study methods is being eroded by a growing focus on causal identification and inference in the positivist social sciences.<sup>3</sup> More narrowly, case study methods seem to fall short even towards observational quantitative approaches due to a general tendency to strive for generalization. Notwithstanding these concerns, case study methods still hold strong.

Case study methods scholars have developed a set of sophisticated techniques to make case study research rigorous and maximize the generalizability potential of case studies (Bennett and Elman, 2010). Partly because of this attempt to engage with other approaches, most of the debate on case studies has focused on case-selection techniques for generalizability purposes and has not engaged as much with case study analysis – that is, tools to conduct a case study and interpret the material. Yet, as Seawright and Gerring (2008: 294) argue, ‘case selection and case analysis are intertwined to a much greater extent in case study research than in large-N cross-case analysis’. The necessity to engage with other approaches has led to a somewhat essentialist understanding of case study methods and has over-shadowed the importance of using case-selection techniques in eclectic and creative ways and engaging more systematically with case analysis of complex phenomena. Case study methods should be seen as methods in their own right, with their own potentials and pitfalls. I contend that more attention should be paid to discuss case selection together with case analysis. Case study methods are both art and craft, and, as such, they should combine both command of the method and creative thinking to leverage inferential power through case selection and to gauge complexity through case analysis. In this chapter, I present the most common strategies of case selection and case analysis and outline ways to combine them more creatively for maximizing inferential power while at the same time capturing complexity.

This chapter comes in six parts. I first situate case study methods in the broader

literature on research methods. Second, I discuss case study methods in relation to what a case is and what it is good for; third, I present different logics of case selection; fourth, I discuss single case study approaches and fifth, I discuss comparative designs. Sixth, I reflect on common practices for conducting case studies and finally, I draw some conclusions.

### **BETWEEN A ROCK AND A HARD PLACE: CASE STUDY METHODS BETWEEN POST-POSITIVISM AND LARGE-N APPROACHES**

Despite being so well established, case study methods find themselves between ‘a rock and a hard place’. On the one hand, post-positivist and interpretivist approaches may work well with case studies but have different underlying ontological, epistemological and methodological assumptions. By post-positivism and interpretivism, I refer to a wealth of rather diverse ontologies and epistemologies that challenge the possibility to describe and explain phenomena in terms of causal relations and the impossibility to separate the object of research from the researcher.<sup>4</sup> The very use of the term ‘case study’, as in the ‘study of a case’, may reflect an underlying objective for generalizability, thereby making the term itself not widely used among post-positivists and interpretivists. Some scholars from post-positivist and interpretivist approaches have started to increasingly reflect upon and make use of case study methods, but they are mainly concerned with issues of generality and explicitly question generalizability as a more or less explicit research objective (Salter and Mutlu, 2013).

Among positivist scholarship, case study methods also hold a slightly uncomfortable place. The focus on a small number of cases (small-N) is what makes them distinct from the other, more widespread set of approaches in political science, that is, large-N approaches making use of statistical

techniques or experimental approaches. With the increasing traction of observational quantitative and experimental methods, case study methods are often under-appreciated, and their utility and breadth of application is widely misunderstood and misused. Within the field of political science and international relations, case studies are often used and seen in a subordinate and complementary fashion to quantitative techniques.<sup>5</sup> To its extreme, within the burgeoning literature using ever more advanced quantitative techniques, I witness a worrying and growing use of illustrative examples as substitute for systematic case study evidence.<sup>6</sup> While illustrative examples are useful to give an indication of the direction and quality of causal relation, they cannot substitute full-fledged case study analysis. Embracing and adopting case study methods may indeed not be a strategic choice: at first sight, time constraints and the pressure to publish more and more quickly do not provide great incentives to graduate students to specialize in case study methods, which are, by their nature, very time-consuming and field-work intensive, are narrated at best in book-format outputs and find themselves very constrained in article format. I still remember when I was desperately trying to fit my 25,000-word case narrative into a 13,000-word limit for the journal *Security Studies* – one of the most generous outlets in terms of word count (Ruffa, 2017). At the same time, engaging with quantitative scholars provides great opportunities. For instance, recent debates on qualitative methods have discussed how to make qualitative case studies more transparent, so as to foster dialogue with quantitative scholars through active citations, among others (Barnes and Weller, 2017; Moravcsik, 2010, 2014).

Notwithstanding these considerations, case study methods also provide unique opportunities on their own for understanding, conceptualizing, developing and testing new theories, and they remain a set of widely utilized methods. As Gerring (2009: 65) puts it, the case study approach ‘is disrespected

but nonetheless regularly employed. Indeed, it remains the workhorse of most disciplines and subfields in the social sciences’. Also, case study methods still hold an important place and perform analysis and cover aspects that quantitative techniques are unable to capture. In particular, they are unique at providing nuances in theories and observing phenomena from up-close, so that one does not need to capture and measure proxies. In other words, using case study methods allows for high validity – ‘the degree to which a measure accurately represents the concept that is supposed to measure’ (Kellstedt and Whitten, 2013: 126). Importantly, they still hold a lot of promise that is not being fully exploited or always given full attention.

## WHAT IS A CASE? WHAT IS IT NOT? AND WHAT IS IT FOR?

### *What is a Case?*

In this section, I define what a case is and is not and reflect upon what it is for. A case is usually defined as an instance of a broader phenomenon under study. George and Bennett (2005: 17) define ‘a case as an instance of a class of events’ and explicitly refer to the generalizability of it, since a case study is ‘the detailed examination of an aspect of a historical episode to develop or test historical explanations that may be generalizable to other events’. Levy (2008: 2) more precisely talks about a case as ‘an attempt to understand and interpret a spatially and temporally bounded set of events’. Occasionally used as synonym of observation in the qualitative realm, those two terms actually differ. As Gerring (2009: 20-21) puts it, in contrast to a case, ‘an *observation* is the most basic element of any empirical endeavor’, yet ‘in a case study, however, the case under study always provides more than one observation’. Those observations may be scattered across time and space within the same case.

Case studies focus on phenomena of specific interest, such as revolutions, wars, decisions and military interventions. The key here – albeit often neglected – is the importance of identifying a case at the smallest unit of analysis possible given the chosen theory. A case study allows to observe the theory at play. It is also important to distinguish between the case and the broader population of cases that the theory aspires to be applicable to. For instance, in his seminal work on the Cuban missile crisis, Allison's (1971) 'case' is the Cuban missile crisis. But this specific case could be seen as part of a large population of cases, which depending on the theory's focus could be coercive diplomacy, crisis management or the operational code of political leaders. When I first started to work on military cultures in peacekeeping operations, I was undecided on whether my cases were national troops deployed in peacekeeping missions or rather peacekeeping missions or, even more broadly, international military interventions (Ruffa, 2018). I have only recently realized that what I defined as 'my case' depended on the kind of literature and contribution I was trying to make – this being, for my project, security studies and the peacekeeping literature. My cases ended up being four different national troops deployed in two different missions. Since I made an argument about how military culture influences the ways in which soldiers behave when deployed in peacekeeping missions, it was reasonable to zoom in at the unit level, since each unit deployed to an area of operation and had full responsibility of implementing the UN mandate in that area – which was part of a peacekeeping mission. As such, case studies under analysis can be anything, ranging from countries to well defined time periods. In other words, some self-reflection on what a case is in a particular research project is key in order to clarify the nature of the contribution that is being made. Relatedly, it is important to reflect upon how high or low on the ladder of abstraction one wants to place her/his contribution (Sartori, 1970).

Once one has an idea about the objective of research – be it theory testing, development

or merely descriptive – a research design requires some assumptions that the objective of research is to identify patterns that might lead to generalizable results. This assumption aside, there is still widespread variation within positivist approaches, mainly in terms of the objective of research and in terms of how explicit the research objective is. The very use of the term 'case study' entails an underlying positivist assumption, in that the objective is to generalize and find patterns that are valid beyond the case under study. The logic underlying case study methods does not fundamentally differ from that of large-N studies: both case studies and large-N studies are based on observational data, meaning a non-experimental selection of the cases or observations under study. The core difference, however, between these two types of methods relates to the number of cases or observation under investigation. Case study methods vary between single case studies ( $n=1$ ) up to 12/15 cases, although the issue is still widely debated. Finally, case studies do not necessarily equal qualitative approaches. While in political science and international relations, case study methods usually rely on qualitative strategies of data collection, they can make use of numbers and statistics for measuring some aspects of the key variables in place (Collier, 2011: 824).

### ***What is a Case... Not?***

A case study is not an illustrative example. Also (but not only) in the quantitative literature, there is a growing usage of illustrative examples to suggest the plausibility of the existence of certain causal relations and the plausibility of underlying mechanisms. Illustrative examples are tremendously useful to suggest that some causal relations might be at play in the empirical domain; to complement a significant correlation with empirical examples suggesting the plausibility of the relations and of its underlying mechanism(s) and to guide the early phases of theorizing as

reality checks. While illustrations are increasingly required and used, their scope and purpose remain different from case studies. A recent paper by Haass and Ansorg (2018) is a good example in this respect. The authors argue that in peace operations with high-quality troops, militaries are better able to protect civilians. They further argue that such better protection happens because ‘high-quality militaries are better able to deter violence from state and non-state actors and create buffer zones within conflict areas, can better reach remote locations, and have superior capabilities to monitor the implementation of peace agreements’ (Haass and Ansorg, 2018: 1). While their paper is an important contribution to the peacekeeping literature, their use of an illustrative example on the case of Mali misses the broader picture that one would hopefully likely get in a full-fledged case study.

Despite a mission strength that was significantly lower at the time than that of MINUSCA (...) in a country about twice the size of the CAR, the UN operation successfully stabilized the situation in Mali and monitored the presidential elections in August 2013. MINUSMA was in a much better position to respond to threats against civilians than MINUSCA in part due to the fact that the mission consisted of, inter alia, highly trained troops from the Netherlands, Denmark, Norway and Finland. (Haass and Ansorg, 2018: 1)

The problem with that illustrative example is that it misses some important underlying dynamics happening within the case. Dutch, Norwegian and Finnish troops are unlikely to have contributed actively to all those mechanisms described because they were not even present on the ground, they deployed in very low numbers, and were only intelligence, surveillance and reconnaissance missions tasked to report back up to the Force Commander via the intelligence command structure. While Haas and Ansorg’s theory is sound and quantitatively supported, further qualitative research could potentially try to understand why we may find this result in a mission like Mali, for instance by exploring within case variations or trying to gauge qualitatively whether there was an indirect effect.

Along similar lines, deciding to focus on a full-fledged case study rather than on illustrative examples could be beneficial from the early phases of research. For instance, in a recent article, my coauthors and I argue that an increase in terrorist threats or attacks influence the level of military involvement in politics by either the military pushing its way in politics or being pulled (Bove, Rivera and Ruffa, 2019). We test this quantitatively and conduct three illustrative case studies: Algeria before the descent into the civil war; France in 1996–98 and 2015–16. The project started with the idea of only proposing some illustrative examples but it was only when we decided to turn them into full-fledged case studies and invested time on them that we discovered a second fundamental underlying causal mechanism. We did not only find a pushing effect of the military in politics but also of a pulling effect— which we then decided to further theorize about. If at all possible for time and length constraints, full-fledged case studies are usually preferable as they allow to capture dynamics that may remain invisible at a first cursory view.

### ***What is a Case For?***

A necessary preparatory step in delving into a case has to do with deciding what kind of research object one has in relation to its level of ambition. Different case-selection techniques would then follow depending on the kind of research objective one has. In their classic book, *Case study and theory development in the social sciences*, George and Bennett (2005) distinguish between six different kinds of case studies depending on the kind of research objective one has, which they adapted from the work of Eckstein (1975) and Lijphart (1971). They distinguish between atheoretical/configurative idiographic case studies, disciplined configurative, heuristic/theory development, theory testing, plausibility probes and building-block studies (George and Bennett, 2005: 75). Importantly, in a

single-outcome study, the phenomenon of interest is not seen as an instance of some greater population of cases. A somewhat similar approach is Beach and Pedersens' third form of process tracing and they describe it as a type of process tracing used to explain why a specific outcome occurred in a specific case and this is really the only occasion in which a type of process tracing does not contribute to advance theory (Beach and Pedersen, 2013).<sup>7</sup> While usually discarded, single-outcome studies can be good descriptions of cases that might be used in subsequent studies for theory building but by themselves do not cumulate or contribute directly to theory (George and Bennett, 2005: 75). They have no ambition beyond describing the phenomenon of interest and thereby get closer to historical work. In some instances, single case studies focus on phenomena that are intrinsically important. For instance, historian Isabel Hull (2005) wrote a book on German institutional extremism during the imperial period until 1918. Even though her research is extremely case-specific, she influenced much theory development within the literature on military and strategic cultures in the following years. In other cases, the potential population of cases appears too heterogeneous to allow for any general statements. For instance, Peter Feaver (2011) published a paper in which he examines the decision-making process that led to the surge in Iraq. In the civil-military literature, many argue that civil-military relations in the United States are so particular that they cannot be generalized beyond the case under study. Single-outcome studies are increasingly used in post-positivist approaches, for instance by focusing on the essence of politics or power shifts and changes. Aside from single-outcome studies, all other types of case study aim at either theory testing or theory development at a varying level of ambition. While theory testing has a deductive approach (from theory to empirics), theory development has an inductive spin (from empirics to theory). Disciplined configurative case studies make use of established theories for explaining a

case, while plausibility probes are theory-testing exercises with a lower level of ambition. Parallely, building-block studies are theory-development exercises with a narrower focus. Even when not used explicitly, these are useful for clarifying the objective of research given the constraints one has. Once the objective of research has been clarified, we can then move on to case-selection techniques.

## CASE-SELECTION TECHNIQUES

Case selection is a powerful tool in the hands of the researcher and the first crucial step for producing convincing research designs. Case selection should be 'an integral part of a good research strategy to achieve well-defined objectives of the study' (George and Bennett, 2005: 83). In case studies, the researcher 'is asked to perform a heroic role: to stand for (represent) a population of cases that is often much larger than the case itself' (Seawright and Gerring, 2008: 294). Developing on existing work, I distinguish among three different kinds of case selection: convenience, random and strategic. For the purpose of this discussion, I am not (yet) distinguishing between single case studies and comparative designs. The first kind of case selection entails selecting a case out of convenience. For instance, one selects a case because one knows the language in a particular country or because one is particularly interested in a case for its policy implications. Such a single case study approach might give some ideas about how the theory plausibly plays out in the case at hand, but it has not been strategically chosen to maximize the generalizability potential of the theory to a population of cases. This particular category of cases is problematic in terms of selection bias, as one might not select it based on its relation to a broader universe of cases.

A second strategy is randomly selecting a case or set of cases. While this is a possibility, it is highly discouraged. In fact, 'serious

problems are likely to develop if one chooses a very small sample in a completely random fashion' (Seawright and Gerring, 2008: 295). With two Monte Carlo experiments, Seawright and Gerring (2008) show that selecting cases randomly 'will often produce a sample that is substantially unrepresentative' (Seawright and Gerring, 2008: 295). Given the considerations above, the third strategy might in fact be the best one. The so-called strategic (or purposive) case selection is based on the idea of strategically selecting a case or pair of cases based on its hypothesized characteristics in relation to a broader universe of cases. Following that logic, one selects a case or compares two or more cases, trying to maximize the chances of capturing causal connections that are occurring within the universe of cases and controlling as much as possible for confounders. Selecting cases is a daunting task, and it is important to be pragmatic about it and combine convenience (such as the profound knowledge of a language or culture) with strategic considerations. A tip I always find useful is to start thinking about cases already when one is taking key decisions about theory. We often hold a romantic idea of first deciding on theory and then moving on to research design and case selection. Yet, this is rarely the case: we often circularly refine theories based on cases and decide on cases based on theory.<sup>8</sup> Doing so allows the research to buy time and reflect upon case selection at an early stage and reflect on tradeoffs among selection criteria, feasibility, previous case knowledge and the like. I discuss options of strategic case selection, first focusing only on one case and then, second, conducting comparative designs.

## **SINGLE CASE STUDIES**

Once the research objective has been clarified, it is important to reflect upon the different kinds of case study that are possible and are available, given the available constraints. A

first important distinction is between single case studies and comparative design. As the term suggests, single case studies focus on one single case, exploring the plausibility of a theory or tracing the causal mechanism at play in a particular context. In comparison to designs with more cases, single case studies have higher levels of conceptual validity, allowing us to take into account the complexity of contextual factors. By contrast, they are unable to control for confounders and may suffer from selection bias. Comparative methods (both in their most similar and most different system versions) allow us to control for confounders and have a greater external validity.

In line with the general discussion on case selection, single case studies can be selected by convenience or in strategic ways. In the first scenario, while there might be very good reasons for doing it, such cases may suffer from severe selection bias and their generalizability potential will be diminished. When selected strategically, however, single case studies hold the promise of combining the richness of focusing on one case with the ambition of saying something about the broader population of interest. Indeed, single case studies can be selected on the basis of their relation to theory, or, in quantitative language, on whether they are situated on the regression line or not (Gerring, 2007; Gerring, 2017)

For this reason, I label them 'empowered single case studies', and they are usually distinguished among four different kinds (Gerring, 2007; Gerring, 2017; Levy, 2008). Such distinction is mainly based on whether the values of dependent or independent variables are known or not. The first possibility is to select a so-called extreme case that has extreme or unusual values on the independent or the dependent variables. It is used for hypothesis generating or probing a potential causal connection but not to perform a full-fledged test of the theory. Such a case does not score very high in terms of representativeness because it does not give us any indication of how well the theory holds, since we do not yet know anything about the relationship

between independent and dependent variables. A second option is a deviant case, which is an outlier in comparison to all the cases that follow the theory, because – as the term suggests – it deviates from a cross-case relationship. A deviant case is useful for theory-development purposes or for generating new hypotheses, because it deviates from a cross-case relationship in a theory and might help detect neglected variables. For instance, in our work on NGO–military relations in complex humanitarian emergencies, Vennesson and I noticed that identity alone would not be able to explain variations in NGO–military relations (Ruffa and Vennesson, 2014). A hidden variable was at play, but we did not know what. Therefore, we selected a deviant case from existing theories, where we conducted qualitative empirical work and identified a neglected variable of interest – namely, domestic institutional configurations. A deviant case allowed us to identify a new variable, which was then ripe for further testing. A third option, which is in fact a variation of a deviant case, is an influential case, which displays influential configurations of the independent variable and makes me accept or refute the theory. It is suited for hypothesis testing as it helps me to make some final decisions about my theory. A fourth option is ‘a crucial case, which is most likely or least likely to exhibit a given outcome. It is based on a qualitative assessment of real crucial-ness’ (Gerring, 2007: 247). Crucial cases play an important confirming/confirmatory or disconfirming/disconfirmatory role in hypothesis testing. While they do not tell us much about representativeness, they are useful to get a sense of whether the theory holds even in a hard case (least likely) or does not hold in an easy case (most likely) and therefore whether it deserves further testing either quantitatively or qualitatively: ‘The inferential logic of least likely case design is based on the “Sinatra inference”—if I can make it there I can make it anywhere’ (Levy, 2002: 442), and by contrast, ‘the logic of most likely case design is based on the inverse

Sinatra inference—if I cannot make it there, I cannot make it anywhere’ (Levy, 2002: 442). A fifth option is the so-called pathway case, which is thought to embody a distinct causal path from the independent to the dependent variable. The pathway case is useful to probe a causal mechanism, and therefore a case that is easy to study at length can be particularly useful.<sup>9</sup> The pathway case should embody some typical relation as expected by the theory and is particularly fruitful in mixed-method analysis. Its main characteristic is that it lends itself to exploring causal mechanisms. So it shares from traits with the typical case that entails the selection of a case that mirrors the typical example of a cross-case relationship: the so-called typical or paradigmatic case. Such a case lends itself well for testing theories and how they hold, and they are representative of the broader population almost by definition. Pathway and typical cases partly overlap but a pathway case is not necessarily a typical case. Sometimes one could select a pathway case which is not typical because it is easy or practical to study.

Single case studies have both strengths and weaknesses. Because they allow for much emphasis on the case, they score high on conceptual validity, in the sense that nuanced and complex concepts can be constructed and measured. Relatedly, single case study can be useful for developing new hypotheses because they allow us to explore the causal mechanism and embark on process tracing (Bennett and Elman, 2007). The work by Katzenstein (1996), for instance, with a least-likely case, has produced some of the most influential recent scholarship in international relations. Recent work on a single case, the Democratic Republic of Congo, has changed the way we think about making peace at the local level (Autesserre, 2014).

On the other hand, single case studies also have some disadvantages. The first and main problem is the case-selection bias, that is, selecting a case that is already known to display certain characteristics. For instance, the

qualitative literature on peacekeeping has suffered from this particular problem, by focusing overwhelmingly on cases of failure rather than on cases of success (Howard, 2008; Pouligny, 2005). They are also not particularly suited for identifying scope conditions or necessity. Set aside typical cases, a single case study is unable to tell us whether the phenomenon we are observing is representative for the population of cases. In terms of inferential leverage, 'empowered single case studies' are more powerful than pure single case studies. Single case studies definitely allow for delving into a case study and its richness, which is great and very important. With some minor adjustments, single case studies can have an improved chance of generalizability. As usual with case study research, it is much about trade-offs, and it is difficult to provide a main takeaway. For sure, selecting a case based on convenience is weakened by the selection bias but also by the lack of objectivity. At the same time, a profound knowledge about the case is sometimes necessary to immerse oneself into a project. In practice, we often do both: we strive to follow a systematic case selection as well as deal with practical considerations. For instance, when selecting peace and stability operations to study, I was looking for a traditional UN peacekeeping mission but I also had to select cases of ongoing missions since I could only collect ethnographic evidence about soldiers deployed (Ruffa, 2018). Compounding case selection logics and practical considerations, I opted for the UN mission in Lebanon. Finally, single case studies have in any case a fundamental problem with confounders, and if one is particularly concerned by those, s/he should consider a comparative case study approach, which will be the focus of the next section.

## COMPARATIVE CASE STUDIES

Comparing cases entails two cases being selected and compared to one another. There

are two main known types of comparative designs: the most similar and the most different system design (Lijphart, 1971; Przeworski and Teune, 1970). In a most similar system case comparison, which builds on the logic of Mill's 'method of difference', two cases are selected on the basis of them presenting similar characteristics on most confounding variables, setting aside the independent or the dependent variables of interest (Mill, 1882: 484). In its purest form, such a case entails that through strategic case selection, the researcher manages to control for confounders. Those cases are selected because those variables do not entail much explanatory power. The best-known alternative to this is the most different system case comparison, which entails two cases being selected on the basis of them varying in every possible respect except the independent or dependent variable of interest. A classic example of this is the work by Theda Skocpol (2015). These two designs are mutually exclusive when thinking of one specific case comparison. However, when it comes to more complex designs, they can actually be fruitfully combined. For instance, in my own work, I combined a most similar system design with a most different system design. I conducted, separately, two distinct most similar system designs by comparing the French and Italian units in the UN mission in Lebanon and the French and Italian units in the NATO mission in Afghanistan. But I then compared Lebanon and Afghanistan, which were the most different types of peace and stability operations I could find that they had a similar outcome and independent variable of interest (Ruffa, 2017, 2018). While in that research the most different system design is notably much less developed, it is an attempt to creatively combine those two approaches. The most similar system design within each operation studied allowed me to gauge the plausibility of my theory by controlling for confounders. The most different system allowed to check whether my theory held in two very different context – thereby maximizing external validity. While usually

cases for comparative designs are selected strategically, recent work suggests the use of matching techniques to systematically select a most similar system design (Nielsen, 2016).

When thinking about comparative methods, a useful distinction is among variable-oriented vs. case-oriented designs. I opted for a variable-oriented comparative study, as opposed to a case oriented one. 'Variable-oriented studies mainly aim at establishing generalized relationships between variables, while case-oriented research seeks to understand complex units' (della Porta, 2008: 198). This differs from case-oriented that 'aims at rich descriptions of a few instances of a certain phenomenon' (della Porta, 2008: 198). While both approaches are legitimate, disagreements persist in terms of whether the underlying logics (generalizations vs. account for complexity) differ or are the same. Most research mirrors the tension between case vs. variable-oriented comparison, including my own. To illustrate, the foci of my analysis are rather complex units, which might have lent themselves better to a case-oriented approach. However, I opted for a variable-oriented approach for three reasons. First, notwithstanding the micro-focus, my ambition was to maximize the inferential strategy beyond the cases under study. Second, I decided to talk with the language of variables as a way to navigate through each case and being able to compare them, since I was using concepts and measurements that had never been used before. Third, I aimed to show that a comparative design with a strategic case selection actually ended up close to standard large-N techniques and fundamentally had a comparable inferential leverage. When actually conducting my comparative case study in the mission, I realized early on that the complexity of the issue at hand, the richness of the cases and the comparative logic necessitated a rigorous way of conducting research. Other alternatives to control for confounders are within case comparisons and longitudinal and spatial comparisons. Within case comparisons have the advantage that

most social, cultural and structural factors are probably somewhat similar. A similar logic pertains comparisons of the same unit in different moments of time (longitudinal) or in different space (spatial).

Conducting the comparative methods is a great opportunity to strive for greater generalizability and controlling for confounders while still maintaining some of the typical richness of small-N approaches. Comparative methods are useful both for developing new hypotheses and testing old ones. They also suffer, however, from two weaknesses. The first is that selection bias persists and, if anything, is worsened by the necessity of selecting good cases with certain characteristics to compare. The second is that they also run the risk of missing the independence among cases and of comparing apples and oranges.

Similar to large-N approaches, the comparative method takes competing explanations very seriously. While statistical methods assess rival explanations through statistical control, experimental methods eliminate rival explanations through experimental control and random sample selection of both the control and the treatment group. While experimental methods have the highest inferential power, statistical methods based on observational data have a similar understanding of the 'control' idea to the comparative method. While observational statistical methods assess rival explanations through statistical control, comparative methods do so strategically. Once a case or set of cases has been selected, the case study has to be conducted, which is the focus of the next section.

## **OPTIONS ON HOW TO DO A CASE STUDY: A FEW OPTIONS**

While the literature on case selection has burgeoned, relatively little is known about what to do when one has actually selected his/her case(s). The widespread assumption is that case selection and case analysis are two

distinct phases, but that is almost never true. Case study methods entail much more of a circular back-and-forth between case selection and case analysis than is usually recognized. This section briefly reviews three non-exhaustive strategies for conducting case studies: process tracing, structured focused comparison and congruence theory.<sup>10</sup> While process tracing and congruence do not require more than one case and in fact are particularly suited for in-depth one-case analysis, the method of structured focused comparison – as the term suggests – requires at least two cases. These three types of case study analysis entail specific strategies of data collection, ranging from individual qualitative interviews, observation, archival research, focus groups and document analysis, which fall outside the scope of this chapter (Kapiszewski et al., 2015; Ruffa, 2019). In the remainder of this section, I briefly present each approach and then provide a broad-stroke discussion on the advantages and disadvantages of each approach to case study analysis.

*Process tracing* is one of the most common techniques and entails ‘the systematic examination of diagnostic evidence selected and analyzed in light of research questions and hypotheses posed by the investigator’ (Collier, 2011: 823). Recent studies have introduced a similar method, called causal process observations (CPOs). A CPO systematically ‘highlights the contrast between a) the empirical foundation of qualitative research, and b) the data matrices analyzed by quantitative researchers, which may be called data-set observations (DSOs)’ (Collier, 2011: 823). Collier and others consider CPOs as equivalent to process tracing.<sup>11</sup> Process tracing is used both for descriptive and for explanatory purposes, and it is particularly well suited for within-case analysis (Beach and Pedersen, 2013; Checkel, 2006; George and Bennett, 2005). Since its first systematic and comprehensive treatment in George and Bennett (George and Bennett, 2005), different kinds of process tracing have emerged, mainly clustering around positivist

vs. more interpretivist research approaches (Beach and Pedersen, 2013). As Vennesson (2008: 232) points out ‘now the most common conceptions of process tracing are more standardized than the original formulation, and they emphasize the identification of a causal mechanism that connects independent and dependent variables. The emphasis is on causality, deduction and causal mechanisms’. In this particular, standardized version of process tracing, four empirical tests have been identified, originally formulated by Bennett and Elman (2010), who built on Van Evera (1997). Those four tests help understand how strongly a theory holds. Passing the test is necessary and/or sufficient for accepting the inference. When delving into the empirics and exploring the validity of the hypotheses, those four tests allow us to understand the strength of the hypothesis based on the empirical support found. The idea is that the hypothesis has to pass an increasingly difficult test; the harder the test it passes, the stronger the hypothesis is holding. If a hypothesis passes the straw-in-the-wind test, the hypothesis is relevant but not confirmed. If it fails, the hypothesis is not eliminated but weakened. If a hypothesis passes a hoop test, the relevance of the hypothesis is affirmed but not confirmed. However, if the hypothesis fails the hoop test, it suggests that the hypothesis has to be eliminated. When the hypothesis passes the smoking-gun test, it is confirmed, but if it fails, it is not eliminated but somewhat weakened. The fourth test is doubly decisive: if the hypothesis passes the test, it is confirmed and eliminates the others; if it fails, the hypothesis is eliminated (Collier, 2011).

This standardized idea of process tracing has gained traction in recent decades, which has implied that ‘although the idea of process tracing is often invoked by scholars as they examine qualitative data, too often this tool is neither well understood nor rigorously applied’ (Collier, 2011: 823). Sometimes scholars claim they are using process tracing when they are not. Alternatively, the

process-tracing method has become so technical that it can be hardly applied.

As Vennesson (2008: 232) points out, ‘something has been lost in the most recent formulations of process tracing’. A more pluralistic and less mechanistic understanding of process tracing could help capture more complex political phenomena – that can be linear, circular and interacting – than can hardly pass the four tests presented above. Finally, a particularly important yet somewhat less emphasized aspect is the sequencing aspect on process tracing, which gives close attention to phenomena as they unfold throughout time (Mahoney, 2010). In whatever form, however, tracing a process between two variables still differs from storytelling. As Flyvbjerg (2006: 237–41) suggests, process tracing differs from a pure narrative in three ways: process tracing is focused, structured and aims at providing a narrative explanation of a causal path that leads to a specific outcome. I contend that process tracing is a great framework but that it should be used pragmatically, otherwise there is a risk of missing the bigger picture. Relating to this, it is important that process tracing is not equated with testing causal mechanisms. As Gerring (2010: 1499) wrote, one should avoid ‘a dogmatic interpretation of the mechanistic mission’ – an explanation that is overly concerned with mechanisms.

A second common approach is less formal and entails systematically developing a set of observable implications to understand which kind of empirical referent one would need in order to find support for the theory. One particular version of it applies only to the comparative method, which is about conducting a *structured focused comparison*. Such comparison is structured because the same questions are asked across the cases, and it is focused because only the questions relevant to understanding the plausibility of the theory are asked, therefore focusing only on certain aspects (Flyvbjerg, 2006; George and Bennett, 2005). Such a method entails the ‘use of a well-defined set of theoretical

questions or propositions to structure an empirical inquiry on a particular analytically defined aspect of a set of events across different cases’ (George and Bennett, 2005). Structured focused comparisons are widely used in both research and teaching contexts, since they allow for stringent and rigorous comparison and at the same time provide a good toolkit on how to actually carry out a comparison (Friesendorf, 2018).

A third alternative to this is the method of congruence, which is often considered important to complement process tracing. Outcomes are congruent with the expectations of a particular theory (Blatter and Haverland, 2012). The method of congruence is insufficient when it comes to causal mechanisms and can be complemented with the consistency of observable implications of theory at different stages of the causal mechanism. While less technical than the previous two, congruence in whatever form is a pragmatic way to approach complex fieldwork terrain.

## CONCLUSION

The greater traction of quantitative methods has posed challenges to the role played by case study methods in political sciences and international relations. Even though case studies can be fruitfully used to complement quantitative techniques, they remain a method on their own, which maintains its specificities, advantages and disadvantages. The challenge for the future of case study methods is to strive for greater empirical rigor and greater transparency (Elman et al., 2010). With the current ongoing cross-fertilization unfolding across subfields (Gerring, 2017), further reflections on what case studies are and what they entail are important, as are the calls for more pluralism and pragmatism. This chapter has highlighted the importance of three dimensions to bear in mind in all phases of research, be it the setting up, the case selection or the conducting the case study phase. First, at the cost of

sounding obvious, it is important to clarify and be explicit about the kind of research objective one has and whether one is opting for the best design given the circumstances one is in. Second, within the case study methods, it is important to be well aware of the most important trade-offs and which design to opt for given the constraints. It is also important to be explicit about the inferential leverage that matters, given the time, budget and expertise constraints. But it ultimately boils down to asking what is the most fruitful way to answer one's research question given one's constraints? Third, case study research implies the fruitful combination of the craft and art of research in the social sciences. While it is always important to engage with a broader population of cases and master the techniques available for case selection and case analysis, it is also important to nurture creativity and 'let the case speak to you'. But, it has also to do with using case study methods to answer research questions by not overemphasizing mechanistic technicism of case-selection techniques but rather appreciating the unique opportunities provided by case study methods to answer complex research questions. The research objective should be to strive for greater transparency and maximize the inferential leverage so as to be able to dialogue with other approaches but, ultimately, to answer relevant research questions.

## Notes

- 1 I gratefully acknowledge Annekatri Deglow's excellent comments on this chapter.
- 2 <https://trip.wm.edu>.
- 3 Very crudely, by positivism I refer to a wealth of diverse approaches that have as ultimate objective of research to identify causal relations (by developing or testing theories; by conceptualizing or describing phenomena) and that believe that reality is distinct from the observer/researcher and knowable (even if only to some extent). For a more thorough discussion, see: Della Porta and Keating (2008: 19–39).
- 4 Della Porta and Keating distinguish between positivist, post-positivist, interpretivist and humanistic approaches in terms of ontology and

epistemology (Della Porta and Keating, 2008: 19–39). I also note that positivism and post-positivism lie on a continuum.

- 5 To the point that several scholars label only quantitative research as being 'empirical', notwithstanding the very strong and deep engagement of case study research with the 'empirics'.
- 6 Often quantitative scholars are asked to add illustrative examples when going through the review process. Ideally, the system could allow for more systematic mixed-methods approaches, where quantitatively focused and qualitatively focused could collaborate.
- 7 I thank Annekatri Deglow for pointing this out to me.
- 8 This process is often called 'abduction'.
- 9 For an alternative perspective to causal mechanisms, see process patterns (Friedrichs, 2016)
- 10 Causal process observations (CPOs) are often used but they will be treated here as synonymous to process tracing.
- 11 For an excellent example of CPOs, see Deglow (2018).

# Comparative Analyses of Foreign Policy

Klaus Brummer

## INTRODUCTION

What makes Foreign Policy Analysis (FPA) a distinct sub-field of International Relations (IR) is the deliberate focus on the 'black box state'. Subscribing to a liberal understanding of international politics, scholarship in this tradition ties a country's external behavior back to its decision makers and/or domestic political structures (Snyder et al., [1954] 2002). Thus, on a *conceptual* level, FPA specifies and 'fine-tunes' Kenneth Waltz's (1959) rather general and abstract 'first image' and 'second image' explanations of international politics by offering a more nuanced and detailed understanding as to what exactly it is that drives behavior on the level of individual actors and the state level respectively. The ensuing greater number of levels of analysis as proposed by FPA represents one promising starting point for comparative research in this particular sub-field of IR since comparisons can be made across a broad set of substantive dimensions.

Another difference between FPA and, particularly, systemic IR theories is *empirical* in nature. Contrary to grand IR theories' tendency to focus on great powers, as most prominently showcased by neo-/realism, FPA is much less centered on explaining the behavior of that particular, and numerically rather small, group of states. Rather, FPA scholarship devotes much more attention to the decisions and actions of 'middle powers' and 'small states'. While entailing the risk of restricting the scope of empirical findings to specific types of states (which, of course, is also the case for theories that focus on great powers only), this broader perspective leads to a marked increase in the number of possible objects of investigation. In so doing, it represents another promising starting point for comparative analysis since the universe of cases is significantly expanded.

Hence, FPA and comparative research go together particularly well. It comes as no surprise, then, that a sub-field called 'Comparative Foreign Policy' exists within

FPA. Yet, efforts in this direction, which were strongly influenced by the behavioralist turn in IR and Political Science more broadly, did not produce the aspired results in terms of identifying ‘a grand unified theory of all foreign policy behavior for all nations for all time’ (Hudson, 2005: 9). After having fallen into disrepute for several decades, a renewed interest in comparative analyses of foreign policy has materialized more recently.

Rather than (unrealistically) aiming for the aforementioned ‘grand unified theory’, the current trend toward ‘back to comparison’ (Kaarbo, 2003) is driven more by middle-range theorizing, knowledge accumulation, and the aspiration to produce policy-relevant research. As Kaarbo (2003: 157) notes, ‘If a researcher wants to investigate many of the traditional factors that explain foreign policy... it is necessary to compare foreign policies across time, space, and issues to understand the general explanatory power of these various influences on governments’ behavior’. That scholars have heeded this call for comparative analyses of foreign policy (though hardly in the tradition of the grand unified theory-building efforts associated with ‘Comparative Foreign Policy’) is illustrated by the fact that around 75% of the articles published in the field’s main journal, *Foreign Policy Analysis*, in the year 2018 featured a comparative angle (esp. across time and/or space).

Building on this renewed interest in comparative analyses of foreign policy, the remainder of this chapter proceeds in four steps: the next section shows how FPA scholarship has specified possible drivers for international politics located on either the level of individual decision makers or the domestic-political level. It is within and across those levels of analysis that a comparative approach to the study of foreign policy can be fruitfully employed. This is followed by a brief overview of landmark comparative studies in FPA along with the presentation of more recent calls to recover and reinvigorate comparative analyses of foreign policy. The final section weaves the different strands of the argument

together and discusses two methods that have become increasingly popular when engaging in comparative analyses of foreign policy. On the level of individual decision makers, it shows how automated content analysis has made huge inroads over the last two decades with respect to the at-a-distance assessment of political leaders, thereby rendering possible meaningful comparisons between leaders within and across countries. On the state level of analysis, the chapter shows how Qualitative Comparative Analysis (QCA) has been fruitfully employed for establishing necessary and/or sufficient domestic-political drivers of foreign policy. The concluding section briefly summarizes the discussion and offers suggestions for future advances in comparative research in FPA.

## **FPA’S MULTI-FACETTED LEVELS OF ANALYSIS**

FPA scholarship does not dispute the importance of systemic factors in explanations of international politics. As Juliet Kaarbo (2015: 208) argues, ‘the international is not by definition exogenous to an FPA approach’. At the same time, FPA does not privilege such factors in its explanations, since many of them – for instance, the distribution of capabilities across the units of the international system and, even more so, the ordering principle of the international system (Waltz, 1979) – are very abstract and also quite stable over time. Therefore, they are ill-equipped to explain the specifics of foreign policy decision making processes or rapid changes in a country’s foreign policy behavior, to give but two examples. Moreover, while a country’s relative material capabilities suggest, or foreclose for that matter, certain types of behavior, states do not always engage in that (allegedly optimal) behavior, as, for instance, the literature on ‘underbalancing’ (Schweller, 2004) has shown. Overall, then, systemic IR theories cannot and, from the viewpoint of on its

key proponents, also should not be used to 'explain the particular policies of states', such as 'why state X made a certain move last Tuesday' (Waltz, 1979: 121).

This is where FPA comes in. This sub-field of IR is not only interested in explaining particular foreign policy processes, decisions, and behaviors of states but has also developed the analytical tools to accomplish those goals. For that purpose, FPA has opened up the 'black box state'. In doing so, it has arrived at more nuanced understandings of the drivers of policy that are associated with leaders and domestic institutions respectively. It is those factors that are privileged by FPA, rather than systemic/international ones, which is why FPA could, at minimum, represent a 'complement' to IR theories and maybe even an outright 'competitor' (Kaarbo, 2015: 208–9).

### ***Specifying the First Image***

A key dictum of much of FPA scholarship is 'who leads matters' (Walker, 2003: 245). Of course, this is hardly a novel argument per se as it, for instance, merely reiterates the general insight offered by Waltz (1959: 16), according to whom 'the nature and behavior of man' is one possible driver of international politics (here: cause for war). However, Waltz did not fully explicate what this 'first image' actually entails. That is, he refrained from systematically elaborating on both the specific characteristics of leaders that might actually guide their decisions and the situations in which individual leaders may be more (or less, for that matter) influential in the making of their respective country's foreign policies and thus in international politics more broadly. Those two gaps have been addressed by FPA scholarship.

A number of situations or contexts have been identified in which decision makers should have the most impact on, and thus make the most difference for, their country's foreign policy. Following Holsti (1976: 30), individual decision makers may matter the

most under several specific circumstances. Those include: 'non-routine situations' or 'unanticipated events' in which established procedures cannot be applied and cognitive mechanisms are likely to kick in; 'highly ambiguous' decision contexts which allow for a multitude of interpretations; or situations in which too much information is available ('information overload') so that certain coping mechanisms are required. More recently, though, Robert Jervis (2013) has argued, with a particular emphasis on US post-Cold War foreign policy, that individual decisions makers might actually matter less than commonly expected. Hence, there is no agreement about the contexts in which – let alone the specific extent to which – decision makers matter: 'The question of the extent to which leaders matter in international politics is as familiar as it is impossible to fully answer' (Jervis, 2013: 154). Still, decades of FPA scholarship do suggest that leaders can make a difference at certain points in time.

Against this background, FPA scholarship has identified several distinct characteristics of decision makers that are supposed to impact the making and outcome of their foreign policies and translated them into a number of analytical approaches. Those approaches are united by a set of underlying assumptions. First, challenging strict rationality assumptions as contained in many mainstream IR theories, decision makers are supposed to behave in a 'boundedly rational' way (Simon, 1957). That is, while they seek to engage in objectively rational behavior, limitations in humans' information processing and problem-solving capacities put limits on accomplishing this goal. To compensate for those limitations, decision makers 'construct a simplified model of the real situation in order to deal with it. [They] behave [] rationally with respect to this model, and such behavior is not even approximately optimal with respect to the real world' (Simon, 1957: 199). Second, the individual characteristics and idiosyncrasies of leaders are held to be key to understand how they construct their

simplified models of the world and thus ultimately their foreign policy choices. Finally, decision makers are supposed to differ with respect to those characteristics in the first place. Based on that assumption, it is possible to explain variation even in the foreign policies of countries with similar material capabilities or domestic institutions. So, it is not only that individuals matter *per se* but, more often than not, it is the specific individuals with their distinct characteristics that are crucial for the explanation of foreign policy.

This begs the question as to what exactly it is about individuals that matters. Drawing on insights from a number of other disciplines, such as social psychology and behavioral economics, FPA scholarship offers a broad range of possible answers, and thus levels of analysis, to this question. Possible explanatory factors include: risk propensities; the use of analogies or metaphors; learning; the influence of ‘hot’ and ‘cold’ emotions; motivations; identities; and attitudes. The following paragraphs offer in some greater detail two additional examples for FPA scholarship in this tradition, pertaining to leaders’ political beliefs on the one hand and information processing capacities on the other.

Operational Code Analysis (OCA) focuses on the political beliefs of decision makers (Leites, 1951; George, 1969; Walker et al., 1998). Operational codes are defined as ‘a set of general beliefs about fundamental issues of history and central questions of politics as these bear, in turn, on the problem of action’ (George, 1969: 191). The approach features 10 beliefs that are grouped into two clusters. Philosophical beliefs refer to decision-makers’ assumptions concerning the fundamental nature of politics, above all whether ‘the political universe [is] essentially one of harmony or conflict’ (George, 1969: 201). Hence, philosophical beliefs are crucial for the definition of a situation. In turn, instrumental beliefs relate to decision-makers’ understanding about ends-means relationships regarding action in the political realm. Most importantly, they provide answers to the question ‘what is

the best approach for selecting goals or objectives for political action?’ (George 1969: 205). Instrumental beliefs are thus decisive for the selection of the appropriate responses or instruments for the policy challenge at hand. Overall, political beliefs are conceptualized ‘as causal mechanisms with steering effects’ (Walker and Schafer, 2006: 7). Numerous applications of OCA have shown that individual decision makers, including non-Western leaders (e.g., Malici and Malici, 2005; He and Feng, 2015), do indeed vary in their political beliefs. Moreover, studies have successfully linked variation in beliefs with distinct foreign policy behaviors and outcomes, for instance by bringing in event data (e.g., Walker et al., 1999).

Integrative Complexity (e.g., Suedfeld et al., 1977; Suedfeld et al., 2011) focuses on leaders’ information processing capacities. A leader’s level of complexity is conceptualized as a ‘state’ in ‘which a person is functioning at a specific time and in a specific situation’ (Suedfeld et al., 2005: 247). The two key dimensions are differentiation and integration. Whereas the former refers to leaders’ ability to grasp multidimensionality by identifying alternative viewpoints and/or acknowledging different dimensions associated with a topic, the latter concerns leaders’ ability to interconnect those perceptions in the form of trade-offs, etc. (Suedfeld et al., 2011: 1009). A leader’s level of integrative complexity at any given point in time can be influenced by a number of factors, both intrapsychic (e.g., value conflicts) and context-specific (e.g., decision environment, political considerations, or the nature of the task) ones. Since integrative complexity is situation-specific, there is not only variation on this variable among leaders, but also a single leader can possibly show huge variation over time. This opens up a multitude of starting points for comparative analyses, for instance with respect to the integrative complexity of one or more leaders depending on the decision context, foreign policy domain, or the political stakes associated with the decision, to name

but a few. Like OCA and the Leadership Trait Analysis (see below for details), Integrative Complexity is also linked up with at-a-distance assessment techniques to render research feasible. Those techniques draw on leaders' speech acts from which quantitative data and ultimately 'scores' of leaders on the variable(s) of interest are derived. In case of Integrative Complexity, a broad array of leaders has been examined, including US president Barack Obama (Suedfeld et al., 2011) or leaders who were responsible for surprise attacks (Suedfeld and Bluck, 1988).

### ***Specifying the Second Image***

FPA scholarship offers an equally broad array of explanatory factors with respect to the 'second image' and thus possible domestic drivers of foreign policy processes and outcomes. They range from exploring interaction patterns in formal or informal small-group settings (e.g., cabinets or committees of the executive branch) to coordination- and decision-making processes within and between governmental organizations and the influence of other types of institutions (e.g., parliaments, the media, or lobby groups) on a country's foreign policy to general attributes of political systems (e.g., parliamentary versus presidential), regimes (e.g., democracy versus autocracy), or societies (e.g., strategic cultures or national role conceptions) and their impact on foreign policy behavior and outcomes. Resulting from this focus on domestic political actors, institutions, and processes, there are multiple cross-connections to Comparative Politics, where many of the same factors are addressed (see Brummer et al., 2019). The following paragraphs briefly outline two perspectives in this tradition in some greater detail, which focus on bureaucratic politics and decision-making groups and coalition governments respectively.

The Bureaucratic Politics Model focuses on inter-ministerial decision-making processes and the outcomes that they produce (Allison, 1971; Allison and Halperin, 1972; Allison and

Zelikow, 1999). The model's core assumptions can be summarized as follows: first, bureaucratic actors' policy preferences are strongly influenced, albeit not determined, by their position in government, hence the famous aphorism 'Where you stand depends on where you sit' (Allison and Zelikow, 1999: 307); second, bureaucratic actors engage in inter-ministerial bargaining processes since none of them wields sufficient power resources as to simply impose their preferences on other actors; and finally, the outcomes of bargaining processes among bureaucratic actors is best described as '*resultants*' in the sense that what happens is not chosen as a solution to a problem but rather results from compromise, conflict, and confusion of officials with diverse interests and unequal influence' (Allison and Zelikow, 1999: 294–55; emphasis in the original). The model's assumptions have been predominantly tested in qualitative case studies dealing with decision-making processes in 'industrialized nations' (Allison and Halperin, 1972: 43). In a few instances, the model has also been applied to non-Western settings, such as the Soviet Union (Dawisha, 1981).

Another type of domestic institution is addressed in the literature on the implications of coalition government for foreign policy. Scholarship on this topic can be grouped into two strands. One explores the implications of coalition government on the process of foreign policy making, for instance, with respect to the effects of junior coalition parties, or different types of coalitions more generally, on decision making procedures (e.g., Kaarbo, 1996; Oppermann and Brummer, 2014). Studies in this direction have predominantly used qualitative case studies, often times in a comparative fashion. The other strand in the literature focuses on the outcomes of foreign policy making by coalitions, for instance whether they end up with more 'extreme' foreign policies, that is, more cooperative or aggressive policies than single-party governments (e.g., Beasley and Kaarbo, 2014). Studies in that direction have predominantly employed quantitative methods.

## LANDMARK COMPARATIVE FPA SCHOLARSHIP

The previous section has shown that FPA scholarship contains a broad array of possible explanatory factors pertaining respectively to leaders and domestic institutions. Comparative approaches to the study of foreign policy have used those variables as their point of departure. The most ambitious among them have tried to integrate several of those factors in a comprehensive analytical framework. However, since such efforts – which date back to the 1960s and the 1970s – did not produce the aspired results, comparative approaches to foreign policy lost importance. This has changed in recent years, however, when calls to recover the comparative analysis of foreign policy has reinvigorated scholarship in this direction.

The foundational text for ‘Comparative Foreign Policy’ (CFP) as a distinct strand of research within FPA, and one of the ‘paradigmatic works’ of the field of FPA more generally (Hudson, 2012: 14), is a book chapter by James Rosenau entitled *Pre-theories and Theories of Foreign Policy* (Rosenau, [1966] 2006). The goal of that ‘pre-theory’ was to process information pertaining to foreign policy in a comparable fashion as a precondition for the subsequent building of actual theories of foreign policy, hence the term ‘pre-theory’. For that purpose, Rosenau came up with five sets of variables that serve as sources for the external behavior of states. Those were: characteristics of individual decision makers; the (bureaucratic or governmental) roles that decision makers occupy; governmental variables; societal variables; and systemic variables. Depending on different types of societies (large or small countries; developed or underdeveloped countries; open or closed polities), those variables were ranked according to their ‘relative potency’ (Rosenau, [1966] 2006: 175). For instance, in the case of a large, developed country with an open polity, the most important variable for explaining that country’s foreign policy was supposed to

be the roles of the decision makers, followed by the societal, governmental, systemic, and individual variables. Building on this foundation, additional concepts were added that were supposed to help at arriving at even more specific and nuanced understandings of the drivers of foreign policy. These included the distinction between penetrated and non-penetrated political systems as well between four different types of issues (territorial, status, human resources, and non-human resources). Those differentiations were supposed to help in ‘facilitat[ing] the formulation of if-then propositions’ (Rosenau, [1966] 2006: 177). However, since ‘[t]he empirical results were less than the protagonist had hoped’ the ultimate goal of arriving at ‘a grand unified theory of foreign policy behavior applicable to all nations and time periods’ did not materialize (Hudson, 2012: 19).

The CREON project (Comparative Research on the Event of Nations) pursued a quantitative cross-national comparative approach that sought to explore connections between different types of nations and specific foreign policy behavior (e.g., East et al. 1978; Callahan et al., 1982). A novel event data set for 38 states for the decade between 1959 and 1968 was compiled as an empirical base for the analysis (for details on the data, see Hermann et al., 1973). With the goal of developing ‘multivariate theories of foreign policy...interrelationships of independent variables with each other and with the dependent variables’ were explored in order to come up with ‘a more complete statement of the processes that produce foreign policy behavior’ (Callahan, 1982: 32). Mirroring Rosenau’s pre-theory, CREON featured three independent variables pertaining to national attributes (size, accountability, development). The combination of those attributes led to eight different ‘nation types’ (e.g., large, open, and developed nations or small, closed, and underdeveloped nations). CREON also featured nine dependent variables with respect to different types of foreign policy behavior. Those included the involvement of bureaucracy, participation by heads of states, different types

of government action ('verbal behavior' vs. 'physical deeds'), and different types of events (e.g., diplomatic, military, economic), among other things (East and Hermann, 1974).

However, neither Rosenau's pre-theories nor CREON produced the desired outcomes. As a result, the comparative analysis of foreign policy 'was largely discredited even by many of its own original founders...The label "CFP" came close to being pejorative in nature' (Kaarbo, 2003: 157). Against this background, Kaarbo (2003: 157) lamented in the early 2000s that 'One of the most disappointing features of contemporary FPA is the relative dearth of comparative study'. She concluded her criticism with a call for a 'return to comparison' along three dimensions: between issue areas, between countries, and over time, using either quantitative methodologies (as Rosenau and others did) or systematic qualitative methodologies (Kaarbo, 2003). Similarly, in the opening article of the then newly established journal *Foreign Policy Analysis*, Valerie Hudson noted that 'the term "comparative foreign policy" has largely disappeared from the sub-field' of FPA (Hudson, 2005: 14). At the same time, Hudson welcomed recent comparative works in which, for instance, several of FPA's leader-oriented frameworks such as OCA and Leadership Trait Analysis (LTA) have been employed in a comparative fashion against the same leader/s since this 'allow[ed] inspection of these frameworks' relative strengths and weaknesses' (Hudson, 2005: 17).

### **COMPARING LEADERS AND DOMESTIC INSTITUTIONS: CURRENT EXAMPLES OF COMPARATIVE FPA RESEARCH**

This section demonstrates that the aforementioned calls for a reinvention of comparative analysis in FPA have been heeded in recent years. Arguably, the main reason for this development has been that explanations

that focus on systemic imperatives and material factors were incapable of accounting for differences in the foreign policy behavior of states with similar capabilities, such as the non-/participation of key US allies in the Iraq war of 2003 (Kaarbo, 2003: 157). Such shortcomings not only suggested that it is necessary to explore the drivers of foreign policy that are located 'inside' a state – be it domestic institutions or individual leaders – but also to do so from a comparative perspective in order to explore how those factors play out differently in varying political environments in order to account for variation in behavior across countries.

FPA is particularly well-suited for comparative analysis given the high number of levels of analysis that it features as a result of the specification of first- and second-image drivers of foreign policy. The challenge is thus not to identify potentially meaningful substantive factors or variables for comparison but, rather, how such a comparison can be conducted in methodological terms. In the remainder of this section, two examples for state-of-the-art comparative research in FPA are presented. In accordance with FPA's focus inside the 'black box state', one example zooms in on leaders and the other on domestic institutions. On the level of individual decision makers, automated content analysis has been introduced to identify and ultimately compare specific characteristics of leaders in a systematic fashion within and across countries based on a huge amount of source material (in form of verbal utterances or speech acts). On the state level of analysis, Qualitative Comparative Analysis (QCA) has asserted itself as a viable tool for ascertaining domestic political drivers, and the interactions among them, of foreign policy from a comparative perspective.

To be sure, quantitative content analysis and QCA are not the only methods that can be used for comparative analyses of foreign policy. Meaningful comparative insights can also be gleaned by well-conducted and systematic qualitative case studies that employ

congruence tests and/or process tracing in conjunction with structured focused comparisons on a number of strategically selected cases to control for confounding factors as much as possible (Kaarbo and Beasley, 1999; George and Bennett, 2005), to give but one additional example. Still, since case-study methods are discussed in other chapters of this *Handbook*,<sup>1</sup> and since automated content analysis-schemes and QCA certainly belong to the best developed and most widely used instruments for that purpose, the following paragraphs aim to provide reasonably detailed insights into those state-of-the-art tools for the comparative analysis of foreign policy.

### ***Profiling Leaders Using Automated Content Analysis***

One of the main dictums of FPA is that leaders matter in foreign policy. This is not solely to suggest that analysts should take into account people in positions of political power when trying to explain foreign policy. Rather, it is the idiosyncratic features and characteristics of those leaders that drives foreign policy making and outcomes and which therefore need to be examined. As mentioned above, those characteristics could relate to decision makers' political beliefs, integrative complexity, risk propensities, or leadership traits and styles. Certain manifestations of those characteristics can be linked up, for instance, to certain types of policy behavior (e.g., a greater or lesser likelihood to use military force), and differences in those characteristics among leaders can help in accounting for different foreign policy behaviors among countries (even among those with similar material capabilities and domestic institutions).

Hence, techniques are required to ascertain the individual characteristics of leaders. Arguably the main challenge associated with an assessment, or 'profiling', of political leaders is access, or rather the lack thereof, to those actors. Indeed, researchers 'rarely have direct access to a leader in a way that

would allow for traditional psychological analysis' (Schafer, 2000: 512). In response, 'at-a-distance assessment techniques' have been developed to ascertain certain characteristics of leaders. Quantitative content analysis has become the primary research method in this regard since it allows for a systematic development of leaders' profiles based on their own statements without requiring direct access to them.

The substantive approaches that have been linked up with at-a-distance assessment techniques look at a variety of different variables, such as: political beliefs in case of OCA, leaders' ability for differentiation and integration in case of Integrative Complexity, or, as discussed in greater detail below, traits in case of Leadership Trait Analysis (LTA). What unites those approaches is that they draw on leaders' speech acts in order to identify specific manifestations of their respective variables of interest. By extension, they also face similar challenges with respect to their source material or choices pertaining to: impression management; audience effects; role effects; or issues of authorship (for details, see Schafer, 2000). Having said that, the internal and external validity of the approaches have been tried and tested in numerous studies so that researchers can use them with reasonable confidence.

Another issue that unites several of those at-a-distance approaches is that over the last 15 years or so, the quantitative content analysis of leaders' speech acts has become automated through the development of coding schemes that can be integrated in specific software packages. Based on LTA (Hermann, 2005), the following discussion shows how leadership traits can be identified based on the automated content analysis of verbal statements and how the ensuing results could be meaningfully used for comparative analysis.

### ***Leadership Trait Analysis***

The main proponent of LTA defines leadership style as 'the ways in which leaders relate

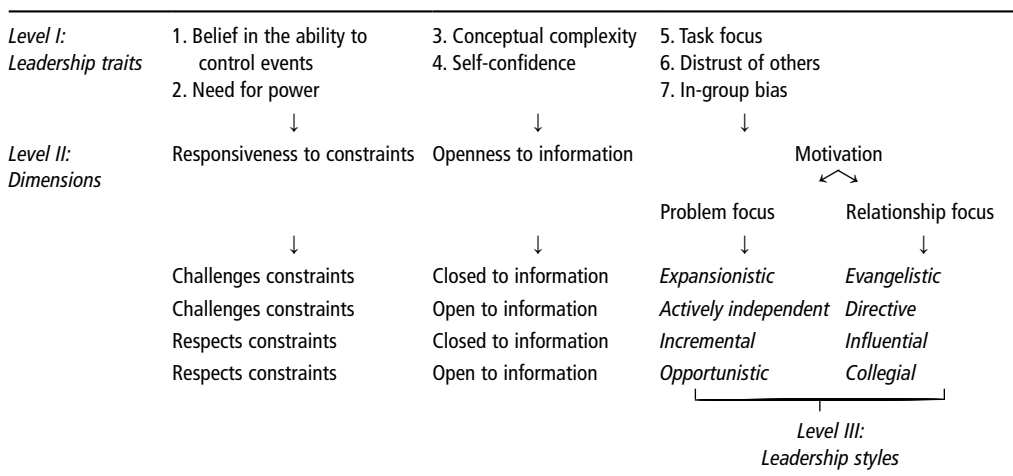

to those around them – whether constituents, advisers, or other leaders – and how they structure interactions and the norms, rules, and principles they use to guide such interactions’ (Hermann, 2005: 181). Hence, a specific leadership style, as well as the distinct leadership traits from which a specific leadership style emerges, exert a significant impact on the way that leaders seek to cope with the challenges and dilemmas of foreign policy decision making. In the final analysis, leadership traits and styles impact the conduct as well as the substance of foreign policy. LTA has been employed in numerous empirical studies. The latter have covered not only US presidents (Keller, 2005; Yi, 2010) or European prime ministers (Van Esch and Swinkels, 2015; Brummer, 2016), but also heads of international organizations (Kille and Scully, 2003; Brummer, 2014) as well as leaders from the Global South (Hermann, 1987; Taysi and Preston, 2001).

LTA can be broken down into three distinct levels (see Table 60.1). The first level focuses on seven specific leadership traits. Those traits, which represent the core of the approach, refer to: belief in ability to control events; need for power; conceptual complexity (i.e., ability for differentiation);<sup>2</sup> self-confidence; task focus; distrust of others; and

in-group bias. On the second level, certain traits are interacted to provide information on more general dimensions. Whether leaders respect or challenge constraints results from their belief in the ability to control events and need for power. Conceptual complexity and self-confidence provide information on leaders’ openness to information, and leaders’ motivation for office-seeking can be inferred from whether they focus on tasks or rather on group maintenance, their general distrust or suspiciousness of others, and whether they exhibit an in-group bias. On the third level, those three dimensions interact to produce a total of eight distinct leadership styles. For instance, a leader who challenges constraints, is closed to information, and focuses on problems is called ‘expansionistic’, whereas a leader who respects constraints, is closed to information, and focuses on relationships is called ‘influential’.

LTA assumes that leaders’ traits (and thus also the ensuing styles) are rather stable over time as well as similar across issue areas.<sup>3</sup> That is, a leader who challenges constraints is supposed to behave this way throughout his or her political career and to do so irrespective of the substantive domain that has to be addressed. Those assumptions have implications for the compilation of the ‘proper’

**Table 60.1 Leadership trait analysis**

Source: own depiction based on Hermann (2005).

source material that can be used for the identification of traits and styles.

Of course, the key question is how the key variables contained in LTA can be identified empirically. This is where the 'at-a-distance technique' for assessing leaders comes into play. LTA assumes that leaders' personalities or, more precisely, leaders' traits and styles can be inferred from their verbal statements (Hermann, 2005: 178–9). Generally speaking, then, leadership traits can be inferred from the systematic content analysis of leaders' speech acts.

More specifically, LTA stipulates a total of six requirements regarding the source material that should be used for empirical analysis (Hermann, 2005, 2008). For every leader, at least 50 verbal statements (ideally: at least 100) must be assembled (requirement one). Each statement should contain at least 100 words (ideally: at least 150) (requirement two). However, those requirements are a legacy of the time period when the coding process was still performed manually; with the advent of automated, computer-based coding (see below), the text corpus can be significantly larger nowadays as the coding even of several hundred thousand words does not take longer than a couple of minutes. Moreover, not just any verbal statement should be used for analysis. Rather, the text corpus must contain only spontaneous statements (requirement three). These are much more likely to reveal the 'true self' of leaders than scripted statements: '[I]nterviews are the material of preference. In the interview, political leaders are less in control of what they say and, even though still in a public setting, more likely to evidence what they, themselves, are like than is often possible when giving a speech' (Hermann, 2005: 179). Relatedly, the verbal statements should have been uttered in different contexts, that is, in front of different audiences, such as parliament or the press (requirement four). Two further requirements follow from the above-mentioned substantive assumptions contained in LTA with respect to the stability of traits across time and issue

domain. Following from this, the verbal statements should cover the leader's entire tenure in office rather than, say, just from his or her first or second term (requirement five), and they should also focus on different substantive issue areas (requirement six).

Source material (i.e., spontaneous verbal statements) assembled in light of those requirements is then content-analyzed. Until the early 2000s, the coding was done manually. Since then, automated coding has become possible with the development of a coding scheme for LTA that has been integrated in the software program 'Profiler Plus' developed by Social Science Automation. The automated coding scheme enables the analysis of much larger amounts of source material in virtually 'no time'. Indeed, the collection of the verbal statements is now much more time consuming than the actual coding process. What is more, concerns about the accuracy of the coding and intercoder reliability are no longer an issue (see below for possible other downsides, however).

The automated coding focuses exclusively on the identification of the above-mentioned seven leadership traits (level I). The ensuing three dimensions (level II) and eight leadership styles (level III) must be inferred by the analyst based on the results for the seven traits. Every trait is associated with a particular set of words or expressions that are supposed to indicate the existence of either high or low manifestations of the respective trait. For all seven traits, the range for the score is between 0 and 1. The lower the score, the weaker the manifestation of the respective trait, and vice versa.

For the purpose of illustration: the source material (i.e., the spontaneous verbal statements that the analyst has assembled for a specific leader in accordance with the six requirements outlined above) contains 100 words that are associated with the trait conceptual complexity; 51% of those words point to a high manifestation of that trait, such as 'maybe', 'possibly', or 'for example'. Conversely, 49% of those words suggest

the opposite, such as ‘always’, ‘certainly’, or ‘unequivocally’. Since the score for conceptual complexity is determined by calculating the percentage share of high-complexity words among all high and low complexity words contained in the source material, our fictional leader would have a conceptual complexity score of 0.51. Indeed, this is the conceptual complexity score for the former British Prime Minister David Cameron, who was responsible for the Brexit referendum in 2016, among other things.

The explanatory power of this score is somewhat limited, though. On the spectrum ranging from 0 to 1 Cameron’s score suggests that his ability to distinguish the complexities of the political environment is rather average. However, the score itself tells us nothing in terms of how well Cameron performs (i.e., above average, below average, or just average) *relative* to his peers of other key foreign policy makers, and hence the main reference group.

At this point, one of the main strengths of LTA – which makes it particularly useful for comparative analysis – comes to the fore. It results from a so-called ‘norming group’. This norming group comprises a total of 284 ‘world leaders’ (Table 60.2). It contains mean scores for all seven leadership traits, not only for the full list of leaders (comprising presidents, prime ministers, and foreign ministers), but is also broken down into, for the most part, six geographically defined sub-groupings, namely: Western Europe, Eastern Europe, Middle East and Northern Africa, Pacific Rim, Latin America, and Anglo-America.<sup>4</sup> The added value of this norming group is straightforward: in practical terms, it renders possible meaningful comparisons between leaders without having to create a profile for more than one leader, and, in substantive terms, its helps to put into context the scores of one’s own analysis.

To return to our previous example: Cameron’s score for conceptual complexity was 0.51. The norming group shows that the average score for this particular trait among close to 300 world leaders is 0.59, with a

**Table 60.2 The ‘norming group’ of leadership trait analysis**

Leadership traits	‘World leaders’ (n=284)
Belief in the ability to control events	0.35 (0.05)
Need for power	0.26 (0.05)
Conceptual complexity	0.59 (0.06)
Self-confidence	0.36 (0.10)
Task focus	0.63 (0.07)
Distrust of others	0.13 (0.06)
In-group bias	0.15 (0.05)

*Source:* own depiction based on Cuhadar et al. (2017): 47 (average scores for ‘world leaders’; standard deviations in parentheses).

standard deviation of 0.06; for the Anglo-American sub-group, it is 0.60 with a standard deviation of 0.05. Based on those numbers, we can tell that Cameron’s trait score is more than one standard deviation below both the world average and the regional sub-group. This is not only a finding in itself but becomes all the more pertinent when taking into account possible implications of different manifestations of conceptual complexity on leaders’ foreign policy behavior. For instance, leaders with a low conceptual complexity are more likely to engage in diversionary behavior (Foster and Keller, 2014). In a sense, one could argue that the domestic political challenges that Cameron had been facing both within his own (in parts strongly anti-European) Conservative Party and from the staunchly anti-European United Kingdom Independence Party (UKIP) provided strong diversionary incentives for him so that he promised a ‘Brexit’ referendum in the hope of rallying at least his own party behind him.

In short, leadership profiling based on automated content analysis represents an ideal starting point for engaging in comparative analysis of foreign policy decision makers, both within and across countries.<sup>5</sup> However, in conclusion, some caveats are in order. First, LTA remains essentially silent about how leadership traits are formed in the first place. Admittedly, however, answering this question

would require a different theory altogether (Horowitz et al., 2015). Second, the norming group contains certain problems. Most importantly, it is not clear which leaders are actually included in that group. As a result, one cannot tell whether the norming group features certain biases for instance with respect to the party-political/ideological background of the leaders or the types of political systems (presidential or parliamentarian) or regimes (democratic or autocratic) within which the leaders operate. It is also impossible to tailor a norming group based on one's specific needs (e.g., a group that includes only female leaders or leaders of democratic countries). Finally, LTA-based automated content analysis is, for the most part, confined to English source material. The only exceptions include Spanish coding schemes for the traits 'conceptual complexity' and 'distrust' and a newly developed German coding scheme that covers all seven traits (Rabini et al., 2018).<sup>6</sup> Hence, analyzing foreign policy decision makers whose first language is not English can become a challenge due to a dearth in source material. To be clear, however, this 'language challenge' relates to the availability of appropriate material, and not to the applicability of LTA to the non-English speaking world, to which it has been applied in numerous empirical studies already.

### ***Comparing Domestic-political Drivers of Foreign Policy Using Qualitative Comparative Analysis<sup>7</sup>***

The method of Qualitative Comparative Analysis (QCA) is a rather recent addition to the methodological toolbox of political science/IR (see Ragin 1987, 2000, 2008; Rihoux and Ragin 2009). QCA brings together insights from variable-oriented and case-oriented research. In so doing, it offers a 'diversity-oriented research [that] emphasizes "types" and "kinds," a formulation that views cases configurationally, as combinations of aspects' (Ragin, 2000: 14) that produce

certain results in a specific-context. As a result, QCA enables analysts to uncover causal relationships between an 'outcome' (similar to a dependent variable) and certain 'conditions' (similar to independent variables). The method is particularly well-suited for (but by no means limited to) 'medium-n' empirical analyses where the number of cases yields too few observations for statistical analyses but too many for in-depth case studies.

More specifically, QCA represents a set-theoretic approach that draws on Boolean algebra. The method can be used to establish the necessary and sufficient conditions for a certain outcome to occur. A *necessary* condition must be present whenever the outcome is observable. However, its presence is not a guarantee for the actual occurrence of the outcome. In other words, there might be instances where the necessary condition is present, but the outcome is not. Hence, the outcome is a sub-set of the necessary condition. In turn, if a *sufficient* condition is present, then the outcome is also always present. However, the outcome might also occur as a result of other conditions. Hence, the outcome is a super-set of the sufficient condition. Moreover, there are conditions that are neither necessary nor sufficient for producing a certain outcome but nonetheless can contribute to producing that outcome (so-called 'INUS' and 'SUIN' conditions). Overall, then, QCA highlights not only that one individual condition can lead to a certain outcome, but also, and more importantly, that certain 'configurations of conditions can be jointly necessary and/or sufficient, while their constituent parts might be neither necessary nor sufficient for an outcome' (Mello, 2012: 429) to occur.

Arguably, the key distinguishing features of QCA as a method are that it focuses on a combinations of factors (i.e., conditions) in producing certain results (i.e., outcomes) – or the non-occurrence (i.e., negation) of an outcome, for that matter – and that it allows for one and the same outcome to be produced by different combinations of conditions. The

literature refers to this as ‘causal complexity’ (Schneider and Wagemann 2012: 76–90). Causal complexity comprises three elements: equifinality, conjunctural causation, and asymmetry. Equifinality means that multiple causal pathways (i.e., individual conditions or, more often than not, specific combinations of conditions) can produce the same outcome. Conjunctural causation suggests that the effects of single conditions unfold only in combination with other conditions. Finally, asymmetry means ‘that insights on the causal role of a condition are of only limited use for the causal role of its absence, and the explanation of the occurrence of an outcome does not necessarily help us much in explaining its non-occurrence’ (Schneider and Wagemann, 2012: 81). To give an example: just because a certain combination of conditions (e.g.,  $x$  is present,  $y$  is absent, and  $z$  is present) leads to a certain outcome, this does not necessarily also mean that the mirror image (i.e.,  $x$  is absent,  $y$  is present, and  $z$  is absent) automatically leads to the non-occurrence of the outcome. Therefore, since knowing why a certain outcome has occurred does not necessarily tell us much about the non-occurrence of the outcome, separate empirical analyses are required: one for the occurrence of a certain outcome and one for its non-occurrence.

QCA features different variants. Arguably, the most prominent ones are crisp set QCA (csQCA) and fuzzy set QCA (fsQCA). The key difference between them is that they are based on different types of sets:

csQCA operates exclusively on conventional sets where case can either be members or non-members in the set. Their set membership is either 0 or 1. In fsQCA, by contrast, cases are allowed to have gradations of their set membership. A case does not have to be a full member or a full non-member of a set but can also be a partial member. The membership scores can all anywhere between the two extremes of full membership value of 1 and full non-membership value of 0. (Schneider and Wagemann, 2012: 13–14)

By implication, csQCA is a special variant of fsQCA, in that it only knows either full

membership or non-membership in a set, rather than also gradated levels of membership as is the case in fsQCA (Ragin, 2000: 156).

Overall, then, whereas csQCA ‘only’ looks at qualitative distinctions, or differences in kind (in the sense of ‘more or less’), fsQCA also focuses on quantitative distinctions, or differences in degree (how much ‘more or less’) (Schneider and Wagemann, 2012: 24–7). Which variant of QCA should be used in empirical analysis is up for the researcher to decide in light of the explanatory factors (conditions and outcome) that are included in the analysis. If the factors yield to a dichotomous classification, then csQCA would be an obvious choice (e.g., single-party versus coalition government). However, if some, most, or all of the factors can be depicted in a more nuanced fashion that also gets at quantitative distinctions, then fsQCA should be used (e.g., when it is not only of importance whether there is a coalition government or not, but whether also the number of coalition parties is relevant for the argument, for instance, with respect to the number of veto players).

### ***Examples for Qualitative Comparative Analyses in FPA***

Contrary to LTA as discussed above – which is first and foremost a substantive approach that has been associated with a specific method (in form of automated content analysis) – QCA does not entail any specific substantive assumptions based on which specific drivers of foreign policy can be ascertained. As a result, QCA as a tool for comparative analysis needs to be linked up with substantive approaches in order to arrive at meaningful findings. With this in mind, virtually any of FPA’s (domestic) levels of analysis can be used in conjunction with QCA. More precisely: a multitude of combinations of FPA’s domestic levels of analysis can be employed in principle, with the specific ‘mix’ being determined not by QCA, but by the analyst’s

theory-driven assumptions about possible drivers (conditions) for a specific phenomenon (outcome). This openness in terms of explanatory factors, or conditions, that can be investigated by using QCA becomes obvious in the following two examples, one relating to csQCA and the other to fsQCA.

csQCA has been used to explain the allocation of the foreign ministry, and thus one of the key portfolios within the ‘foreign policy executive’ (Hill, 2016), in governing coalitions. More specifically, Oppermann and Brummer (forthcoming) explore why the senior party of a coalition government (i.e., the party with the largest seat share in parliament of all parties involved in the governing coalition) refrains from taking over the foreign ministry and instead agrees to allocate this portfolio to a junior member of the coalition government (i.e., a party with a relatively smaller seat share in parliament). The latter represents the ‘outcome’ under examination. Drawing on the portfolio allocation literature from Comparative Politics (Laver and Schofield, 1990) and the FPA literature on parties (Rathbun, 2004) as well as coalition governments and foreign policy (Kaarbo and Beasley, 2008), the authors identify five ‘conditions’ as possible drivers for that outcome. Those are: the relative size of coalition parties; the proximity of the foreign policy positions; the party family of the junior coalition party; the salience that coalition parties ascribe to foreign policy; and allocations of the foreign ministry to junior coalition partners in the past. Representing INUS conditions, they find that for a sample of 18 European countries, the combination of the conditions ‘relative size’ of the junior party (i.e., when it is almost as large as the senior party) and ‘past allocations’ to a junior party holds the most explanatory power.

The fsQCA example selected for this chapter addresses the use of economic statecraft in international politics. Squarely embedded in the literature on the ‘normative power Europe’ (Manners, 2002), Boogaerts (2018) examines the sanctions behavior of

the European Union (EU) in reaction to the Arab Spring. Although using fsQCA, the outcome variable is dichotomized in the sense of whether the EU has adopted (partially) autonomous ‘restrictive measures’ (i.e., sanctions) against a total of 13 Arab states in the years 2011 and 2012. The four conditions, however, are coded on a fuzzy scale. They refer to: the violent suppression of protest by Arab states; the EU’s material and security interests vis-à-vis those states; prior instances of restrictive measures in the economic realm; and transitional void (akin to the breakdown of an authoritarian regime). Perhaps most importantly, the article finds that ‘human rights violations do not constitute a sufficient condition for EU sanctions in the MENA region’ (Boogaerts, 2018: 423) but only play a role in conjunction with other conditions, which casts doubts on the (self-) depiction of the EU as norm-driven actor.

## CONCLUSION

The most characteristic feature of FPA as a distinct sub-field of IR is that it opens up the ‘black box state’ and examines the decision makers that act as well as the political processes that unfold inside that box. In so doing, FPA has ‘fine-tuned’ Waltz’s first- and second-image perspectives by offering a broad array of distinct characteristics respectively of leaders and domestic institutions that plausibly serve as drivers of states’ external behavior. It is within and across the ensuing greater number of levels of analysis that a comparative approach to the study of foreign policy can be fruitfully employed.

It goes without saying that comparative analyses, especially when comparing countries (rather than, say, the evolution of a specific policy within one country), is demanding. It requires researchers to be familiar with the histories of several countries, the functioning of those countries’ political institutions, and the political culture of the respective countries,

among other things. In addition to expert empirical knowledge, familiarity with the languages of the countries under examination is also extremely valuable (though, I would contend, not a *sine qua non* condition since it would significantly restrict the number of countries, hence cases, for examination, especially in non-collaborative projects). Having said that, there are several upsides of comparative approaches to the study of foreign policy. Most importantly, it allows researchers to get a more nuanced and, at the same time, also a more comprehensive understanding of how key drivers of foreign policy – which can be associated with either individual leaders or domestic institutions – play out in different political environments which, in turn, is a prerequisite for ascertaining the more general, cross-country effects and influence of those factors on state behavior.

To accomplish the goal of comparative analyses of foreign policy, a number of well-specified analytical tools are at the disposal of analysts. This chapter has presented two of them in some greater detail. First, automated content analysis can be used to identify idiosyncratic characteristics of leaders which, in turn, can be linked to specific types of foreign policy behaviors by those leaders and ultimately to specific foreign policy outcomes. Second, QCA can be used to examine the interaction of several domestic-political drivers of foreign policy. Automated content analysis enables analysts to develop personality profiles of individual leaders ‘at-a-distance’ based on the processing of huge amounts of leaders’ verbal statements. It thus solves the problem that researchers do not have (regular) access to decision makers. In turn, one of the key strengths of QCA is that it takes both conjunctural causation and equifinality seriously. So rather than narrowing down explanations of foreign policy behaviors or outcomes to one specific variable, QCA allows for the interaction of several explanatory factors, and it also suggests that one and the same outcome can be produced by different combinations of factors.

However, both methods feature certain drawbacks from which the following avenues for future research can be inferred. To date, automated content analysis, which primarily relies on the mining of leaders’ speech acts, is for the most part limited to English-language source material. It is not by accident, therefore, that many studies focus on leaders from the English-speaking world, for whom source material usually exists in abundance. Conversely, analyses of leaders whose mother tongue is not English more often than not run into problems in terms of source material, since utterances in English tend to be few and far between, official translations are hard to come by, and the option of researchers themselves engaging in translations of texts usually entails prohibitive costs. Therefore, automated coding schemes should be developed to enable the analysis of leaders in their own (non-English) language. A positive side-effect of this would be to further de-center the field of FPA away from the United States and the Anglosphere more generally.

Moreover, future comparative FPA scholarship should bring together leaders and domestic institutions. The examples provided above have shown that comparative analyses tend to focus on either one or the other, with little interconnection and thus cross-fertilization between those two areas. Most palpably, while taking into account a variety of institutional factors, QCA studies usually do not incorporate leader-specific variables in their analyses. Indeed, leaders’ characteristics are not readily available for turning them into crisp or fuzzy sets. Rather, this would require separate analyses in which the specific manifestation of certain characteristics of leaders (i.e., those which the theoretical literature qualifies as a possible condition for the outcome under examination) are established. Based on those scores, leader-specific factors could be represented by crisp or fuzzy sets, thus be incorporated into a QCA study. For instance, one could hypothesize that a prime minister’s need for power (as one of the seven traits contained in LTA) is one condition for

his or her willingness to give away key foreign policy portfolios to junior coalition partners, with the assumption being that the higher the leader's need for power, the less willing he or she is to cede control of, say, the foreign ministry to another party. Such integrated perspectives promise to offer a fuller picture of the domestic drivers of foreign policy by interacting explanatory factors pertaining to both leaders and domestic institutions.

## Notes

- 1 For details on case-study methods as well as on process tracing (and structured focused comparisons), see the chapter by Ruffa, Chapter 59, in this *Handbook*.
- 2 'Conceptual complexity' is not to be confused with 'integrative complexity' mentioned above, since the former refers to an essentially stable 'trait' while the latter addresses a context-specific 'state' (Suedfeld et al., 2005: 247).
- 3 While variation across 'time, audience, and topic' (Hermann, 2005: 180) is not categorically ruled out, the clear majority of the empirical studies using LTA (implicitly or explicitly) assume that traits and styles are essentially stable and, very importantly, sample the source material for their empirical analysis accordingly (i.e., without differentiating between issue areas or over time).
- 4 The latest norming group overview can be obtained through the Profiler Plus website (profilerplus.org).
- 5 Both the Operational Code Approach and Integrative Complexity can be used in a similar fashion. For details on how those approaches and quantitative content analysis have been integrated, see Schafer and Walker (2006) and Suedfeld et al. (2005).
- 6 The Spanish coding schemes are already available from profilerplus.org; the German coding scheme will be made available there as well.
- 7 For a more detailed discussion of QCA, and set theoretic methods more generally, see the chapter by Duşa, Chapter 57, in this *Handbook*.

# When Talk Isn't Cheap: Opportunities and Challenges in Interview Research

Claire Greenstein and Layna Mosley

Many substantive questions and theoretical claims in political science can be usefully evaluated using various forms of qualitative analysis, from process tracing and comparative historical analysis to focus groups, ethnography, and interviews (Bennett and Checkel, 2014; Grzymala-Busse, 2011; Kapiszewski et al., 2018). Descriptions and analyses using qualitative-data-gathering techniques can help scholars to generate causal claims, build theories, provide specific examples of the more general processes assumed by formal and statistical models, and evaluate hypotheses.<sup>1</sup>

Interviews of elites or members of the mass public can play an important role: researchers might ask policymakers when and how they decide to disclose information on nuclear proliferation (Carnegie and Carson, 2019), query investors about how they evaluate the risks represented by various types of political institutions and political events (Mosley, 2003), or discuss with members of the public when they are willing to commit violence

against – and when they are willing to protect – their neighbors belonging to different ethnic groups (Fujii, 2008). These interviews often provide access to information that does not exist in other forms and that plays a key role at various stages of the research process.

Yet, despite the potential benefits of interview-based research, its use in political science has been quite limited in recent years. As political scientists are increasingly drawn to using ‘big data’ (e.g. machine-learning techniques used to code large bodies of text), and as concerns regarding causal identification privilege some questions and approaches at the expense of others (Huber, 2013; Samii, 2016), one might question the utility of interviews as a research method. In addition, emerging norms of data access and research transparency (Lupia and Elman, 2014) may create tensions for researchers who use interview-based methods: researchers must respect the guarantees of confidentiality and anonymity typically offered to interviewees – whose livelihoods and even lives sometimes

depend on human subject protections – and yet researchers must also offer enough information about interview respondents and responses to allow reviewers, editors, and readers to evaluate the conclusions they draw from interviews (Moravcsik, 2014a; Wood, 2007). Moreover, access to interviewees is not always guaranteed: potential interviewees, especially public figures, may be hesitant to speak to social scientists, and recent high-profile breaches of research ethics by political scientists may intensify their concerns (Johnson, 2018; van Noorden, 2015).

Indeed, while interviews are acknowledged as being an excellent method for identifying causal mechanisms, as well as for being the only means for assessing some types of causal claims (Kapiszewski et al., 2015; Mosley, 2013), fewer than 10% of articles published in a sample of top political science journals between 2000 and 2017 incorporate interviews, as opposed to 58% using solely quantitative methods (Pepinsky, 2018). It is worth noting, however, that while qualitative empirical approaches have overall become less common in the most prestigious journals (Pepinsky, 2018), the use of interviews in these outlets has remained steady (albeit low; see below) since the early 2000s.

And, despite the challenges associated with using interviews, many scholars continue to rely on interview data to inform all stages of their work. This is not out of loyalty to an obsolete method but rather a reminder that interview data lend themselves to developing theories, supporting causal claims, and understanding complex social phenomena in a depth that other methods cannot match. Interviews often allow social scientists to examine the causal mechanisms that underlie the correlations revealed by statistical analyses. Interviews can also facilitate the design of better survey questions, as well as of better lab and field experiments. For those interested in process tracing, interviews are a valuable data source (Bennett and Checkel, 2014; Tansey, 2007). Indeed, interviews provide rich and oftentimes surprising data that

cannot be obtained in any other way, and, when used properly, they can shape and support work that is both rigorous and innovative.

Thus, in this chapter, we offer a case for continuing – or even expanding – the use of interviews in political science research. We start by providing a brief look at the utility of interviews as a methodological tool and discussing important data collection and reporting practices. Next, having established why and how scholars use interviews, we assess the current state of interview research in political science by offering evidence regarding the prevalence of interviews and how their usage varies across different subfields, journals, and books. Finally, we present an overview of the opportunities and challenges that will likely face scholars who employ interview research in the future. While we cannot resolve the tensions and tradeoffs inherent in the use of interviews, we can and do draw attention to them. In doing so, we hope to prompt more researchers to consider how interviews might enhance their own work, and, for those with an interest in the method, we aim to provide the basic information they need to use interviews in an appropriate and effective way.

## **INTERVIEWS: WHEN AND HOW TO USE THEM**

Other works examine the use of interviews in detail, providing a range of practical advice (Kapiszewski et al., 2015; Leech, 2002; Mosley, 2013; see also Rubin and Rubin, 2011). These analyses also discuss in detail how scholars of a wide range of political phenomena can productively use interview-based data. Although we offer a brief discussion of some key issues regarding interviews, we encourage those interested in interview methods to consult these works as well.

Interviews can be used at multiple stages in the research process. First, they can help scholars to generate causal claims at the start

of the research process, as when graduate students use pre-dissertation fieldwork to establish the plausibility of potential questions and theoretical approaches. For instance, a researcher might go into the field expecting to find a link between A and B, only to find that interviewees rarely mention A in connection with B, while C surfaces much more frequently. Interviews allow scholars to discover the lay of the land and establish an evidence-based direction for a novel research agenda (Anria, 2018; Greenstein, 2018; Niedzwiecki, 2018; Petrova, 2018; Vera-Adrianzen, 2017). A series of unstructured or semi-structured elite interviews may reveal a set of common factors that inspire the formulation of a plausible causal mechanism or an overarching theoretical framework. And interviews with members of the general public can provide insight into perceptions, behavior, and attitudes that indicate a link between two seemingly disparate areas of study.

Second, interviews can be employed in the theory-testing process to assess the veracity of proposed causal mechanisms and specific causal hypotheses. This is particularly true when the issues being studied are difficult (or impossible) to quantify or have not generated much quantitative data yet. For instance, researchers examining the social impact of a new environmental policy may not be able to quantify the outcomes they are interested in studying, but they can speak to affected individuals directly and gather data on their topic of interest that way. In fact, interviews can still be useful even if the relevant social phenomena can be quantified, because in some cases the newness of a policy means that researchers might have to wait years before there are enough data points to test a theory. However, rather than putting this project on hold, they could find answers to their research question by interviewing the bureaucrats who designed this policy, the legislators who voted to pass it, the staffers in charge of implementing it, and the businesses and individuals affected by it. Such interviews could serve to either test the researchers' proposed

causal story or to illustrate the mechanisms that are assumed to operate in this theory (which are then tested using other evidence). Provided that researchers are able to reach a significant number of diverse interview respondents – and sometimes this is a serious challenge – interviews could even be conducted in stages, with the first round of interviews being used for theory generation and the second for theory testing.

Indeed, thanks to the rich, complex data that interviews yield, interviews can actually be used to test theories more directly than many other methods can. When conducting an interview, researchers can ask specific questions about the exact event or issue that interests them, regardless of whether that thing happened in the past, the present, or has yet to occur at all. In cases where such blunt or open questioning is not possible, scholars can still overcome barriers to acquiring useful data by building a relationship with interviewees that facilitates openness or by phrasing and sequencing their questions in a way that yields pertinent, if veiled, information about the topic of study. This type of one-on-one interaction with people who participated in, observed, and were affected by particular policies, events, or processes allows researchers to collect data that are immediately relevant to the research question, to avoid the use of proxy measures, and to directly assess the validity of competing theories.

Compared with many other methods, interviews may offer comparatively easy access to pertinent information. Scholars who use big data must usually rely on information that other agencies or entities have collected over time, regardless of whether those data were obtained in a rigorous manner or whether the variables in the dataset correspond perfectly to the researchers' variable of interest. Researchers who use survey data might get lucky and acquire the resources they need to conduct a survey with their ideal questions and ideal sample population, but it is far more likely that they will have to rely on results from surveys that already exist, regardless of

how well that survey's questions and answers correspond to the researcher's objectives. Archival researchers, too, often must confront frustrating gaps between their research questions and the available data, particularly when their topic of study is one that did not generate an extensive paper trail. Interviews, in contrast, allow scholars to ask knowledgeable individuals a number of direct questions about specific topics and thereby directly test, support, confirm, or discard a working theory.

In the digital era, interviews may become an even more important source of information, as individuals – especially elites – worry about communicating sensitive information via email or text. In part, this reflects concerns about the security of communication and about the likelihood of data breaches, either intentional or accidental. It also reflects an awareness that written materials may well persist in archival form. As a result, individuals involved in political processes may prefer to communicate via voice or video chat or to discuss issues in person. These methods protect privacy, especially if they do not involve recorded interchanges, but they do not leave a trail for future archival researchers. Indeed, interviews almost certainly will continue to be the only way to access certain kinds of critical information, necessary to identify causal processes and evaluate causal claims.

Interview data also can be used to test theories in mixed-methods studies. Researchers can use interview data to suggest what patterns we should discover when analyzing large-*n* data. For instance, Mosley (2003) draws on interviews with investment professionals to test the expectation, based on theories of default risk, that only some types of government policies and political events should affect the pricing of sovereign bonds. She pairs these interview-based data with statistical analyses of the correlates of sovereign-bond interest rates.

Researchers also might use later-stage interviews to gain feedback on their proposed theories and causal mechanisms. This is somewhat distinct from theory testing, as

one does not want to 'lead the witness' in terms of biasing one's findings. But, to the extent that the researcher has already gathered substantial interview data to test her theory, she might be interested in the extent to which real-world experts find her theoretical claims plausible. There is useful information to be gained by people who shaped particular events and were affected by certain phenomena, if a theory aligns with their experience. Researchers could also ask interviewees what *they* think the causal story is: 'In your experience, what role has X played in Y?' 'Some of my other respondents have indicated that X influenced Y. What do you think?' 'You've mentioned X a lot; how important is it for causing Y?' These responses do not substitute for the use of broader data for theory testing, and researchers must be aware of challenges to the accuracy of interview data (Mosley, 2013). But keeping in mind the limits of positionality, fallible memories, and respondents' desire to feel helpful or appear amiable, researchers can nonetheless use answers to these questions to gain insight from how later-stage interviewees perceive their political worlds. Moreover, sharing the findings from one's study also may be a modest means of 'giving back' to the communities in which one conducts research: participants gain a sense not only of what the researcher's specific questions are but also of the broader way in which answers to these questions inform social science research.

Third, interviews can supply data that help to justify the assumptions upon which a study is based, as when interviews offer insights into how individuals understand and interpret their experiences vis-a-vis politics (e.g. Fujii, 2010; Soss, 2015). Or, for researchers who employ formal models to analyze strategic interactions, interviews can reveal the motives of key actors – civilians who do or do not elect to join rebel groups, for instance (e.g. Baczko et al., 2018; Henshaw et al., 2019; Weinstein, 2007). Along these lines, interviews can be particularly useful when studying relatively new topics (e.g. the

effects of social media on mobilization and protest, how labor unions organize workers in the gig economy or service sector, or the ways in which gender, race, and sexual orientation intersect to affect legislators' policymaking effectiveness). In such situations, established literature may be of limited use, and the generation of informed theories and testable hypotheses may benefit from – or even depend on – the 'soaking and poking' aspect of interview-based work. Interviews offer concrete data that, in the absence of established literature, back up the researcher's claims and help justify certain theoretical and methodological choices.

Both positivist and post-positivist researchers can utilize interviews, as described above. Differences in epistemological perspectives, however, imply that different scholars will approach interviews differently. Post-positivist scholars tend to note the subjective nature of interview (and other) data. That is, interview evidence reflects the particularities of the researcher who collected it: a female graduate student from an elite US university, conducting interviews in a foreign culture, will receive a different set of answers than a male full professor from a European university, conducting interviews in his home culture. Post-positivists argue that while these differences render 'objective' analysis quite difficult, they are themselves informative. That is, they reflect how positionality affects the research process, as well as how interviewees understand their position relative to that of the researcher. Furthermore, even though the responses are necessarily influenced by the identity of the interviewer, the interview data do provide a range of viewpoints that a researcher can then use to show the diversity (or similarity) of thought on a given issue by a given set of respondents.

From a positivist perspective, on the other hand, interviews can be used to generate empirical data, which, while not free from the possibility of measurement error (Mosley, 2013), offer opportunities for objective analysis. Positivist scholars should still

pay attention to how their data-gathering strategies affect their responses (Bleich and Pekkanen, 2013), but they tend to worry less about how their gender, ethnicity, or professional status might color the responses they receive. They would assume that different researchers asking the same questions of the same individuals would receive relatively similar responses.

This is not to say that a positivist approach to interviews ignores the challenges of collecting and analyzing interview data. Certainly, information acquired from interviews may not paint the full picture. But this limitation applies to every type of data: archival evidence assumes that materials have been preserved in a representative fashion, but this is not necessarily the case. Archival materials may have been created in ways that bias the historical record; conflicts, natural disasters, and resource constraints may limit the future availability of such materials. Survey data, especially that collected by third parties, are limited by low response rates, the absence of directly pertinent questions, or poorly conceptualized items. And while focus groups may offer opportunities to understand the role of deliberation (Karpowitz et al., 2014) in group decision-making, they may offer less insight at the individual level: some participants will talk much more than others, and participants' stated (versus underlying) opinions may shift as a result of the group's conversation. One also could express concerns about the reliability and validity of work based on statistical analyses. While large-*n* analyses allow one to make claims regarding broader causal processes, they require the accurate operationalization of oftentimes complex concepts, as well as attention to the challenges of causal identification. Indeed, to the extent that the use of observationally generated quantitative data presents inferential challenges (e.g. Samii, 2016), some scholars may eschew their use in answering some questions. This, again, may represent an opportunity for using interview data instead.

Another means of addressing the measurement and inferential challenges associated with quantitative analysis is the use of mixed-methods approaches. Ideally, the advantages provided by each type of method – formal, statistical, or qualitative; observational or experimental – compensate for each method’s disadvantages. Researchers are then able to triangulate evidence, offering stronger support for a theory: interview data paired with archival data permit systematic process tracing; interview data and statistical data complement each other by offering both causal and correlative support for a given theory; interview data and formal models combine to illustrate both the experience of and the logic behind a given phenomenon.

For instance, Bunte (2019) posits that domestic political coalitions help explain the ways in which governments of developing countries access credit – do they borrow from the Chinese government or from the World Bank? His cross-national time-series analyses offer some support for his claims, but they rely on somewhat rough measures of domestic interest groups; to complement this evidence, he deploys an extensive set of interview data, based on fieldwork in three Latin American countries. Taken together, these two forms of evidence offer consistent support for his hypotheses. Similarly, Brooks (2009) draws on interviews with national policymakers, private investors, and staff members of intergovernmental organizations to test her claims about the conditions under which Latin American governments reform their social security systems. Again, these interviews offer evidence that is largely consistent with the quantitative data and statistical analyses she also reports. As we show in the next section, many scholars are already using interviews in conjunction with other methods, but, unfortunately, this applies mainly to books, not to journal articles. Indeed, the relatively low incidence of interview data in top journal publications indicates that the discipline could do a better job of capitalizing on the advantages of interview data.

## THE USE OF INTERVIEWS IN POLITICAL SCIENCE

To what extent are interviews used by political scientists? We answer this question by drawing on data from Obermeier and Pepinsky’s 2018 analysis of articles appearing in six top discipline and subfield journals (*American Journal of Political Science*, *American Political Science Review*, *The Journal of Politics*, *Comparative Politics*, *Comparative Political Studies*, and *World Politics*). In their study, Obermeier and Pepinsky (2018) coded the methods – quantitative, qualitative, and experimental – employed in every article published during 2017, as well as those published at five-year intervals from 1965 to 2015. Because we are interested in the more recent use of interviews in political science research, we limit our analysis to the articles published in 2000, 2005, 2010, 2015, and 2017. Of the 1,269 total articles included in these six journals for these years, Obermeier and Pepinsky identify 297 as using qualitative methods. A significant proportion of these use a mixed-methods design, as 139 of these 297 also employ formal, quantitative, or experimental techniques.

For each article coded as employing qualitative methods, we consult the article to determine whether it uses interviews as all or part of its empirical strategy. We identify 125 articles – 42% of those using qualitative approaches but only 9.8% of the total articles published during those years – as using interviews in some capacity. By subfield, 111 of these are in comparative politics, 12 in international relations, and two in American politics.

Figure 61.1 plots these articles as a percentage of all articles in Obermeier and Pepinsky’s sample for a given year and as a percentage of the subset of articles that were coded as using qualitative methods. It is perhaps not surprising that under the broad umbrella of qualitative methodologies, interviews are an important evidentiary tool. It is perhaps more surprising to find that even as much of the discipline has turned its attention

**Figure 61.1 Interviews in political science journals, 2000–17**

to survey and field experiments and the use of ‘big data’, the use of interviews has remained fairly steady – as a proportion of total articles – across this period. Among articles using qualitative methods in part or in whole, scholars used interviews much more often in the last decade – that is, in the years 2010, 2015, and 2017 – than in 2000 and 2005.

It is worth noting that, regardless of the year, interviews are used in only a small percentage of the *total* articles published in these six top journals. Their prevalence ranges from 7% in 2000 to a high of 13% in 2010. In 2017, the most recent year examined, interviews were used in 10% of the published articles. Moreover, this estimate is likely higher than what is extant in the discipline overall, given that interviews are most commonly used in the comparative politics subfield and that two of the journals in the dataset focus on comparative politics. Thus, it is reasonable to assume that the percentage of overall articles using interviews would be even lower were we to focus our analysis on journals in other subfields or on other discipline-wide outlets.

Certainly, these data paint only a partial picture. One could use a broader set of journals – such as those that receive greater numbers of submissions employing qualitative methods and/or additional journals with high impact factors – and potentially find different patterns. We therefore also use data from Wilson (2017), who relies on a longer time frame (he categorizes articles from 1906 through 2015), and who includes a larger number of top-tier journals (he codes the six journals analyzed in Obermeier and Pepinsky, 2018, as well as *International Organization* and the *British Journal of Political Science*). The dataset’s associated search engine<sup>2</sup> relies only on article titles and abstracts to identify terms used in these publications, which may mean that some articles end up being misclassified. Nonetheless, it identifies 175 articles (from a total of 25,845) containing the word ‘interview’. These results show a clear temporal trend in the use of interview data: only a few of the hits occur prior to the mid-1960s (Figure 61.2). Of course, what is less clear from this evidence is the extent to which interviews form a core part

The term 'INTERVIEW' appears 175 times out of 25,845 articles.

**Figure 61.2** Longer-term patterns in political science articles

of each article's empirical methodology; they might be used for vignettes rather than as key sources of data. One also might imagine that some pieces employing interviews do not mention these in their abstracts and therefore do not appear in the search results.

Even so, these data indicate that interviews are relatively uncommon in journal articles. While it is impossible to pinpoint exactly why this trend exists, we do know that using interview data in articles faces hurdles on both the researcher's side and the editor's side of the publication process. One challenge for researchers who rely on interviews is that it is often difficult for qualitatively-focused scholars to present information from, for instance, country case studies within the confines of journal word limits. Thus, we might expect to find interview data being used more frequently in books than in articles. Interviews also might be less frequently used in journal articles if it is the case that journal reviewers are more skeptical about the conclusions drawn from interview-based evidence, especially when these reviewers are unable – generally for human subject protection reasons – to access the full interview transcripts or recordings and so are prevented from validating the ways in which authors draw conclusions

from interview materials. More broadly, the attention given to causal identification in recent years creates additional hurdles to work using all sorts of observational data, including interviews, because such data are (rightly or wrongly) less likely to be seen as “rigorous”. These concerns may prevent authors from submitting work that relies partly or entirely on interviews. And, to the extent that scholars' records are evaluated based on their placement of articles in top discipline-wide or subfield journals, the perceived difficulties with placing interview-based work in journals may further deter scholars – especially graduate students and untenured faculty – from relying on (or even utilizing) interview-based approaches.

To gain a different sense of the use of interviews in political science, we also collected information on the use of interview methods in political science books published by university presses. For this analysis, we aimed not to measure the use of interview methods as a percentage of all methods or all published works – which one certainly could do, given sufficient resources to code a wide set of monographs – but rather to gain a sense of the ways in which scholars tend to deploy interviews in book-length projects. We recruited

political scientists to complete a short survey, using Facebook and Twitter to disseminate the link. Participants were recruited in two waves, in September 2018 and December 2018–January 2019. The recruitment posts were aimed at scholars who had published, or had in press, a political science book using interviews; we specified 2016–18 as the relevant time frame.<sup>3</sup> Those who opted into the study completed a short survey via Qualtrics, asking for the book's title and year of publication and about its use of interview-based evidence.

Our survey yielded 84 books. Based on our categorizations, the books fell mostly into the comparative politics subfield (n=51, 61%), although the American politics (n=9, 11%) and international relations (n=24, 29%) subfields are better represented among this set of books than in the article data above. The topics of these books are quite diverse, ranging from US state legislatures to post-conflict peacebuilding and from the use of drones to transnational labor activism.

We asked respondents whom they interviewed, as well as how they used interviews. The responses are summarized in Figures 61.3 and 61.4.<sup>4</sup> Elites and policymakers are the most common type of interviewees, used in 87% of the books reported; 39% of books rely on interviews of members of the mass public, and, of course, this implies that some books – approximately 31% – draw on both types of interviews.

We also asked survey respondents about the ways in which their books use interview evidence. The responses are summarized in Figure 61.4. Interviews are most commonly employed as part of a multi-method evidentiary strategy: over 80% of respondents categorize their use of interviews as 'one among many forms of evidence'. It also is quite common – representing half of the books described – for scholars to use interviews to develop theoretical claims. In 43% of cases, authors noted that they use interviews both to develop theory and hypotheses and as one type of data among many. What is less common, at

**Figure 61.3 Interviews in political science books, % of responses**

**Figure 61.4 Uses of interviews in political science books, % of responses**

least among those responding to our survey, is a reliance on interviews as the sole form of empirical evidence (27% of responses) or in a more limited – vignette or 'window dressing' – sense (6%). That interviews are rarely used in this very limited sense is quite striking, given that interviews are sometimes criticized as being useful for eye-catching anecdotes but for little else. The responses to our survey contradict this viewpoint, as our data indicate that scholars who use interviews are overwhelmingly using interviews to collect systematic empirical data.

Our survey of books is based only on those who responded to our call for participation.

It does appear, however, to confirm our supposition that interview-based evidence tends to appear more frequently in book-length rather than article-length publications.<sup>5</sup> This belief is further supported by data from Cambridge University Press' 2017 book catalog for politics, which consisted of books published in 2016 and 2017 (and one in 2014). According to our coding, out of 285 books offered in that year's catalog, 117 of them (41%) include interviews that were conducted by the author, and, echoing the result of the survey, these interviews were overwhelmingly used as a primary or complementary source of data, not as a source of vignettes.

Our analysis of the use of interviews suggests, then, that they are important within research that uses qualitative approaches but that qualitative-based approaches often do not feature prominently in top discipline-wide journal outlets. Our data are limited to a small set of journals (albeit with high impact factors), and we might find a greater overall prevalence of interview-focused methods were we to examine a wider set of publications. Moreover, interviews may inform the theory development reflected in articles, without being reported as a direct source of evidence. For instance, Ballard-Rosa et al.'s (2019) analysis of sovereign borrowing and domestic political institutions relies heavily on a large-n dataset of government bond issues. But the expectations developed in that piece – which link investors' assessments of political institutions with government debt managers' desires to access credit – draw significantly on interviews with investment professionals and government officials.

Yet our data likely reflect more than just an under-counting of interview-based methods in journal articles. More importantly, they reflect some of the (real or perceived) challenges associated with using interview-based approaches in article-length pieces and with finding success for those articles in the peer-review publication process. These challenges appear to be less of an impediment for book-length work. But given the overall shift

away from books and toward articles, we might worry that political science researchers are missing opportunities to deploy what is often an effective research method. In the next section, therefore, we describe some of the challenges associated with interview-based research, and we suggest some means of addressing or mitigating those challenges.

### **CHALLENGES OF INTERVIEWS: PERENNIAL PROBLEMS AND CONTEMPORARY CONCERNS**

While interviews offer researchers a flexible and versatile tool for understanding a range of political phenomena, their use is not without challenges. Some of these, such as the difficulty of acquiring proper training, the cost of interview research, and the ethics of working with vulnerable populations, are decades old. Others, such as concerns about striking a balance between confidentiality and human subjects protections versus data access and research transparency, have become more pronounced in recent years. In this section, we discuss some of these challenges; offer strategies for addressing the concrete hurdles, such as cost; and provide a look at how the discipline as a whole has addressed debates on the pros and cons of interviews, such as how to weigh privacy and human subjects protections, on the one hand, against data transparency, replication, and verification, on the other.

#### ***Reliability, Validity, and Verification***

First, as perhaps evidenced by the limited prevalence of interview evidence in many discipline-wide journals, some audiences worry about the validity and reliability of interview evidence (see also Mosley, 2013). Indeed, interviews may be brushed off as little more than anecdotes, selected to support a

researcher's framing or argument. This reaction may be explained, in part, by the use – although limited in recent years, given the data presented in Figure 61.4 – of interviews as 'window dressing'. Pithy pull quotes that catch a reader's eye, often selected because they are clever or thought-provoking, also raise concerns about representativeness, either of the entire interview with that individual or of the broader set of individuals interviewed for a project. While the desire to provide color for a project – especially one that may also use more typical forms of data – is understandable, it is also incumbent upon researchers to address concerns about how their interview data are collected, how the data are useful for crafting theories and testing hypotheses, and where potential sources of bias might exist.

While certain corners of the discipline might still protest that interviews are not systematic, comprehensive, or reliable in the way that quantitative may – or may not – be, researchers can increase confidence in their analyses by adhering to best practices regarding the collection, description, and analysis of interview data. Just as scholars who use quantitative methods are expected to refrain from p-hacking and reporting a rare specification that yields the desired results, to provide a clear description of how various concepts are operationalized and coded, and to supply the data and code used to replicate analyses, scholars using interviews should give as much information as possible (within the confines of human subjects protections) regarding their empirical strategies. While interview data will almost always be observational in nature, scholars can nonetheless address concerns about their inferential validity.

One important step in increasing the reliability of interview data is ensuring that respondents are selected as systematically and comprehensively as befits the goals of the project. Bleich and Pekkanen (2013) offer a model for this in their 'Interview Methods Appendix', which reminds scholars that when designing a study, it is important to consider what types of individuals will be

interviewed. There are many different ways to sample subjects (see Kapiszewski et al., 2018; Lynch, 2013; Martin, 2013), and one's analytical goals should drive one's choice of sampling strategies. The IRB process, a required component of interview-based research for scholars based at US universities (and sometimes beyond), also requires some reflection on how interviewees are chosen.<sup>6</sup>

Bleich and Pekkanen (2013) offer guidance on how to organize the selection of potential interviewees, as well as how to report the process by which interviewees become part of the dataset. They suggest that potential interviewees could be categorized by their profession or position within a given organization ('central banker', 'legislative staffer'), by the interests they represented in a given policy debate ('advocates for a policy' or 'opponents of a policy'), by their country or region of origin, or according to many other attributes that align with a study's theoretical claims. In some cases, a project may necessitate interviewing specific individuals rather than simply interviewing anyone who is a member of a certain category. Researchers often impose selection criteria when defining their sampling strategies; the point is to offer a transparent discussion of these strategies (as well as how effective they were in terms of efforts to recruit interviewees and problems of non-response to interview invitations).

Of course, one's project may not lend itself to specifying a comprehensive set of interviewees *ex ante*. When interviewing elites, a scholar may not always know which individuals were relevant to a given policy decision, and when interviewing members of the mass public, a scholar may rely somewhat on convenience or snowball sampling, which involves gaining the trust of a growing circle of individuals along the way. It is also particularly difficult to identify specific interviewees in advance when one's research occurs in conflict-prone or non-democratic settings or when one's research question involves sensitive topics such as anti-regime activities or sexual violence (e.g. Fujii, 2010).

But even when these concerns affect *ex ante* research design, the researcher should offer an *ex post* summary of with whom she spoke, with whom she attempted to speak but was unable to arrange an interview (the non-respondents), and how each of these individuals fits the broader aims of the empirical analyses. Beyond that, the topic and goals of each specific project should guide what additional types of interview metadata are relevant and necessary to report. For instance, a study on women's health policies should disclose what percentage of respondents were women, whereas the researcher might decide that the gender distribution of interviewees is less relevant for an analysis of how political elites advocate for party positioning on various economic issues. As a baseline, though, researchers should discuss the methods by which their sample of interviewees was recruited, including whether convenience and personal connections played a role.

Scholars also should describe, either in the main text or in a readily available supplementary appendix, the mechanics of the interviews. Assuming a semi-structured or structured approach, these metadata ought to include the questions asked of interviewees. This allows readers to assess whether respondents had incentives to misrepresent the facts or to paint past events in a more favorable light. Next, scholars should report how the interview was recorded (written notes, audio, video, or some combination), the length of each interview, and the date on which the interview occurred (one might expect that interview data could be affected by important political events). Scholars also might note how they sought to ensure the reliability and validity of interview data; for instance, did they consider using text analysis to identify systematic patterns in interview transcripts? Or did the researcher check the accuracy of interview responses – in cases where a given individual's actions in a specific instance are a matter of public or journalistic record – against third-party data?

Although we often think of interview data as being presented in the form of quotations

from the interviews, summary statistics of the mechanics and content of interviews can be helpful as well. Presenting interview data in this summary format also has the advantage of making it both easy and quick for readers to assess the reliability and validity of the data. For instance, if a medium-to-large set of individuals of a similar type are included in the sample, scholars might provide overall counts and percentages regarding the content of those interviews. For instance, what proportion of legislative staffers identified mentioned the importance of NGO or business sector lobbying? Or, when asked to describe their time horizon for making investments in developing countries, what was the distribution and mean of responses given by professional investors (Mosley, 2003)? Such summaries also allow the author to put into context specific comments or anecdotes that are drawn from individual interviews.

Establishing confidence in the reliability and validity of interview data is also helped by reflecting upon and reporting one's position relative to one's interviewees (Cammatt, 2013; Soss, 2015). We know that female scholars receive different answers than male researchers, that respondents sometimes offer different answers to co-ethnics than to perceived outsiders, and that one's identity as, for instance, a 'professor from a US university' affects both the access and answers that interviewees receive as they conduct their project (Kapiszewski et al., 2018; Su, 2017; Wedeen, 2010). It is true that the attributes of the scholar are somewhat fixed, and researchers may not know how they are being perceived or judged by interviewees. But even if we do not know exactly *how* positionality is affecting the data, it is important to acknowledge that it *is*. Thus, an engagement with these issues signals to readers that scholars are aware of context-specific challenges to reliability and validity, and, by providing data on these factors, readers will be better able to understand and assess how the data-gathering context has influenced the results (or not).

Citations of specific interview-based evidence offer another avenue for researchers to reassure readers about the credibility of the data presented. For instance, a citation might include a description of the interviewee's type and the date of the interview, thereby signaling the competence of the interviewee without compromising their identity (if guarantees of confidentiality or anonymity were given). Then, when specific passages draw on specific interviews, the interview can be referenced by number or by using such descriptors. These citations could also point to a repository (embargoed for a period of time) for interview data.

For their part, journal editors and reviewers should bear in mind the inherent tension between the protection of human subjects, on the one hand, and data access and research transparency (DA-RT), on the other.<sup>7</sup> While authors should provide some information about how they collect interview material, they are typically unable to reveal interviewees' identities or to provide reviewers with full transcripts from interviews. To do so would usually violate ethical principles for conducting human subjects research, especially when interviewees might suffer professionally or personally were information to be shared with a broader audience. Moreover, violating these guarantees would almost certainly make potential interviewees less likely to agree to be interviewed by other political scientists in the future.

These considerations reveal a fundamental tension between the discipline's move toward data access and research transparency, on the one hand, and research ethics, on the other. This tension would be difficult to resolve under the best of circumstances; doing so is rendered more difficult by the fact that, as a profession, political science has created very few formal ethical guidelines for itself. For instance, the latest (2012) iteration of the American Political Science Association's *Guide to Professional Ethics in Political Science* offers a very limited discussion – only a few sentences in length – of scholars'

responsibility to protect individuals and communities or of how political scientists ought to weight the benefits of social scientific research against the potential harms to individuals, groups, and democratic processes (e.g. Desposato, 2015). Silence on ethical issues (also see below) matters not only for interview-based research but also for field experiments, which include real-world interventions. Indeed, in 2015, the then-APSA president David Lake appointed a committee to further develop guidelines for ethical research, but given that such guidelines have not yet become part of the discipline's norms and practices (or part of what informs reviewers and editors), it is unsurprising that researchers generally struggle to balance the call for more open presentation of research materials with a concern about the confidentiality of interviewees' responses.

To a large extent, this tension is more about the data-access component – versus the research-transparency element – of the general call for scholarly openness (Bütte and Jacobs, 2015; Lupia and Elman, 2014). In most cases, although certainly not all, it is fairly easy for scholars who use interviews to be transparent about their study design and protocols without compromising the identity or the responses of study participants. The thornier question comes on the side of data access: to what extent should scholars make available, for instance, notes from or transcripts of their interviews? Granting wider access to the data might increase reviewers' confidence in the conclusions being drawn (Moravcsik, 2014a, 2014b), but it almost always violates the conditions under which interviewees consent to an interview study. Therefore, defining what DA-RT means in the interview context remains an important challenge.<sup>8</sup>

For those seeking to publish their works in political science journals, there may be a middle ground between transparency and violating human subject protections. As a condition of an article's acceptance, qualitative researchers could be asked to submit their work for verification to a trusted third party. The verifying

entity – for instance, the Qualitative Data Repository (QDR) at Syracuse University<sup>9</sup> – would be given confidential access to all materials (including interview transcripts), and the author could indicate how these underlying materials were used to generate the claims made in the manuscript. QDR could produce a verification report, shared with journal editors prior to publication, to which the authors would respond, addressing any concerns about the extent to which the interview evidence supported their claims. QDR could also hold these materials in a digital repository, where the typical provisions would include not releasing the data for 50 years. Of course, scholars would need to receive clearance from the Institutional Review Board (IRB) to take any of these steps, which may complicate matters for researchers who want to use data they collected before such norms were in place, but journals could consider making exceptions for work that uses older data.

The QDR is, in some ways, analogous to the third-party verifications of quantitative analyses that already take place in political science when the dataset contains proprietary information. In those circumstances, the author provides the verifying entity (e.g. the Odum Institute at the University of North Carolina at Chapel Hill, in the case of the *American Journal of Political Science*) with the complete dataset, as well as the required code for analysis.<sup>10</sup> But when the replication materials are posted, variables representing proprietary data are not included (a protocol that is clearly communicated both to authors and readers). Indeed, the *American Journal of Political Science*, which has required verification of the results reported in empirical articles since 2014, in 2019 submitted its first manuscript to QDR for verification and archiving. Although the article in question draws much of its data from archival rather than interview materials, it does, like most interview-based articles, use qualitative evidence to test its primary hypotheses, and it reports those data largely in a supplementary appendix (Carnegie and Carson, 2019).

It is important to note that scholars may need to anticipate the use of qualitative verification and repository mechanisms: when asking interviewees for informed consent and when filing IRB applications, they would have to indicate that materials might be confidentially shared with a replicator and perhaps embargoed in a repository. Still, despite the additional up-front work that would be necessary in order to acquire approval for these measures, such verification and depositing could allay some concerns regarding the accurate use of interview-based data.

### ***Interview Training***

Students in political science graduate programs in the United States often note that their methods-related training gives less attention to qualitative than to formal and quantitative methods. As new political scientists are often expected to have fairly extensive training in statistical and formal methods, less time is left for coursework in techniques such as archival analysis and interviewing (not to mention thematic courses in students' major and minor subfields). Students who intend to engage in fieldwork in other countries also may find it challenging to develop foreign-language skills, particularly given most programs' assistantship requirements and the pace at which they are expected to produce publishable material (Kapiszewski et al., 2015).

Still, there is certainly the potential to incorporate interview methods courses into graduate programs – after all, political methodology now exists as a distinct subfield alongside substantive subfields in many US political science departments. New journals devoted solely to articles on political methodology also have arisen; in addition to *Political Analysis*, which published its first issue in 1989, scholars can now publish exclusively methodological articles in *Political Science Research and Methods* (started in 2013) and *The Journal of Experimental Political Science* (started in 2014). However, 'methods' is

often a shorthand for *quantitative* methods, and classes in qualitative methods – including interviewing – remain rare in political science departments.

Graduate students therefore may be less inclined to consider the use of interview-based approaches – meaning that the trends described in the first section of this chapter could be reflecting supply as well as demand – when they design their own research projects. Alternatively, students who do decide to employ interview methods may receive little formal training, being told instead to ‘just talk to people’ (Mosley, 2013). Of course, some of the skill in conducting interviews and using interview evidence is developed during the interviewing process. But there is much that students can be taught and many issues that they should be reminded to consider when designing and planning an interview-based project. For instance, some interviewing strategies work better than others (and some things that work for, e.g., a tenured male academic, may be less effective for a female graduate student), and there are best practices that greatly enhance the quality and usability of the data collected, too. These practices are not mysteries; they are strategies that professors can and should communicate to graduate students.

Given that there are better and worse ways to conduct interview research, it is detrimental to the discipline as a whole to advise researchers to ‘just go talk to people’, leaving them to work out the rest through trial and error. It is very unlikely that a student who wanted to use Bayesian statistics or machine learning would be advised to figure out how to do things once they had collected data for their job-market paper or that a graduate student interested in strategic interaction would be expected to write a formal model of crisis bargaining without any graduate coursework. Interviewing is a methodological tool like any other, and political science students should have the opportunity to learn how to do it in a political science department.

Of course, some political science departments do offer courses on interviewing, and

we strongly encourage such offerings. But most graduate students who wish to use interviews are left somewhat to their own devices. Sometimes they look to anthropology, sociology, public health, or related fields for interview-related training, which, while beneficial, still might not adequately prepare graduate students for their fieldwork. Much political science interviewing involves discipline-specific considerations, as may be the case when interacting with past policymakers, who may have incentives to provide overly favorable accounts of their actions and decisions, or when asking opposition party members about anti-regime protests in non-democratic contexts. Similarly, the ways in which interview data are collected, recorded, reported, and interpreted vary across disciplines; a political science graduate student may require additional training in how best to develop a rapport with interviewees, given that she may not spend large amounts of time living and working at the fieldwork site. Thus, we emphasize the need for including interview training in political science departments.

That said, given the time and course constraints facing both graduate students and faculty, it might be easier to provide interview training as part of a broader course on qualitative or field research methods instead of as a stand-alone course. Regardless, in addition to preparing graduate students to conduct their research, offering some form of interview training helps signal that not only do faculty expect emerging scholars to embrace principles of theory development, hypothesis testing, and causal inference, but also that they acknowledge that methodological choices should be driven by the question at hand rather than the reverse. Implementing these curricular and attitudinal changes may be more difficult in some places than in others, but doing so would improve the quality of interview research and enhance the discipline as a whole.

To the extent that interview training remains unavailable in many political science departments, however, graduate students (as

well as faculty) who aspire to add interview-based components to their empirical analyses should be encouraged to seek training from other sources. These include not only standard course offerings in other disciplines but also short courses (offered by university-based social science data institutions, as well as at the APSA annual meeting) and summer institutes (e.g. The Institute for Qualitative and Multi-Method Research's summer program includes a module on interviewing).

### ***Time and Money***

Another potential obstacle to conducting interview research is the cost of traveling to speak with people in person. The time and money – as well as the impact on the earth's climate – that must be expended in order to travel to meet with potential respondents can be overwhelming, especially for graduate students and other scholars without generous research budgets. Scholars based in the United States, for instance, may find that the best times (given their teaching schedules) for research-related travel also feature the highest airfares.

These challenges are especially daunting for graduate students, who may have to finance their research trips personally. Graduate students in comparative politics are particularly likely to face this problem, given that the subfield values fieldwork of some sort or another. Dissertation committees, journal referees, and hiring committees often reward researchers who can show that they have visited the countries they study and met with individuals involved with the topics at hand. This fieldwork is expected to consist of several months, or at least several weeks, in a given country, which often means that students must take a leave of absence from their home university for a semester or travel during the summer. Graduate students therefore may find that in the absence of grant funding, they need to simultaneously finance fieldwork and take leave from income-generating teaching.

Moreover, graduate students may face contending pressures to conduct qualitative research abroad but also to limit (compared with prior generations) the time it takes to complete their PhD. This pressure, coupled with more limited area-studies training, may disadvantage graduate students in political science (relative to graduate students in other social science and humanistic disciplines) when competing for fieldwork funding (Agarwala and Teitelbaum, 2010). Although untenured faculty generally receive more compensation and research funding than graduate students, they are still likely to face challenges in finding material resources and time for extended research trips. Even tenured faculty may find it hard to travel for interview research, given their administrative, advising, and/or teaching responsibilities – as well as their desire, sometimes, to limit travel in order to minimize time away from partners, children, and aging relatives.

Field experience is, of course, invaluable; it often allows scholars to discover things and to develop a sense of causal processes that cannot be gained via secondary sources. In some contexts, interviews cannot be arranged prior to one's arrival at the field site; if one needs to identify possible interviewees once on the ground or build trust with community leaders in order to gain access (Reno, 2013), then travel is almost certainly necessary. And, while the interview itself is a key source of data, so is the surrounding metadata: how does an interviewee introduce themselves to the interviewer, or how does an interviewee relate to other colleagues at the office? To what extent is the interviewer welcomed into the community or received with suspicion, given their nationality or perceived professional background?

Nevertheless, not only *can* researchers with limited funds still conduct interview research, but they *should* also be encouraged to do so if interviews are a suitable method for developing or evaluating their research question. In some instances, creative thinking can help to reduce travel costs. For instance,

a researcher studying foreign direct investment might consider attending a conference targeted at professionals who work on investment promotion. The conference sessions themselves can provide useful background information, and the researcher can set up meetings with (and perhaps surveys of) individuals from a variety of countries, who will all be in the same place for the meeting (e.g. Bauerle Danzman, 2017). And when academic conferences are held in the same location as potential interviewees – for instance, for scholars of the US Congress or of international financial institutions when APSA is held in Washington, DC – it may be possible to schedule in-person meetings.

Technology also can enable further use of interviews. Phone, Skype, and FaceTime interviews can be excellent alternatives, particularly when time and money are tight. Certainly, making explicit the process of informed consent and developing clear expectations about whether the interaction is recorded are especially important in these settings, and researchers may need to work harder to develop an interpersonal rapport with interviewees. Still, these sorts of distance interviews are almost always better than no interviews. They also may be used to ask follow-up questions once the researcher has returned home from a face-to-face interview, had time to process the data, and identified a point that needs further clarification.

Such workarounds may not be appropriate or feasible for all research questions, of course. Depending on the country and the type of individual being interviewed, potential interviewees may have limited phone and/or internet access. Elite respondents might have their contact information online, but arranging meetings with them may require navigating their administrative staff. By contrast, mid- and lower-level government staffers may be difficult to identify and locate from afar. The same may be true for members of the general public, although social media could facilitate the identification of such individuals (Côté, 2013). Conducting

interviews in a second or third language also may be harder over the phone, and the absence of body language can complicate attempts to translate across cultural divides. These problems should not be taken lightly, and, in some cases, they may preclude gathering satisfactory data without in-person interviews. However, many researchers will find that they can maintain the integrity and quality of their research without always having to expend the time and money that traditional, in-person interview research entails.

## ETHICAL CONSIDERATIONS

When designing any empirical research project, political scientists should consider the ethical issues it presents: how, for instance, would providing information to some individuals about candidates' voting records affect not only individual voting behavior, but also an election outcome (see Desposato, 2015)? Or how might priming individuals to focus on racial resentment in the context of a survey have effects for future political and social behavior? Interviews also might retraumatize participants who are asked to recount violent events or inadvertently endanger respondents from non-democratic political systems if answers to sensitive questions are later shared with a broader audience. These concerns are not to be taken lightly, and it is the responsibility of researchers to seriously consider the potential harm that their work could cause to interview participants (Wood, 2007).

Often, these types of ethical considerations are first outlined and addressed in the context of acquiring formal approval for a research project. Researchers at academic institutions in the United States must typically acquire approval for interview work from their school's IRB, which reviews all research involving human subjects. Other countries, as well as some subnational entities, also have IRBs or their equivalents,

meaning that interview-based research projects may require review by multiple bodies. It is often at the point of completing human subjects research certification, or in the process of creating documents for IRB review, that scholars consider the requirements for informed consent, as well as how best to protect participants' confidentiality and/or anonymity (Brooks, 2013).

University-based IRB protocols are designed to ensure that studies meet federal ethical guidelines; for academic institutions, it is the threat of withdrawal of federal funding or other government sanctions that typically motivates the IRB process. In this context, researchers are asked to document how they plan to minimize or eliminate the potential harm that interviewees could incur as a result of agreeing to participate in a research project. IRBs vary significantly in how they approach interview-based projects: for instance, some require the scholar to list a specific set of individuals to be interviewed as part of the approval process. Other IRBs allow scholars to specify types of interviewees, without providing specific names *ex ante*.

It is important to remember, however, that the IRB process does not exhaust the limits of a researcher's ethical obligations. IRBs are designed primarily to protect the university and the researcher from legal liability, not to ensure the absolute wellbeing of research participants. Additionally, despite the best intentions of IRB members, these individuals cannot possibly be familiar with the specific research context in which every proposed research project will occur. This, in turn, necessitates a certain amount of transparency on the part of the researcher; if researchers are not forthcoming, IRBs may not be fully aware of the potential hazards to subjects involved.

Thus, it is the duty of each individual researcher (or, in some cases, each member of a larger research team) to familiarize themselves with the context in which the interviews will be taking place and to do their due diligence in safeguarding their respondents' wellbeing. The precautions necessary to

ensure respondents' safety may change over the course of a study; topics that were banal at the start of a research project can become flashpoints as a result of unexpected events, or a researcher can realize that they have misjudged the sensitivity of their research topic and need to adjust their questions or data-security measures accordingly. In such situations, it is incumbent upon the researcher to move beyond the protective measures that were included in the original, IRB-approved research protocol and ensure that respondents are not subjected to physical or emotional harm by granting an interview. This is particularly true when the research involves interviewing members of vulnerable groups – for instance, victims of wartime sexual violence or members of an underground opposition movement in a repressive society.

While the protection of human subjects should be of primary concern to researchers, such protections sometimes appear to be in conflict with emerging trends toward data access and research transparency. As we note above, transparency regarding the interview process helps to increase confidence in interview-based analyses, but data access raises thorny ethical and practical questions. Recording and/or sharing interview notes or transcripts is at odds with many human subjects protections, whether interviewees are elites or members of vulnerable populations, and, even if the interview recordings or transcripts can be made available, they will be devoid of potentially important contextual variables, given the protections typically promised to interviewees, as well as the potential for positionality and interviewer effects. This, in turn, leads to an increased likelihood that the data will be misinterpreted, which could cause embarrassment, distress, or harm to the original respondent. Thus, it is understandably difficult to acquire IRB approval and respondents' consent to share recordings, notes, and transcripts.

Although the difficulty of sharing – much less replicating – interview data has not grown over time, the perceived magnitude

of the problem has, because political science is placing more importance on making the research process as transparent as possible. The discipline increasingly, and often for good reason, puts a premium on providing verification or replication materials. Although this is a laudable effort, it does conflict directly with the ethics of interview research, which privilege respondents' privacy and safety above all else. In some cases, the need to protect interviewees' confidentiality simply makes it impossible for researchers to satisfy both the discipline's emerging norms and the standards of ethical research.

Researchers can still provide some transparency about their data without releasing full interview transcripts, as we note above. Again, we recommend that scholars report summary statistics about respondents either in tables in the text or appendices. As the number of interviewees increases, it might even be possible to supply some fairly detailed data (about the interview sample as a whole) while still protecting respondents' confidentiality. The data could consist of information that is useful in any study, such as the occupations of interviewees or their geographic location, or it could be worth reporting only because it is relevant to the topic at hand, such as an overview of respondents' migration histories, average number of years that informants spent in parliament, or interviewees' religious identity. Of course, researchers must record these characteristics from the start; trying to collect this kind of data after the fact is tricky, if not simply impossible. Still, if scholars are systematic and intentional about the way they solicit, collect, and publish interview data, there are ways to provide a measure of much-needed transparency and still abide by the ethical rules of human subjects research.

Depending on the context, it also can be difficult to ensure that respondents are providing truly informed consent when they agree to allow their words to be made publicly available. This is less likely to be a problem when interviewees are elites who

share the same language and culture as the researcher, but explaining academic research and publishing practices across linguistic, cultural, and/or educational divides can be a fraught process. In some cases, scholars may technically have a respondent's consent to cite and provide free access to the interview data, but their sense of a respondent's level of understanding will compel them to withhold identifying information for certain quotations or to keep certain segments of an interview private (e.g. Wood, 2007).

Even when individual respondents are amenable to having their responses made publicly available, such openness can threaten to undermine other interviewees' willingness to offer information. Seeing the details of supposedly private meetings and conversations referenced in scholarly pieces or reading about one's profession or political strategies portrayed in an unflattering light can cause future interviewees to think twice about granting access to interested scholars. It also is possible that what seems to interviewees like harmless information to reveal at one point in time may seem more harmful in the future, as individual or national political circumstances change. Similarly, if interview data are used and misinterpreted by scholars who were not present for the interview but rather accessed the transcripts online, a formerly willing interview respondent may decide not to participate in future research. This may not occur frequently, but the risk exists.

The potential damage to researchers and their colleagues can be even greater when researchers share data without respondents' consent. Such privacy breaches need not be the result of ill intent; researchers may incorrectly file an interview, forget to mark whether a respondent agreed to be quoted by name, or have a laptop stolen. This need not be a catastrophic event; depending on the topic and the respondents, a privacy violation of this sort may cause no harm and attract no attention. However, it is distinctly possible that such violations of research ethics will threaten not only one's own scholarly enterprise, but also

access for future researchers. This underscores the importance for researchers of carefully documenting consent for each interviewee, of keeping files secure through encryption or strong password protection, and of regularly considering how changing circumstances in the interviewee's political context may change the meaning of informed consent.

The issue of proper training becomes even more critical in this light – an emphasis on proper technique, best practices, and familiarity with IRB requirements, as well as broader ethical considerations and guidelines, will help ensure that potential interview respondents remain willing to discuss and share their experiences with scholars.

## CONCLUSION

This chapter has discussed certain unique characteristics of interview research, the challenges associated with interview-based approaches, and ways to improve and expand the use of this tried-and-true method. As we have shown, even in a world in which most of the methodological attention is on causal identification and the use of big data of various forms, interviews remain both relevant and useful. Consequently, graduate programs should help their students to acquire proper interview training, departments and journals should encourage scholars to utilize interviews in their research, and researchers should familiarize themselves with the advantages and drawbacks of this unique method.

As the data in the second section of this chapter demonstrate, interviews remain a small but integral part of political science research. In light of increasing privacy concerns and the hesitancy of elites to leave digital footprints, they may come to play an even more central role in projects that seek to make and test causal claims. Certainly, the discipline would benefit richly from ensuring that both current and future researchers are aware of the utility of interviews for their

projects, have the training they need to conduct interviews professionally, and understand the pitfalls and positives of interview research. With better training and a more professional approach to conducting interviews, political scientists may find that interviews are appropriate for a wider range of projects than they had considered. This, in turn, may make researchers more likely to incorporate interviews into their own work, which would increase the use of original data, expand the wider availability of interview data, and allow scholars to make more valid and robust causal claims.

Our discussion of the issues surrounding interview research both acknowledges and demonstrates that it may take much longer to responsibly gather, analyze, and present interview data than it does to write an article using a pre-existing quantitative dataset. However, given the ways in which interviews can contribute to the development of theory, the testing of hypotheses, and the richness of the discipline, there are strong reasons for researchers to invest in interview research and for journal editors to set clear standards that will facilitate the publication of interview-based work in political science outlets. Interviews may not be trendy, statistically complex, or methodologically innovative, but, as this chapter shows, they are an invaluable resource for scholars in every subfield.

## Notes

- 1 We thank Elizabeth Osman for assistance in gathering the Cambridge University Press catalog data reported in this chapter.
- 2 [https://mcwilson215.shinyapps.io/comparative\\_trends/](https://mcwilson215.shinyapps.io/comparative_trends/)
- 3 This study was deemed exempt by the IRB at the University of North Carolina at Chapel Hill (Study #18-2544), and it was approved and declared exempt (Protocol H18360) by the Institutional Review Board at the Georgia Institute of Technology.
- 4 In many cases, respondents chose more than one category to describe their use of interviews, so the percentages in Figures 61.2 and 61.3 sum to more than 100.

- 5 One also might code dissertation abstracts for the use of interviews; this would offer a better gauge of the use of interviews among doctoral students.
- 6 It is worth noting that even among US universities, the requirements of the IRB with respect to specifying interviewees and interview questions vary dramatically across institutions.

# Focus Groups: From Qualitative Data Generation to Analysis

Virginie Van Ingelgom

## INTRODUCTION

The idea that interviewing several people at the same time might be more advantageous than interviewing them separately was discovered a long time ago.<sup>1</sup> In a focus group, a set of people are invited by a researcher to discuss a political topic or a set of social issues and are queried concerning their ideas, beliefs, or perceptions. The researcher plays the role of a moderator and a discussion is takes place between the participants. Robert K. Merton's 'focused interview' was only one among several suggestions about the reasons and the ways to interview several people at the same time (Merton and Kendall, 1946). Merton's model became successful in the field of applied research and consulting, where its technical aspects were refined during the 1970s and the 1980s (Copsey, 2008). In the 1990s, social sciences rediscovered the method and a variety of uses and techniques now exist.<sup>2</sup>

This chapter presents the focus group method as a strategy of data collection. Focus

groups may be common to many disciplines, but its uses vary greatly. If interviewing has been a fundamental technique of data collection in political science and international relations, focus groups are still less commonly used than face-to-face interviews or even oral history (Kapiszewski et al., 2015). This chapter deals with the question of how this method is specific in its contributions to political science and international relations.<sup>3</sup> There is indeed a strong relationship between discipline, theory, and practices, as opposed to a tendency to generalise a one-size-fits-all approach to using focus groups. For example, the number of participants involved or the role of the researcher can vary greatly depending on the objectives of the research and the subfield or research. Whereas marketing research will mobilise larger focus groups with 10 to 12 participants, an in-depth political sociologist fieldwork project on citizens attitudes towards European integration will prefer gathering four to six participants. This chapter does not provide a practical

how-to guide for organising and facilitating focus groups.<sup>4</sup> Instead, it unpacks the methodological choices for using focus groups in political science and international relations, which is the primary purpose of this chapter. Therefore, the image of this method that is drawn here is necessarily selective.

The method presented in this chapter embodies most of the challenges and specificities of qualitative research. However, what chiefly characterises focus groups is the richness of the data collected as the purpose is to obtain group data, and not only data associated with particular individuals (Kapiszewski et al., 2015: 201). However, this richness is costly in comparison to what can be achieved with more standard research methods, such as face-to-face interviews or survey questionnaires. Using focus groups not only requires more resources than other qualitative methods, it also requires a large series of decisions to be made concerning the different technical aspects involved from design to moderation. More importantly, analysing focus group data leads to specific challenges, at least for research purposes. Thus, it seems quite important for researchers to get a clear idea of the characteristics and consequences of this method before using it. This chapter aims to help the reader decide if the method is appropriate to her own research project, which is the secondary purpose of this chapter.

By reviewing all the difficulties of focus group research, the chapter will come across most questions faced by qualitative researchers, both epistemologically and technically. By focusing on its specificities, it will present the trade-offs, pros, and cons of using focus groups but also of using different types of focus group. More precisely, the topics covered by the chapter will be organised as follows: first, the chapter identifies the domains and research questions where using focus groups is the more useful in political science; then, the chapter discusses the design of focus groups including sampling, questioning, and moderating, as well as issues related to their practical organisation; and finally, yet

importantly, the chapter puts a strong emphasis on analysis – from general principles to specific challenges of analysing focus groups before turning to some concluding remarks.

## **INTRODUCING FOCUS GROUPS TO POLITICAL SCIENTISTS**

Beyond the actual definition of the focus group, the scientific uses of focus groups as a strategy of data collection are quite diverse. Indeed, focus groups can be used in very different epistemological frameworks. The success of the focus group as a strategy of data collection is in part due to its appropriateness for research questions and the role accorded to it in the research design. Therefore, before one goes into its practical dispositions, it is important to understand the uses of focus groups and their appropriateness in political science.

### ***What is a Focus Group?***

Focus groups fall within the qualitative research tradition in political science and international relations. ‘Collective interviews’, ‘group interviews’, ‘discussion groups’, or ‘focus groups’ all refer to interviews conducted with several respondents at the same time. In order to define more precisely what is meant by the term focus group in this chapter, the three-point definition provided by David L. Morgan – an author who was essential in developing this method for use in social sciences – is a useful starting point. He defines a focus group ‘as a research technique that collects data through group interaction on a topic determined by the researcher’ (Morgan, 1996: 130).

Three elements stand out in this relatively inclusive definition. First, the focus group is a research method designed to collect data. Thus, focus groups are intended for research interests – in other words, for collecting discursive data aimed for systematic analysis.

Second, in the focus group, the source of data lies in the interaction within the discussion group; the relations that characterise them are not reduced to the relationship between the facilitator and interviewee but require the interactions of a collective discussion between the participants. Third, and finally, the focus group supposes the intervention of the researcher in the creation of the group discussion in order to collect data, as they will pose questions and facilitate the discussion – even if the participants shape the direction and the emphasis of the discussion. Thus, data are provoked and collected by a researcher on themes that they have chosen.

This definition enables one to exclude a series of configurations similar to focus groups, such as collective interviews used outside a research context (e.g. marketing or training purposes).<sup>5</sup> It also enables one to distinguish this method from other procedures including multiple participants but ones that do not allow the emergence of interactive discussions between them – such as group experiments aimed to record actions rather than discourses.<sup>6</sup> This definition also excludes direct observation of naturally occurring political discussions that cannot be described as interviews because the researcher does not intervene in the creation of data. Collective interviews, therefore, cannot be conflated with ordinary conversation, such as what might occur in everyday life.<sup>7</sup> The framing of the discussion is always made clear by the presence of a moderator who imposes the subject on the participants and makes sure – in a more or less direct manner – the discussion is kept alive. The researcher selects the focus. Originally, in Robert K. Merton's 'focus interview', interviewees were involved in a particular concrete situation – for example, watching a movie – that was the focus of the interview (Merton and Kendall, 1946). In contemporary political science, collective interviews are organised around topic(s) rather than common experience (Duchesne, 2017). The focus group also differs on these different points from the citizen conferences initiated by

political actors as a way of including citizens in the political decision-making process and reinforcing deliberation and public debate – often called 'mini-publics' (Grönlund et al., 2014; Jacquet, 2018).

### ***The Different Approaches to Focus Groups in Political Science***

Apart from this common definition, there are many practices of focus groups across disciplines or even researchers. Focus groups became prominent in the social sciences in the 1980s, having been developed and standardised over a few decades within the market research profession (Morgan, 1997). The adoption of this strategy of data collection in social studies was due to two factors (Duchesne et al., 2013). First, researchers on the margins between the social sciences and marketing pushed for the focus group to be used as a method that was likely to collect – in a more advantageous way than the individual interview – a substantial number of opinions in a short period of time (Krueger, 1994). Second, researchers in the social sciences saw this as a way to depart from an essentialist approach to opinions (Wilkinson, 1998). The focus group method enables the analysis of the co-construction of meaning thanks to the recording of interactions between participants. Thus, in political science, the practice of focus groups stems from a historical and classical tension between positivist and constructivist approaches.<sup>8</sup> Nowadays, and as discussed more broadly in the field, many researchers seem to adopt elements from both traditions (Soss, 2006).

This dual heritage is still evident today. On the one hand, the method is easily accepted and promoted in its canonical form by social scientists who use statistical methods, despite their concern about the group dynamic as a potential source of bias compared to the expression of individual opinions. On the other hand, researchers who emphasise the interpretive nature of data analysis, and who

see in it an instrument adapted to innovation and to methodological experimentation, also particularly value focus group research (Morgan, 1993; Barbour and Kitzinger, 1999). Thus, focus groups as a research tool – and as a research choice – gives rise to potentially contradictory methodological debates stemming from the distinct disciplinary backgrounds and epistemological assumptions of researchers (Barbour, 2007: 2). These contradictory uses are, at the same time, at the heart of the richness of this methodology. Thus, focus groups are a very flexible research method and therefore have a wide variety of applications: exploratory research, explanatory research, and evaluation research, for example (Hennink, 2014).

Exploratory research is one of the most common applications of focus groups in political science. The group dynamic makes focus groups an ideal method of data collection to explore a topic about which little is known. David M. Farrell and Michael Gallagher (1999) emphasised this point in their focus group research on voters' attitudes towards electoral systems – a topic that is not the subject of intense debate in the electorate. The authors wanted to explore what UK voters know and do not know about electoral systems. Once the basics of the four different systems were clarified, the participants of the focus groups demonstrated that there was clear evidence of support for change, though with little agreement over the preferred system. Mobilising focus groups discussion, Farrell and Gallagher's research reveals a certain ambivalence over the importance attached to constituency representation.

The exploratory use of focus groups also reveals a related advantage in that it has been applied in situations where there was a substantial difference in perspective between researchers and participants (Barbour, 2007; Morgan, 1996: 133). Here the advantage comes from the group dynamic that enables the participants to talk in their own terms as they are discussing together. This argument has been developed in the context of studies

on the risks of HIV within the male homosexual and bisexual community (Barbour 2007). However, it seems that it can be usefully applied to topics in political science as well. Indeed, a minimum of reflexivity regarding the profile of a given political scientist and their generally very specialised perspective calls into question their ability to consider the political issue in terms that correspond to the perceptions of less competent or politically interested people. As Pamela J. Conover et al. (1991: 805) underline, the group dynamic assures that 'participants talk to one another in their own language, rather than simply reacting to the questions and language of an interviewer in a one-to-one situation'.

This exploratory research application of focus groups should not undermine the potential of focus group as an effective tool for explanatory research. There are numerous examples of focus groups as a primary method in research about politics (Akachar et al., 2017; Billig, 1992; Damay and Mercenier, 2016; Delmotte et al., 2017; Duchesne and Haegel, 2004a, 2010; Duchesne et al., 2013; Frazer, 1988, 1989; Gamson, 1992; Hopf, 2002; Jarvis and Lister, 2012; Marsh et al., 2007; Stocker et al., 2016; White, 2011). Focus groups provide an opportunity for the researchers to gain access not only to certain political beliefs or attitudes, but also to identify the underlying context in which they develop – subsequently enabling an understanding of *how* participants think about political issues and not only of *what* they think. For example, in public opinion research, 'focus groups are valuable in revealing the process of opinion formation, in providing glimpses of usually latent aspects of this process, and in demonstrating the social nature of public opinion' (Delli Carpini and Williams, 1994: 62). By forcing participants to 'think out loud', focus groups enable an observation of the process of opinion-formation in action and in interaction with one another.

As the principal asset of focus groups is to provide a tool for participants to discuss

and debate, focus groups have proven useful for studying (de)politicisation and, more precisely, to understand how citizens ‘talk politics’ or resist the idea of discussing politics (Conover and Searing, 2005; Gamson, 1992).<sup>9</sup> In this respect, focus groups – when designed appropriately – can generate data on how citizens get involved or not in political discussion (Duchesne, 2017). Focus groups are particularly useful for studying topics that are considered either sensitive or difficult for people, as the dynamic of group discussion helps individual participants to get access to more ideas or to express things that would otherwise be too difficult. Political issues are not only complex, but also contentious.

Moreover, the focus group is a research tool that gives a voice to the research participant by giving them an opportunity to define what is relevant, salient, or important for understanding their experience or perception. Here, the non-directive approach of a focus group is essential in order to assess the salience of a political issue.<sup>10</sup> Robert K. Merton and Patricia L. Kendall (1946: 545) already argued in this line in the 1940s, asserting that the non-directive approach:

gives the subject the opportunity to express himself about matters of central significance to him rather than those presumed to be important by the interviewer ... it uncovers what is on the subject's mind rather than opinion of what is on the interviewer's mind. Furthermore, it permits subject's responses to be placed in their proper context rather than forced in the framework which the interviewer considers appropriate.

Finally, focus groups provide an effective tool for evaluative research, in particular for the evaluation of public policies, to examine the effectiveness of a program or policy instrument (e.g. Hsiao-Li Sun, 2012; Shek, 2017). The idea is to uncover the strengths and weaknesses of policy instruments in an evaluative perspective. Traditionally, public health policies have been largely evaluated through the use of focus groups (Basch, 1987). For example, focus groups have been used to examine how the LGBT community processed media messages about HIV/AIDS

and how they influenced peoples' perceptions of AIDS (Kitzinger, 1994).<sup>11</sup>

### ***Combining Focus Groups with Other Methods***

Originally, in Robert K. Merton and Patricia L. Kendall's ‘Focused Interview’ in the 1940s (1946), focused interviews were used to clarify the results of experiments – watching film series in order to study the role of mass communications in the dynamics of attitude formation and change (Delli Carpini and Williams, 1994). In this tradition, focus groups continue to be used not only with experiments, but also with participant observation, face-to-face interviews, and surveys (Morgan, 1988: 30–6). In particular, studies using both focus groups and opinion surveys, drawing on qualitative and quantitative data, are very common. Thus, one specificity of focus group research is that it has been widely used alongside other methods in mixed methods studies (Hennink, 2014: 17).<sup>12</sup> David L. Morgan cited more than 60% as the number of empirical publications using focus groups along with another method (Morgan, 1996: 130). As a result, the combination of methods has been the object of close attention in manuals on focus groups, methodological reflections anchored more broadly in a concern for triangulation (Barbour, 2007: 46–7; Caillaud and Flick, 2017). David L. Morgan (1993, 1996: 134–6) pursued this reflection in depth, proposing a conceptual framework that identified four different ways of combining qualitative and quantitative methods – and collective interviews and opinion surveys in particular. For example, focus groups can be used before conducting a survey to identify salient issues in the current political debates on which to develop survey questions, refine a question's wording, or specify relevant response categories in order to increase data validity (Conover et al., 1991). They can also be used as a microscope to understand surveys' answers (Van Ingelgom, 2014).

### ***When not to use Focus Groups in Political Science?***

If the approaches are multiple – exploratory, explanatory, or evaluative – focus groups are not always the most appropriate method to use and can lead to poor quality research. Most of misuses of the focus group method result from the collective nature of data collection. To this regard, when compared to traditional research methods, focus groups must be placed on a continuum between ethnography's emphasis on naturalness and unobtrusiveness on the one hand, and the greater control provided by experiments and in-depth interviews on the other (Delli Carpini and Williams, 1994).

On the one hand, compared with ethnographic approaches such as participant observation, the setting of a focus group is less natural, in the sense that the researcher creates the situation to be observed in order to collect her data. If naturalness is of primary importance, then the focus group is not the most appropriate tool as the setting will remain artificial. On the other hand, compared to experiments, the logic of the focus group – even in a very positivist approach – is not in isolating specific cause and effect relationships. More precisely, to assess the adequacy of the method, one needs to consider the collective and interactive dimension of the data collected. The group dynamic is at the heart of most methodological problems.

To this regard, focus groups are less suitable for eliciting personal experiences or individual narratives from each participant. Even if participants may share their individual story with other participants, who can be strangers, there is insufficient time to provide a personal narrative about a specific topic. Moreover, due to the dynamic of discussion, individual narratives will be fragmented, incomplete, or even confused as other participants interrupt or question each other. Of course, this is less of a concern for focus groups with fewer participants (Barbour,

2007). If the researcher is attempting to collect data on individual narratives, then they should carry out individual interviews. In other words, a focus group is not simply a means for obtaining accounts of individuals, rather it is 'a means to set up a negotiation of meanings through intra- and inter-personal debates' (Crang and Cook, 1995: 56).

Finally, the choice of focus groups as a research tool is based on the conviction that individual attitudes are not given, but instead result from a process of construction that occurs using speech in a collective and sometimes even contradictory context (Duchesne and Haegel, 2004b; Duchesne et al., 2013). Thus, focus groups assume – contrary to surveys – that attitudes, opinions, and perceptions are developed in part in interaction with other people and opinions cannot be observed in a vacuum as individuals do not form opinions in isolation. At the heart of the method is the analysis of shared meanings and disagreements. Thus, obviously, focus groups are not an appropriate method to measure attitudes (Barbour, 2007: 19).

### **DESIGNING AND CONDUCTING FOCUS GROUP RESEARCH**

Even if focus groups are tailored to particular research questions, any researcher aiming to conduct focus group faces the same set of important choices. Who to recruit as participants? How to recruit participants? How many groups to run and how many people to gather in each group? How to stratify participants in each group? There are no definitive answers to these questions and certainly no one-size-fits-all approach to using focus group in political science and international relations. Nonetheless, there are general guidelines and important considerations when conducting focus group research that can improve methodological rigour and, thereafter, the quality of data produced (Hennink, 2014).

## ***Research Design and Sampling***

Like any other strategy of data collection, focus groups call for due attention in developing an appropriate and rigorous research design. As, 'the essential purpose of focus group research is to identify a range of perspectives on a research topic, and to gain an understanding of the issues from the perspective of the participants themselves' (Hennink, 2014: 2), effective sampling is key to the success of focus groups and to determining their comparative potential (Barbour, 2007: 3). By providing access to a wide range of political views, perceptions, or experiences, the group setting increases the likelihood of unexpected results emerging from focus group analyses (Delli Carpini and Williams, 1994).

As the focus group is a qualitative methodology, participants are not selected by means of systematic random sampling. The purpose of qualitative sampling is, indeed, to reflect the diversity within the population under scrutiny or to select a group in order to observe within-group dynamics rather than aspiring to recruit a representative sample (Kuzel, 1992). As underlined by Richard A. Krueger and Mary Anne Casey (2009: 66), the purpose of focus groups research is 'not to infer but to understand, not to generalise but determine a range, and not to make statements about the population but to provide insights about how people in the groups perceive a situation'. Thus, the objective is never to aggregate individual attitudes from a systematically random sample in order to generalise about a wider population. If this were the aim, then focus groups would inevitably be negatively evaluated, as even dozens of focus groups gathering hundreds of participants would never be representative of the entire population (Stanley, 2016).

The logic behind sampling is instead theoretical, as the researcher theorises on the dimensions that are likely to be relevant in order to give rise to differing political beliefs, perceptions, or experiences. Thus, 'sampling relates to the anticipated use of

the selected criteria in making comparisons once the data have been generated. In other words, purposive sampling allows for the data to be interrogated purposefully, that is, in order to carry out systematic comparison' (Barbour, 2007: 58). Sampling is central and theoretically driven; comparison and segmentation are at the core of a focus groups research design.

## ***Comparison and Segmentation***

Since the groups are the main unit of analysis, it is a classical rule to convene these to facilitate comparison. The question of the comparison is central when it comes to group composition and to the number of focus groups that are ultimately conducted. Indeed, the question of how many groups to hold reflects the comparative research design. The number of groups is determined by the comparisons that the researchers wishes to make and thus by the sub categories the researcher wants to target. The more segmented groups are – for example, by education, country, or age – the more groups will be necessary to complete the research design.

However, it is fundamental to consider that each participant may potentially meet several of the desired criteria in terms of diversity – for example, education, age, political affiliation. Then comparisons can be made based on fewer groups than sampling might suggest, as intra-group comparison is also an important tool of analysis. Moreover, the number of groups to be conducted is not only guided by the comparative research design, but also by the principle of 'saturation' (Glaser and Strauss, 1967). Saturation is 'the point at which information collected begins to repeat itself. After reaching the point of saturation, any additional data collection becomes redundant, because the purpose of qualitative research is to uncover diversity and context, rather than a large number of participants with the same type of experience' (Hennink, 2014: 43).

*An Example of a Comparative Research Design: Citizens Talking About Europe (Duchesne et al., 2013: 160–195)*

The *Citizens Talking About Europe* (CITAE) project was set out to gather and record discussions between citizens in Paris, Brussels, and Oxford on the subject of Europe. In analysing what makes sense for the participants in these discussions, the aim was to understand how citizens (de)politicise European issues. The CITAE project convened 24 focus groups, each consisting of four to eight participants. Groups were constituted according to a two-fold criterion of social and national differences (double-layer design). The sampling strategy builds on survey research that shows the profound effects of national as well as social differences on attitudes to European integration. Therefore, the groups were constituted in such a way as to differentiate social and national characteristics. Thus, the social homogeneity pursues both a methodological and a theoretical objective. From the methodological perspective, it was essential to ensure a minimum of shared comprehension, linguistic rapport, and relatively easily communicable social experiences between the participants in a group. At the same time, it was important to avoid striking social differences of the kind that generate domination effects. Three social categories according to occupation – workers (and/or unemployed, or casually employed), employees, and managers – were distinguished. The research team also added a fourth category, party activists, with the idea of gathering competing partisan views of the subject. Finally, the CITAE research team convened two of each category of groups in order to control the effects of group dynamics and to reach saturation.

**Double-layer design**

	<i>Belgium</i>	<i>France</i>	<i>UK</i>	
Working class	2	2	2	Saturation?
White collars	2	2	2	
Managers	2	2	2	
Activists	2	2	2	
	Saturation?			

Researchers have reported on the results of as many as 66 focus groups (Liebes and Katz, 1990), 37 focus groups (Gamson, 1992), and as few as six focus groups (Damay and Mercenier, 2016; Delmotte et al., 2017). A well thought out comparative research design should, however, lead the researcher to keep the number of focus groups to a bare minimum as the researcher should also consider time constraints – recruitment, transcription, and analysis of focus groups are all very time consuming.

When it comes to the theoretical sampling criteria – also called segmentation – of the groups, in political science research in particular, social stratification is made necessary

by the characteristics of focus group method itself. Speaking in public, especially on political subjects, is socially determined. There is the matter of greater or lesser ease of expression, and of confidence in the ability to say what one is thinking and to convince others about what one believes. There is also the matter of the use of words, the structures of language, and cultural references. Thus, one of the golden rules when selecting the participants for a given focus group is to secure social homogeneity in order to minimise domination. Education and occupation of participants are a classical proxy in order to achieve social homogeneity.

Of course, many focus groups discussions have a dominant participant who monopolises the discussion, is always the first to respond to a question, or provides lengthy comments (Ritchie and Lewis, 2003). Nevertheless, social homogeneity determined by the education and/or the occupation of participants – and attentive moderation – will limit the risk of domination and ensure that the other participants are not completely overshadowed or inhibited.

### ***Recruitment Strategy and Selection of Participants***

Whether working on quantitative or qualitative data, the quality of recruitment is a decisive factor in the reliability of the survey. In the case of focus groups, the issue is twofold. Because, by recruiting, one builds not only a sample according to criteria that will weigh on the comparative analysis, but also a group whose interactions will be decisive for the quality of the material (Duchesne and Haegel, 2004b: 45). Although collective interviews are not more complicated than individual interviews in terms of recruitment, they are in terms of their implementation. For example, if an error of selection occurs in an individual interview, the interview in question can always be set aside in a later phase of analysis. This is less the case for collective interviews. Such an error may hinder, or even compromise, the group discussion and the interpretation of the overall results for that group. Of course, the interactions that take place in the context of these collective interviews always involve a certain ‘social alchemy’ and are, as a result, at least partly unpredictable. However, the recruitment should enable the researchers to anticipate what will take place as much as possible, notably by controlling the social homogeneity of each group.

Obviously, one considers that a good discussion dynamic would be one that enabled each participant to express themselves and thus to understand others and to be understood. This means that participants must

speak the same language, each are able to identify and ‘gauge’ their participants as quickly as possible after meeting them, and to situate themselves in relation to the other participants. From this perspective, the recruitment aimed to avoid bringing together people that are too far removed from each other socially in order to facilitate discussion. Convening smaller groups is thus also important. With groups of four to seven participants, participants are in position to talk to each other and everyone has an opportunity to secure the floor (Duchesne, 2017).

The process of recruiting a sample that fits the desired research design can be time-consuming. Thus, the first question to consider is whether pre-existing groups or constructed groups best correspond with the research question. A common method is to use a key informant, who is sometimes paid, to be an organiser and who convenes a group of acquaintances – for example, friends, neighbours, or co-workers. Familiarity facilitates the dynamic of group discussion. However, by delegating the composition of the groups to key informants, researchers risk weakening the social stratification of the groups and/or, ending up with only very competent participants.<sup>13</sup> The issue of political competence is often at the core of many classical political science questions and thus should be carefully thought of. As William Gamson remarks (1992), interviewees who use personal contacts tend to recruit from amongst their acquaintances people whom they believe to be the most likely to talk in public and who, accordingly, are mainly found to be amongst the most educated. Thus, interpersonal recruitment does not allow a choice of all participants and the certainty to recruit lay citizens, which can be fundamental to the study of (de)politicisation, for example (Duchesne, 2017). Familiarity between the participants may also lead to many implicit discussions that are difficult to interpret for the researcher.

Artificial groups – defined as groups gathering strangers, differentiated according

to theoretical sampling criteria – could be preferred because they typically avoid all of the aforementioned problems. In order to have maximum control over the selection process, researcher can choose to construct groups that are lacking any kind of pre-existing sociability – in other words, groups in which the participants were not previously acquainted with each other or the researcher. A common and tempting general strategy is delegating recruitment to specialists – for example, opinion polling companies (Baglioni and Hurrelmann, 2016).<sup>14</sup> Nevertheless, such companies tend to work with files of volunteers who often end up being almost focus group specialists, something researchers in political science might also want to avoid. Researchers may be keen to make contact with a public that most often eludes opinion surveys and eludes focus groups when recruited by professional research agencies. Researchers could want to reach a population that is most often excluded (or self-excluded) in opinion surveys, those whose feeling of competence – particularly political competence – is low, thus predisposing them to avoid this kind of participation. As Sophie Duchesne (2017: 371) underlines, ‘it is well-documented that the more remote people feel from the political field, the less likely they are to accept to participate in interviews, in general, and, in particular, in interviews on political topics’ (Gaxie, 1978). Having to speak publicly in front of strangers on potentially controversial political subjects while being recorded for two hours or more is clearly a particularly unusual and potentially harrowing experience that might discourage certain potential respondents.<sup>15</sup> Having in mind the comparative potential also increases the likelihood of including groups that might be otherwise overlooked (Barbour, 2007). For instance, Marsh et al. (2007: 59) mobilised focus groups to research political participation – and more precisely how young people understand and experience politics. By engaging with 12 focus groups, including 65 participants, these researchers contrasted

responses from a ‘politically active’ group with those from a ‘politically inactive’ group. Consequently, using a financial incentive to attract these types of participants is sometimes considered indispensable.

For the same reasons, the subject of the discussion could not be communicated to the potential participants in order not to discourage citizens who are not interested in (or even repelled by) political issues from participating. Selecting a venue regularly used by participants is also essential in order to limit the cost of participating as well as to help participants to feel more quickly at ease and comfortable. For example, Heidi Mercenier realized her focus groups in community and youth centers (Delmotte et al. 2017). It is worth noting that a venue could also have particular associations for participants. For example, a focus group held in a university building may lead participants to feel the need to show expertise on the matter in hand or to feel as if they were back in school. If the question of knowledge or expertise is central to the research question, perhaps a university building should be avoided. Here, reflexivity on the settings and the relationship between the researchers and the participants is fundamental.

Depending on the research objectives, recruiting participants who, on the one hand, do not know each other and, on the other hand, present specific characteristics, necessitates a sometimes costly recruitment system. Researchers could want to obtain detailed socio-political information from respondents in order to select those who ultimately participate in the focus groups and suit best their research objectives and their comparative research design. A questionnaire could therefore be given to all those who replied to advertisements or any other recruitment strategy<sup>16</sup> in order to select the final participants.

In practice, a variety of ways exist to recruit participants: community gatekeepers, informal networks, advertisements, leaflets, posters, formal services, etc. William Gamson (1992: 16) set up recruiting tables at community events such as festivals, fairs, and flea markets,

whereas Tamar Liebes and Elihu Katz (1990) approached members of different communities and asked them to recruit additional participants. Jonathan White (2011: 230) recruited taxi drivers across 10 cities in the UK, Czech Republic, and Germany directly at the taxi rank at a time that coincided with low customer demand. Multiplying the recruitment strategy is, most of time, a good way to go, particularly in order to recruit different profiles.

### ***Discussion Guide and Moderation***

Setting up collective interviews also involves a series of choices linked to procedures of the organisation of the discussion itself. Due to the extent that the researcher is active in the construction of the research, a high degree of reflexivity is necessary, at least in retrospect.

It is important to distinguish first between structure that controls questioning and structure that controls the group dynamics. In managing group dynamics, a less structured approach allows participants to talk as much or as little as they please, while a more structured approach means that the moderator will encourage those who might otherwise say little and limit those who would otherwise dominate the discussion. When it comes to the focus group questions, a less structured discussion means that the group can pursue its own interests, while a more structured approach means that the moderator imposes the researchers' interest, as embodied in the questions that guide the discussion. It is crucial to allow participants to speak freely and not to force them to redirect the flow of the discussion onto the topic because this allows the groups to ignore the topic and to address matters that interest them.

A key factor that makes groups more or less structured is, thus, the number of questions. In focus group research, the aim of the discussion guide is twofold: to foster productive discussion and to elicit useful data that meet the research objectives. Hennink (2014: 48) underlines that 'a discussion guide is a

pre-prepared list of topics or actual questions used by a moderator to guide the group discussion'. Therefore, 'the moderator uses the guide as a resource to maintain the balance between the researchers focus and the group's discussion' (Morgan, 1997: 48). The discussion guide is thus a checklist to ensure that the different dimensions of the topic under scrutiny are covered throughout the discussion. While the non-directive approach is one of the main characteristics of the focus group method, in academic research, the discussion guide is often structured around pre-designed questions and probes. This structuration helps to enhance the comparability in data analysis as the study population is often divided into subgroups.

Concretely, the first few moments in a focus group discussion are critical. In this brief time, the moderator must give enough information so people feel comfortable with the topic, create an open atmosphere, provide the ground rules, and set the tone of the discussion. The best introduction is often the honest admission that researchers are there to learn from the participants, and so the goals for the session should be expressed in those terms. The discussion begins with broad questions to launch the dynamic among group participants so that they begin to feel comfortable and competent. A central objective is to get each participant to give some meaningful response or opening statement. One should easily be able to respond. The initial question should be something that all the participants would be interested in. Beginning with a general question that emphasises the participants' interests lets the researcher hear the participants' point of view rather than starting with the researcher's interests. Thus, there is an opportunity to discover new ways of thinking about the issues. As importantly, they have to be worded with the appropriate level of vocabulary and syntax. This is of course challenging when the sample encompasses people with quite varied social – and possibly national – backgrounds. Typically, follow-up questions are used when necessary to clarify participants' opinions.

On the guiding and moderation of the discussion, there is also a fair amount of variation in existing research. The CITAE team opted to conduct a discussion that was largely non-directive but structured by managing the dynamic of the group discussion (Duchesne et al., 2013: 160–95). The conduct of the sessions was based on a schedule of scripted questions put to the groups in a rigorously standardised manner in every group. Sessions lasted about three hours (a long period by comparison with other focus group studies) and were structured around five questions, taking about 30–45 minutes each. This left open large time slots for discussion between participants, following Robert K. Merton and Patricia Kendall's (1946) advice to 'not introduce a given topic unless a sustained effort is made to explore it in some detail'. Of course, longer-lasting groups face the challenge of arousing the interest of the participants for three hours.

Vignettes and imagined scenarios have been successful as a means to prompt group discussion (Gamson, 1992; White, 2011). In William Gamson research, the moderator was showing the participants Jonathan White presented a card at the beginning of the group. Tamar Liebes and Elihu Katz (1990) had their groups begin by watching an episode of *Dallas*, and then used the show to structure the discussion that began with very general questions and became more specific as the discussion progressed. In the end, the objectives of the research should define the length and the depth of the focus group. However, the researcher should always keep in mind that not leaving enough time for discussing collectively a topic, a question, or an idea is a mistake and that the group dynamic is essential and the discussion should be prompt.

## ANALYSING FOCUS GROUPS

Focus group data are typically analysed using conventional methods for qualitative

analysis.<sup>17</sup> However, analysing focus group data provides its own set of challenges. Of course, the method of analysis selected depends on the purpose of the study and the approach to analysing focus group data varies from study to study. Again, it is not the intention here to provide a 'how to' guide for analysis focus group data, but rather to underline some specificities of analysing focus group data in political science research.

### **Data Collection**

The analysis of collective interviews differs from the outset by the potential diversity of the available material. The data stream begins with field notes and recordings taken during each focus group, continues with the debriefing following the groups, and goes into transcripts. Thus, focus group data include documented observations made by the research team throughout the sessions. Indeed, a note-taker should be part of the team and attend the group discussion to develop a written summary of not only the key issues raised, but also of the group dynamic (Hennink, 2014: 83–5). Field notes cover the arrival period, the break, and the period after the discussion closed and before the participants' departure. These notes include all comments made and all conduct and action that the team members present were able to observe and recall. The debriefing notes are essential and constitute as such the first step of the interpretative analysis.

Transcription remains the essential element of the corpus. Indeed, many analytical approaches require data to be transcribed to produce a written record of the discussion for analysis (Hennink, 2014: 87). In the case of face-to-face interviews, for the most part, the methods of analysis proposed in the manuals rely on text analysis. In the case of focus groups, this reduction to the text is more difficult to operate. The degree of

precision of the transcription needed obviously depends on the type of analysis one intends to conduct. For example, content analysis or thematic analysis requires a verbatim transcript, whereas conversational analysis has additional transcription norms, because understanding how participants express themselves is as important (Hennink, 2014). In this latter case, the transcription needs to include details on hesitations, pauses, and word emphasis but also on body language, when relevant. In any case, it is thus important that the transcripts reflect as

finely as possible what occurs in the collective interviews.

Research that requires a careful record of who was speaking to whom will require either a video recording or an assistant that takes notes throughout the group interview. The key difference between audio and video recording is the intrusiveness of the latter. As all the efforts that went into recruiting is wasted when a 'technical problem' causes a loss of data, it is advised to pay equal attention to the quality of the recording. Ensuring the quality of the recorded data is crucial.

*Example of Transcribing Conventions: Talking About the Royal Family (Billig, 1998: 24)*

The main signs used in the transcriptions are as follows:

= to be found at the end of one speaker's utterance and at the beginning of another's: no audible gap between the two speakers. This would be expected if the second speaker were interrupting the first, who then gives way.

[ two or more speakers making utterances at the same time.

(.) short pause. If the pause is of sufficient duration to be measurable, then the time is indicated in seconds: i.e. (2) indicates a pause of two seconds.

... omitted or inaudible material.

{ } clarificatory addition, often referring to tone or gesture i.e. {laughing}.

underlining of words in the text indicates emphasis through raised voice; capitalisation indicates particular emphasis or volume.

Moreover, as focus group research is conducive to a diversification of the modes of moderation, it also contributes towards producing complementary material, which the group itself elaborates at the request of the moderator. This complementary material could also be analysed. As part of the CITAE research, Sophie Duchesne also analyses the cards produced by the participants to answer the question 'who profits from Europe?' in order to understand and characterise the social gap existing in the reactions to European integration (Duchesne et al., 2013).

### ***General Principles of Focus Group Analysis***

As stressed by Sue Wilkinson (1998: 169), 'focus groups are distinctive ... primarily for the method of data collection (i.e. informal group discussion), rather than for the method of analysis'. Thus, focus groups analysis follows the general principles of qualitative data analysis. Some of them are however more important to keep in mind when analysing focus groups.

First, as with other research methods in social sciences, focus groups can benefit from

the classic advice that decisions about how to collect the data will depend on decisions about how to analyse the data. The degree of structure in the collective interviews and the segmentation of the group composition points to the obvious influence that the research design has on the subsequent analysis of the data. For example, although using a more structured approach in collecting data does not force the use of a group-by-question grid in the analysis, using a less structured approach certainly limits the value of this option.

Second, the analysis should follow two important general principles: the analysis is systematic and continuous. Systematic analysis means that the analysis strategy is documented and that all the material is analysed. The interactive nature of the data reinforces the need for the systematisation of data analysis. Researchers must continually be careful to avoid the trap of selective perception. Data analysis is also sequential and continuous; data collection and analysis are concurrent. As already mentioned, the debriefing notes taken after each focus group are the very first step of interpretative analysis. The principle of saturation is anchored also in this concurrence of data collection and analysis as the number of focus groups to conduct is determined through iterative process until information saturation is reached (Hennink, 2014: 43).

Third, the analysis can focus on the group taken as a whole or on the interactions between the participants. Concretely, this leads to choosing between focusing the analysis on the content of the opinions collectively expressed – or, on the contrary, on the way in which they are elaborated (Duchesne and Haegel, 2004b: 83). In the first case, one will initially characterise each of the groups, synthesise the content of what was expressed, and then conclude by comparing the groups. While in the second case, one will have to individualise participants to understand better what is happening at each moment of the discussion. Although the group is the main unit of analysis, most of the time the analysis needs also to take into account individuals

within the group (Barbour, 2007: 129). However, the analysis should never be at the level of individuals only.

Finally, as Monique M. Hennink (2014: 87) underlines, ‘approaches to data analysis can broadly be divided into those that break-up data into segments or themes for analysis (e.g. content analysis, thematic analysis) and those that do not break-up data to analyse the whole narrative (e.g. discourse analysis, conversation analysis)’. As useful as this categorisation is, in fact, this distinction should rather point to the two steps of analysing focus groups rather than be seen as two alternatives. These two steps are interpretation (mainly based on an analysis of alliances and sensitive moments) and data reduction (mainly either by categorisation or condensation and systematic comparison). There is, indeed, a need to retain something of the richness of the data collected, while ensuring that the amount of data generated are analysed systematically and comparatively (Frankland and Bloor, 1999). Those two steps are described in the next sections.

### ***Interpretation: Alliances, Sensitive Moments, and Experiential Knowledge***

The main challenge of analysing focus group data is reflecting and utilising the interaction between participants and taking into account group dynamics (Kitzinger, 1994). This could be very challenging as the discussions in focus groups are marked by the fragmented and disorganised nature of the reasoning of participants. This is particularly true at times when the discussion becomes heated, and when the participants tend to talk at the same time. The transcripts consist of many sequences that are difficult to understand for anyone who merely reads them – that is, for anyone who looks for meaning only in the content and the sequence of utterances. Participants react, gradually, to what is said and to what they hear. In order to not to

take quotes out of context, interpretative analysis is thus an essential first step. The interpretative phase helps researchers to begin the process of incorporating the data.

Before trying systematically to analyse and compare the data, it is necessary to go through a stage of interpretive construction of the meaning of the utterances exchanged. Relating utterances to the development of relations between the participants in order to understand meaning has been developed by Michael Billig (1992). From conversations between close relatives about the British Royal family, he shows how arguments are adapted to the reputation of the interlocutors: someone considered to have strong opinions will be led to retain his role, to construct his discourse, and to adapt his responses in order to always have the last word. By contrast, the CITAE groups were made up of strangers without any prior reputations to maintain (Duchesne et al, 2013).<sup>18</sup> However, their interventions could certainly be interpreted as reactions of participants to each other and impressions of group members that were developed over the course of the session. These reactions tended to be strengthened after a while in terms of more or less explicit alliances. The interpretive analysis therefore provides a framework from which one could analyse how participants constructed their interventions and adapted their positions or opinions according to interactions with those whom they wanted to express an agreement or disagreement. In the same vein, the relationship established between both participants and the moderator is part of the data construction and should be taken into account in the analysis. For all of this, making syntheses and summaries of the groups proves to be a useful step in the interpretative analysis.

When it comes to using interaction between participants to generate data, interpreting the data from focus groups requires distinguishing between what participants find interesting and what they find important (Morgan, 1997). When participants discuss a topic at length, this is a good indication that

they find it interesting, but it does not necessarily indicate that they find it important. In addition, specific attention is necessary for researchers to understand the strategies that participants adopt to deal with perspectives that are difficult to express – both because of their emotional charge and their complexity.

In particular, Jenny Kitzinger and Clare Farquhar argue for the analytical potential of ‘sensitive moments’, defined by their emotional charge and indicated by ‘explicit comments from the research participants, hesitation and awkwardness, reactions of surprise or shock, individual defensiveness or tentative collective exploration’ (Kitzinger and Farquhar, 1999: 156). The simple idea behind this concept is to be particularly attentive in the analysis to moments ‘where something is happening’ in the group discussion. In order to deal with those ‘sensitive moments’, participants may employ humour in expressing their points of view rather than speaking about them directly (Liamputtong, 2012: 175). Of course, they can also simply remain silent. Silences are thus also a valuable resource for analysis in terms of group interaction, as well as discourse content. Indeed, what is not said can be as important as what is said (Barbour, 2007: 141). Blake Poland and Ann Pedersen (1998) propose a useful analytical distinction between ‘silences of estrangement’, where issues have no salience for participants, and ‘silences of familiarity’, where issues are not mentioned as they are taken for granted.

Finally, Jenny Kitzinger and Clare Farquhar (1999: 171) stress that ‘above all, when groups delved into and began to address sensitive issues in depth, this provided invaluable information about the place of personal experience within public discourse’. Thus, eluding experiential knowledge is also a useful tool for interpretation (Stanley, 2016). William Gamson found that experiences in the form of anecdotes have a specific place in discussions. Participants frequently made their point by ‘telling a story’ that sought to make a broader point about

how the world works (Gamson, 1992: 122). Those stories are sometimes from television or newspapers, but the majority of anecdotes are about themselves or at least someone they know personally – such as family, friends, and co-workers.

### **Data Reduction: Systematic Comparison and Coding**

Michael Billig's research, *Talking Of the Royal Family*, is based on 63 focus groups recorded in over 2,800 pages of typed transcript. The longest transcript of a single interview was 150 pages (Billig, 1998: 18). The CITAE project includes 2,400 pages of typed transcript for 24 focus groups conducted in three different countries (Duchesne et al., 2014). Thus, data reduction is often a necessary step in the analysis of focus groups but should always come after a careful phase of interpretation of the data.

Rosaline Barbour (2007) underlines that three basic factors influence the salience given to a topic: (1) how many groups mentioned the topic? (2) How many people within each of these groups mentioned the topic? (3) How much energy and enthusiasm did the topic generate among participants? On this last point, the interpretative analysis is of course of precious help. The two former factors call for systematic comparison. Systematic comparison, focusing on both inter- and intra-group differences, helps qualitative data analysis to overcome the limits of purely descriptive accounts (Barbour, 2007: 131). It helps also to avoid the danger of selective recall of, and attention to, some data and neglect of other contradictory data (Frankland and Bloor, 1999). Pre- or post-questionnaires and field notes are useful here to record details on participants and to further explore intra-group differences and similarities.

Since qualitative analysis is essentially comparative, indexing data facilitates comparative analysis by gathering all data on a particular topic under one heading (Frankland

and Bloor, 1999). It also helps when managing the data – field notes and debriefing notes should also be coded. Commonly, researchers are interested in the themes that emerge from the data. This kind of analysis is referred to as thematic analysis – or frame analysis – and is processed through systematic coding. The process of coding involves researchers reading and re-reading the text and assigning codes, which relate to the content of the data and are of interest to the researcher's analytic framework. In a first stage, codes are likely to be quite broad, and then to become narrower and more focused as the work continues. Coding fulfils the essential function of linking the different parts of the corpus to each other. It enables the systematic comparison between different excerpts of the text that are attached to a given code applied throughout the entire corpus. The use of Computer-Assisted Qualitative Data Analysis Software (CAQDAS), such as Atlas.ti and NVivo, enables the application of code to text to be reviewed, tested, and revised (Vila-Henninger, 2019). Because of their search and retrieve facilities, CAQDAS enables researchers to find patterns and divergences in large datasets.<sup>19</sup> Such packages facilitate the qualitative analysis and ensure that the analysis incorporates the entire data set.

Once coded, the transcripts can be systematically analysed, both qualitatively and quantitatively. Qualitative analysis involves going back to an interpretative analysis, but only on a selected portion of the data collected. For example, relying on CITAE dataset, Virginie Van Ingelgom (2013, 2014) retrieved and analysed all the statements made by participants stating in the pre-questionnaire that their country membership to the European Union was neither good nor bad. By comparing those statements, she was able to construct a typology that identifies three mechanisms of depoliticisation: ambivalence, indifference by distance, and indifference by fatalism. Quantitative analysis includes the examination of the frequency of certain kinds of statements by groups or

by individuals. In the same study, Virginie Van Ingelgom was able to demonstrate that those ambivalent participants were not less competent or able to discuss European affairs than others were. However, counting should still be understood in line with qualitative epistemology. Counting is important in identifying patterns in the data and not in using numbers in ways to attach significance to the actual values (Barbour, 2007: 131). In general, researchers present findings through a combination of direct quotes taken from the group discussions, interpretative summaries, and comparative tables.

## CONCLUSION

While interviewing has traditionally been an essential technique for gathering data in political science and international relations, focus groups are not yet a core mode of data collection in this field. However, more and more researchers are mobilising this technique of data collection in an innovative way and very often in combination with other techniques, such as opinion polls. Yet, while organising a collective discussion may look easy or straightforward to an outsider, it involves much more than sparking a conversation between participants, at least when focus groups are used for research purposes, as this chapter has demonstrated.

The purpose of focus groups is indeed to collect and to analyse group data for research objectives on a topic focus constructed by the researcher. They are a very demanding technique, but they provide a rich and detailed set of data about participants' perceptions, beliefs, and frames in their own words. Focus groups represent a flexible research tool, as they may be quite general or very specific; highly structured or non-directive; stemming from positivist to interpretative traditions. Of course, the most important differences among interviews with individuals, oral histories, and focus groups are the number of participants

involved, the role the researcher plays, and the structure of the interaction (Kapiszewski et al., 2015: 193–4). These three elements define the type of analysis that can be undertaken but stress at the same time the trade-offs between these three techniques of data collection. Each type of interviews has characteristics, advantages, and drawbacks<sup>20</sup> – so does the focus group. The aim of this chapter was to give the reader the key to decide if focus groups are an appropriate technique for data collection for their research. Indeed, as for any research technique of data collection, the decision to use it must be based on the appropriateness of the method for obtaining answers to specific research questions (Stewart and Shamdasani, 2015: 177).

Thus, as useful as any methodological chapter as this one could be, the main and concluding advice to be given to any researcher that intends to engage with focus groups research should be to get familiar with the very convincing work that mobilises this technique of data collection. This chapter has built on those examples of innovative and rigorous research. They are the best illustrations of when and how to use focus groups in political science and international relations and therefore should be on any reading list.

## Notes

- 1 Myself, I also discovered this idea a long time ago thanks to Sophie Duchesne. Any errors in this chapter are mine and only mine. She was so generous to teach me everything she knew about this very demanding methodology. I would like to thank her for her continuous commitment to ambitious research, as I would like to thank all colleagues and students that I have had the chance to work with in order to generate data through focus groups in the last fifteen years. A special thank to the students who I have been teaching this method to over the years, in particular those of the ECPR Winter and Summer Methods Schools.
- 2 This chapter concentrates on focus groups as used by political scientists and IR specialists, even if political parties and administrations increasingly employ the techniques to uncover attitudes

- towards political campaigns or public policies (Savigny, 2007). Note also that focus group research has evolved recently by the introduction of virtual focus groups (Bloor et al., 2001: 74–88; Lobe, 2017; Stewart and Shamdasani, 2015: 157–76). Addressing specific issues related to virtual focus groups is, however, beyond the scope of this chapter.
- 3 Based on the results of a survey of a US political science faculty, Kapiszewski et al. (2015: 190–1) detail in their chapter on interviews, oral histories, and focus groups that 81% of field research projects reported made significant use of interviews. This percentage varies across subfields: 92% for comparative politics, 84% for IR scholars, 84% for Americanists, and 50% for political theorists. Overall, according to this survey, focus groups represent 13% of field research projects. Their survey also underlines that while only 6% of the reported fieldwork projects carried out in the 1960s and 1970s in the United States employed focus groups, 15% of the projects from 2000 onwards did so (Kapiszewski et al., 2015: 201). To our knowledge, the use of focus groups in international relations is very rare. However, the chapter will include examples of research conducted on attitudes towards the EU in order to offer researchers in international relations relevant examples.
  - 4 In order to find a practical how-to guide, the reader can refer to the existing plethora of focus group handbooks (Barbour, 2007; Bloor et al., 2001; Hennink, 2014; Liamputtong, 2011; Morgan, 1997; Stewart and Shamdasani, 2015).
  - 5 Note that, in our view, the label ‘focus groups’ is very inclusive. Thus, collective interviews for research purposes also qualify as focus groups. The main differences in this case will be the kind of moderation that is used, and in particular, how active the facilitator is in the discussions.
  - 6 Note that this definition will thus exclude original Merton’s ‘focused interview’ from the current practices of focus groups. Robert K. Merton (1987: 550) underlined this point in his *The focused interview and focus groups*, when declaring: ‘the truth of the matter is that there can’t be many people in the field of social science and certainly none in the related field of marketing research who know less about focus groups than I’.
  - 7 The obvious methodology here is ethnography. Nina Eliasoph, Camille Hamidi, and Katherine Kramer Walsh spent years observing people discussing political issues (Cramer Walsh, 2004; Eliasoph, 1998; Hamidi, 2010).
  - 8 For a stimulating illustration of this tension, see Liam Stanley’s (2016) piece in *Politics*.
  - 9 For a well-detailed argumentation on how to use focus groups for studying (de)politicisation, see the recent chapter by Sophie Duchesne (2017).
  - 10 According to Robert K. Merton and Patricia Kendall (1946), an effective focused interview has several interrelated characteristics: non-directedness, depth, range, and specificity. More recently, Sophie Duchesne (2017: 376–8) renewed the arguments in favour of adapting the non-directive approach to focus groups when developing questions and moderating.
  - 11 To this regard, and in extension, the method is also associated more closely with political marketing. In this perspective, political parties have increasingly employed focus groups to gauge citizens’ attitudes towards particular policies since at least the mid 1990s (Savigny, 2007). However, as those focus groups are used outside a research context, they are not included in this chapter as it deals with focus groups as a strategy of data collection for research purposes.
  - 12 On mixed method research design, see Harbers and Ingram, Chapter 58, this *Handbook*. The aim of using qualitative and quantitative methods in combination is to gain a broader understanding of the research issue that no single method alone can provide, each approach illuminating different dimensions of an empirical object under scrutiny.
  - 13 As such having competent participants is not a problem, but it could be depending on the objectives of the research. For example, if ones want to understand how the European integration process is perceived, gathering only participants highly competent on European matters and very interested in the topic will lead to misleading conclusions.
  - 14 Another tempting strategy is recruit students (Bruter, 2005). If this could be justified for realising a pilot or for exploratory research, strong reflexivity is needed as students are a very specific target group when it comes to political issues and politicisation.
  - 15 In order to record and being able to transcribe precisely the discussion, it is common to use video recording and/or audio recording, but this has an obvious cost as it can be perceived as intrusive by some participants.
  - 16 While pre-interview questionnaires might produce some interesting biographical data, the risk is also to atomise the group as extended silences are a bad way to begin discussion – and could take up valuable time better devoted to collective, rather than individual, activities (White, 2011: 239).
  - 17 On qualitative data analysis see Harbers and Ingram, Chapter 58, this *Handbook*.
  - 18 Sophie Duchesne and her team developed their own way of analysing interaction, drawing on

Michael Billig (1992) and Jenny Kitzinger and Clare Farquhar (1999). Each of the 24 discussions analysed was the subject of an interpretive narrative account by Sophie Duchesne, Elizabeth Frazer, or Florence Haegel. Using the video recording, the transcription, the questionnaires filled in by the participants, and the observational notes written by the team after each group session, she constructed an account of the discussion, and everything that happened around it, by responding to the following questions: what happened between the participants? What conflicts were avoided and what conflicts were engaged with in the discussion? What agreements or what consensus was found and how? How did alliances between group members develop? What divisions did they reveal? What were the subjects of discussion, explicitly and implicitly? What resources did the participants mobilise? The final document took the form of a narrative about the participants and their conduct within the group. The template is detailed in Duchesne et al. (2013: 190–2). For a detailed explanation on the way to mobilise alliances in the study of (de)politicisation, see Duchesne (2017).

- 19 Note that CAQDAS are, of course, also used for interpretative coding. Silences, sensitive moments, disagreements, experiences, and so on, can be coded as well.
- 20 For a systematic comparison of those advantages and drawbacks, see Kapiszewski et al (2015).

# Interpretive Approaches in Political Science and International Relations

Xymena Kurowska and  
Berit Bliesemann de Guevara<sup>1</sup>

When I first started writing about diversity work as institutional plumbing over 10 years ago, I did not expect I would be in touch with plumbers asking if I can use their images of leaky pipes. Research: it is where we end up. (Ahmed, 2018)

The inclusion of a chapter on interpretive approaches in the *Handbook on Research Methods in Political Science and International Relations* (PS&IR) illustrates the growing interest in the practice of interpretive research. It demonstrates the realisation that attention to meaning and context – the objective of interpretive research – enhances our analyses of politics. The resort to local knowledge in interpretive analysis provides means to address puzzles of contemporary politics that positivist tools cannot unpack. Through the introduction of interpretivism, the traditional bipartite division of social-scientific methods into quantitative and qualitative ones gives way to a tripartite modality that consists of quantitative-positivist, qualitative-positivist, and qualitative-interpretive methodologies (Yanow, 2003). The position of interpretive

approaches in PS&IR remains, however, ambiguous, despite the long interpretive tradition in the social sciences and humanities (and in policy analysis more specifically), as well as the wealth of recent publications explaining interpretive approaches in PS&IR (Bevir, 2000; Schwartz-Shea and Yanow, 2012; Lynch, 2014; Yanow and Schwartz-Shea, 2014; Bevir and Rhodes, 2016; Rhodes, 2017; Heinelt and Münch, 2018; Bevir and Phillips 2019; Steele et al., 2019) and the established status of interpretivism in adjacent disciplines, such as sociology, social anthropology, and human geography. Arguably, this ambiguous status reflects the difficulty of integrating the philosophy and methodology of research, which the opening quote illustrates: in interpretive research, the insight comes in the process of growing engagement and a cross-field search for apt metaphors, where the researcher is a supplicant who learns with others, rather than an expert who tests on others. Interpretive knowledge production relies on an iterative

back-and-forth between theory and lived experience, that of the researcher and of her interlocutors.

In this chapter, we first address persistent misunderstandings that have affected the reception of interpretivism in PS&IR and have often led to an unwarranted application of positivist assessment criteria to interpretive research projects. We briefly discuss the overlaps with and differences to poststructuralism and critical agendas more broadly and focus in some detail on how interpretivists understand theory and method. In contrast to formalised methods, interpretive approaches, crucially, do not use a method template. Rather, method is always specific to, and may change with, the context of the research problem. It cannot be mandated *a priori*. Second, we describe the aims and features of interpretive research and illustrate them through references to existing interpretive scholarship. These examples demonstrate the importance of systematicity in interpretive analysis, which follows the principle of a situated method selection and prioritises flexibility and the shifting of research strategies in accordance with contextual demands. In the third part, we discuss examples of interpretive research in action. We examine the question of reflexivity as the interpretivist counterpoint to positivist objectivity, the extensive contribution of Lee Ann Fujii to the development of interpretive methodology, and the specific usefulness of art-based methods for interpretivist research. As practicing fieldworkers, our emphasis is on interpretive data generation through fieldwork; we do, however, point to some research practices in interpretive policy analysis (IPA) as a starting point for our readers to explore other interpretive approaches that would deserve an elaboration on their own.

## **CLEARING THE GROUND: REVISITING THE BINARIES**

The difference between interpretivist and positivist traditions has primarily to do with

ontology and epistemology rather than methods *per se*. Positivists are philosophical dualists: they situate themselves as separate from the world they observe. They can then study this world through standard procedures that are independent from the context under study. Such a ‘view from nowhere’ is a necessary condition for producing warranted positivist knowledge (Nagel, 1989). Interpretivists are philosophical monists who reject the possibility of transcending context.<sup>2</sup> Centrally, interpretivists reject the correspondence theory of truth, that is, the notion that we can establish an unequivocal correspondence between the truth or falsity of a statement and the real state of affairs. In their view, such an operation is impossible because there is no ‘direct’ access to reality: the ‘view from nowhere’ is an illusion, all the more dangerous as it masquerades as truth. We rather get to ‘know’ reality, or make sense of it, by continuously interpreting it, most pertinently through language as the most common means of representation. Yet language cannot represent reality or truth in a total sense because it is socially mediated and temporally and geographically conditioned (Lynch, 2014: 16); it never quite encompasses reality. While it may be used to frame and manipulate, language effects cannot be fully controlled, so it is misleading to see language as a precise tool in the hands of either the researcher or any other social actor. Quite the opposite: we may find ourselves and the social actors we study ‘positioned’ by language, when larger discourses define who we are. The classic illustration of this condition in International Relations literature is Carol Cohn’s research into the world of nuclear defence intellectuals. Cohn shows how these experts distance themselves from the harm that the nuclear weapons they advocate can cause by constructing a pseudo-neutral ‘technostrategic’ lingo. While being replete with gendered/sexualised metaphors and related emotions, such lingo constructs a reality based on a claim to objectivity that pretends to be purely rational and is immune

to critique (Cohn, 1987). Yet Cohn is also taken by surprise when she catches herself increasingly using that lingo as a result of her participatory observation. This reflexive moment triggers a major shift in her central research question from ‘How can they think this way?’ to ‘How can anyone think this way?’ (Cohn, 2006), including the researcher.

Demonstrating the normative background of allegedly neutral or law-like concepts takes centre-stage in interpretive research. Oren (1995) reveals, for example, how the claim of a democratic peace, that is, the claim that democracies do not wage war against other democracies, which is widely regarded as one of the few laws in International Relations, is a historically specific and value-laden agenda. Klein (1994) shows how deterrence is a social global practice that changes in meaning, since the process of threat construction that underpins deterrence depends on the conception of the underlying values to be defended. Tannenwald (1999) traces the non-use of nuclear weapons as an evolving normative prohibition that over time has stigmatised nuclear weapons as unacceptable weapons of mass destruction. What transpires in such research is that every fact has a normative grounding.<sup>3</sup> Interpretivists insist that ‘facts’ arise within the context of a prior set of beliefs or theoretical commitments (Rorty, 1989). Any claims to neutrally describe an external reality are suspicious. The fact–value binary is not only untenable, it also tends to impose meaning rather than prevent bias: distance is both a stance and a cognitive-emotional orientation (Kondo, 1986: 75). Interpretivism shows in this context that ‘there are no “real” entities, only culturally mediated social facts, and [...] social science is always perspectival and entwined with the pursuit of moral or material goods’ (Schaffer, 2016: 2). This position must not be confused, especially in the age of post-truth, with relativism or ‘anything goes’. It is instead about making sense of power and ethics as constituents of meaning, an objective that remains at the core of the interpretive

research agenda (Lynch, 2014). Considering power relations as contingent social and historical arrangements derives from the constructionist sensibility behind interpretive research: interpretivists see reality as socially produced. Such a sensibility goes hand in hand with a baseline criticality – famously introduced by Cox (1981: 129) – between critical and problem-solving theory: interpretivists are critical researchers as they do not take the world as they find it but inquire how the social order came about. They deal in reconstructions, however, rather than post-structuralist deconstruction. In other words, they reconstruct the ways in which problems are socially understood, but they tend to fall short of a substantive poststructuralist critique that deconstructs the logic behind social representations of such problems (Bacchi, 2015) and the concomitant exclusions that such representations bring about.

In view of its conceptual commitments, interpretivism in PS&IR is then better thought of as an approach with a matching methodology, rather than a set of methods. Methodology here denotes a logic of method selection and application according to the conceptual setup of the project. Because of the contrasting ontological and epistemological holdings of positivist and interpretivist approaches, methods cannot be mixed arbitrarily (Yanow, 2003). Methods applied within one research project need to be compatible with one another, as well as respond to the overall research problem, since epistemology is ‘a skin, not a sweater’ (Marsh and Savigny, 2004: 165). There is therefore doubt among interpretivists about both mixed-method designs and analytical eclecticism, which advocate forsaking paradigmatic differences in favour of pragmatic combinations of methods (Sil and Katzenstein, 2010). For one, such pragmatism may end up in a ‘neither/nor’ research design, that is, one which is consistent neither with positivist nor interpretivist evaluation criteria, possibly giving rein to self-confirmatory research. More fundamentally, the logic of method application and

interpretation of results as a rule unfolds from within a paradigmatic position. Failing to disclose such a position does not translate into methodological pluralism. Calls for pragmatic complementarity may in fact subordinate interpretivist concerns to positivist models under the cover of methodological pluralism.

The emphasis on consistency does not mean, however, that methods should be boxed for exclusive use within specific approaches. Rather, what appears as a single method can be understood and used differently within positivist and interpretivist projects. The notion of data collection versus data generation is a useful way to think about this distinction, as it also reflects understandings of what constitutes empirics. In very general terms, positivist data collection assumes the existence of observer-independent information that is picked up in accordance with a prior research design. It requires a preceding construction of variables and hypothetical causal chains, which are tested on new material/information. In interpretivist data generation, data are not to be found but are made in concrete settings as a result of encounters with humans and non-humans. Data generation reflects the premise of the emergent research design, that is, one which crystallises in the process of research through learning in the field. If positivists have a prior idea of what constitutes their data, for interpretivists it is rather the evolving research question that renders things data. Sources of data are context-specific and they may include numbers, in the sense of the meaning that numbers evoke.<sup>4</sup> Here, certain established dichotomies begin to crumble.

Stone (2016), for example, proposes an interpretive theory of quantitative analysis that collapses the typecast distinction between qualitative and quantitative analysis as different styles of perceiving the world. Quantitative analysis gets its meaning from narrative: counting is in fact metaphor-making, numbers do not speak for themselves unless authors narrate their studies for audiences, and counting is itself an act of

power imposing a certain order on the world (Stone, 2016: 169). Bevir (2014) develops a distinctive narrative form of explanation that unpacks political action interpretatively and shows that the division of labour between approaches that 'explain' and those that aim at 'understanding' is a misconstruction. Ginger (2014) builds an interpretive framework for content analysis, which is usually seen as a positivist method producing numeric data for statistical treatment. Ethnography can similarly be applied both 'for information' through positivist data collection and 'for meaning' through interpretive data generation (Wedeen, 2010). Positivist ethnography explicitly aspires to adjudicate truth claims – what Jessica Allina-Pisano (2009) refers to as 'peeling the onion'. In her pledge for realist ethnography, she suggests that an understanding of the ways people think about their world 'can be a necessary condition for the collection and use of reliable empirical data about them' (2009: 55). International Relations saw some controversy over the early reduction of ethnography to an empiricist data-collection machine (Vrasti, 2008), so it is crucial that the field makes room for ethnographies based on different ontologies.

Interpretive sensibility can help further methodological pluralism in this context, as it rejects methods determinism. What defines such sensibility, following Geertz's (1993) famous statement, is not a matter of methods but of 'thick description'. Thick description is about sorting out structures of meaning by distinguishing frames of interpretation at play and how their co-existence produces friction. Any type of data in interpretive research, whether coming from a mass survey, the analysis of documents or an ethnographic interview, should be treated as evidence of meanings embedded in action (Wagenaar, 2011; Bevir and Rhodes, 2016: 18). For this purpose, method as tool is a misleading metaphor. It presupposes that the researcher has a clear sense of the product that the use of the tool is supposed to manufacture, yet method is not a 'system for offering more or less

bankable guarantees' that guides us to our destination (Law, 2004: 9). Excessive focus on procedure diminishes the ability to generate data through exposure and surprise and may lead to instantiating the initial assumptions from before the research. Good scholarship is characterised instead by making intelligent connections between subject matter and method (Hellmann, 2009), so method is never something outside of the material. It is performative rather than representational: the use of method actively shapes knowledge production, rather than being an application of a neutral procedure. In this sense, methods are practices of world-making: they are acted upon within research but also represent political choices and create new entities (Aradau and Huysmans, 2014: 598).

Finally, the understanding of the role of theory and the distinction between theory and empirics in interpretive research also needs clarification. Generally speaking, positivists treat research and theories they test or build as a replication of the social-political world. Interpretivists see research findings as resulting from intersubjective, meaning-focused processes that themselves interact with, and potentially shape, the studied world (Schwartz-Shea and Yanow, 2012: 40). Interpretive research action unfolds in tacking back and forth between the theoretical and the empirical, the abstract, and the concrete. This means that interpretivists do not in a direct sense test theory. They arrive at theoretical arguments via a recursive and iterative back-and-forth between theoretical frameworks and the experience of data generation. Theory and empirics feed on and fold into each other, and interpretivists seek to articulate this process. Burawoy (1998), for example, talks about interpretive theory reconstruction in contrast to positivist theory testing. Such reconstruction starts with an existing theory to be elaborated and deepened by probing 'negative cases' and inconsistencies. Theory is a scaffolding that keeps the researcher steady, guides the dialogue with participants, and provides the means

for thematising the researcher's participation (Burawoy, 1998: 5). Fieldwork constitutes in this context 'a sequence of experiments that continue until one's theory is in sync with the world one studies' (Burawoy, 1998: 17). Wilkinson (2014), in contrast, takes a more decentering perspective on theory in fieldwork. She objects to 'decanting empirical material into theoretical containers', that is, cleaning up data so that they fit into pre-existing theoretical categories. She recommends instead that an interpretive researcher temporarily and consciously neglect theory while in the field, in order not to impose meaning (2014: 394). In a more radical move informed by a transformation of his theoretical framework while in fieldwork, Zirakzadeh (2009) suggests learning how to discard theories. This is not theory rejection; the suggestion rather gets to the heart of the inescapable requirement for any interpretive social scientist to, as Taylor (1971) puts it, confront one's language of explanation with that of the self-understanding of one's subject. Such confrontation does not mean accepting the language of the participants at face value. But it requires learning with and from them, a process that theory may obstruct if treated as prior to experience. It is by tacking between concrete details and conceptual abstractions that we can refine and undermine, negate and create novel explanations about politics.

## **PREMISES AND COMPONENTS OF INTERPRETIVIST EXPLANATION**

The objective of interpretive research is to make sense of meaning and meaning-making practices of contextually situated social actors, the researcher being among them (Schwartz-Shea and Yanow, 2012). The core premises of interpretive research include the focus on the polysemy of such meaning and a dialectics between embeddedness and variability of social practice, the analytical use of concepts that derive from context, abductive

logic of inquiry, and reflexivity. In the following, we will discuss these premises in turn.

Interpretivists concentrate on meanings as opposed to laws, rules, and correlations between social categories or deductive models because they see meanings as constitutive of action and therefore necessary to make sense of, if we are to explain political action (Bevir and Rhodes, 2006). Meanings are holistic but not necessarily rational or conscious. Explaining an action requires locating it in the wider web of meaning, which differs from both the quantitative-positivist explanation, based on correlation, and the qualitative-positivist explanation, based on causation. For an interpretivist, it is not sufficient, for example, to explain a voter's party choice by either correlating it with an attitude to social justice as detected through a survey or by hypothesising a link between a voter's identity (determined through context-independent variables) and their party choice, and then testing the hypothesis through structured interviews. What interests her is how a participant makes sense of other relevant meanings that link their self-understanding to the vote. How do people name their circumstances, for example, including their place in a community, in a way that makes certain choices sensible and contextually appropriate for them? How is social justice contextually understood, beyond the slogan itself and as experienced in daily life, and how does this connect to other ideas that form a political stance? As we will develop below, the fact that most participants use a given term does not mean consistency of meaning across such users. Even though they use similar terms to describe social justice, for example, they may still understand its meaning differently. Such difference can only be captured and linked to political action through methodologies attuned to meaning. An interpretivist will then be curious how respondents to a survey interpret the issues they are asked to express opinions about, as well as how they make sense of the questions themselves, beyond the categories assigned by the researcher (Walsh, 2009). The

responses will depend on such interpretations, a connection that a survey cannot identify and explore. Similarly, structured interviews constructed to elicit data for the researcher's prior hypotheses may miss the contextual logic and vocabulary of political action that fall outside the hypothesised parameters.

If interpretivist political scientists see political life as action laden with meanings, they differ in how they conceive of such meanings. The most significant divide is between the hermeneutical and poststructuralist traditions that diverge in their views on the nature of political subjectivity. Those working in the poststructuralist tradition see subjects as constituted in discourse. As such, subjects are produced by language and so is their action and their sense-making (Bacchi, 2015). In other words, poststructuralist scholars see meanings as derived from quasi-structures governed by hegemonic discourse and thus reject a strong notion of autonomy. Discourse analysis in International Relations tends to adopt such positions (Milliken, 1999; Hansen, 2007; Epstein, 2008; for policy analysis, cf. Howarth and Griggs, 2012). Bevir and Rhodes (2006) take issue with the ensuing take on the individual as a product of a fixed ideology, with little capacity to change it. From within the hermeneutical tradition, they suggest the concept of 'situated agency' that reflects the contextual construction of the subject and their interaction in the world, with a mediating rather than determining role of theory and ideology. The 'knowability' of such a process can only be assumed from within the contextualised perspective of the subject, whether situational member or researcher (Schwartz-Shea and Yanow, 2012). The implication is that the 'observer' can only 'understand' by participation, by learning how (not) to put things to use within the field. Oftentimes, as we know from ethnomethodology, blunders and unintended interventions lead to such insight. Shehata (2006) notes, for example, that his intrusive presence and the extent to which he challenged social-class taboos as

an Egyptian-American scholar working in an Egyptian sweatshop contributed greatly to how he came to understand the operation of social class in Egypt. This is a good illustration of how it is 'by mutual reaction', that is, by engagement rather than detachment, that we discover the properties of the social order (Burawoy, 1998: 14). That is also the interpretive answer to the question of what value close personal observations bring to the study of politics. Such proximity requires, however, an acknowledgment that the practitioner's point of view is as important as the researcher's, and this challenges the claim to control over the research process (Fenno, 1986). We tend to neglect that social actors know more about what they are up to and its consequences than social scientists give them credit for (Giddens, 1990: 309). The interpretive interactive data generation with participants is a form of co-construction of knowledge that collapses the distinction between the observer and the observed or subject and object of inquiry.<sup>5</sup>

The logic of inquiry that best suits such a practice of knowledge production is abduction (Schwartz-Shea and Yanow, 2012; Lynch, 2014). Abduction differs from induction in that theoretical influences are acknowledged in the process of data generation, but it also differs from deduction. Abduction does not test theories brought to the local environment; research is instead about a continuous iterative recursiveness between the theoretical frameworks, the socio-political and institutional parameters that the researcher is situated in, and the lived experience of the situational members and the researcher. Abduction works by making sense of the present perplexity by resorting to past experience, making analogies from case to case, and probing concepts in new situations. It thus relies on a 'processual merger of creativity, experimentation, testing and adaptation' (Hellmann, 2009: 641). As a form of hunting for clues to make a diagnosis under conditions of uncertainty, abduction is by default inconclusive. It is a mode of inference

that concentrates on experience and practical consciousness. It looks for congruent categories without assuming their completeness or primacy (Onuf, 2013: 98–107). Abduction is thus guided by a radical premise, as seen from traditional research designs in PS&IR, that, '[n]othing new can ever be learned by analysing definitions, that is, by restricting the intellectual operation to the deductive and inductive modes of inference, because in these cases the possible knowledge is already included in the premises' (Rytövuori-Apunen, 2009: 644).

Questioning the definitional approach implies a distinct perspective on working with concepts in interpretive research. The meanings of key concepts and the concepts themselves 'emerge' *in situ* as the researcher learns what is meaningful to situated members, rather than being defined *a priori* and brought to the field to be tested (Schwartz-Shea and Yanow, 2012: 38–40). In other words, instead of prior identification of concepts and their definition and operationalisation into variables, interpretivists learn the key concepts while in the field. This also applies to researchers working with text, as they learn meaning by analysing how concepts are used and positioned. Zirakzadeh (2009) provides an instructive account of having to abandon the concept of 'modernisation' in his research on ETA (Euskadi Ta Askatasuna), a Basque nationalist liberation organisation, in Pamplona. As his fieldwork progressed, politics no longer appeared to take place amid a large-scale transformation of a premodern society into a modern one but involved street-level episodes and small, local organisations (Zirakzadeh, 2009: 106). 'Modernisation' failed to capture the multi-dimensional and programmatically eclectic local politics. He then also decided to abandon an associated survey he had designed before the fieldwork, as it revealed to have little to do with how nationalists and local residents in general understood their political disagreements (Zirakzadeh, 2009: 104). As he grew despondent in the field, an unexpected

event ‘abducted’ his attention towards the local ‘asociaciones de vecinos’ (community or neighbourhood associations) representing the heterogeneity of local politics. This ‘hook’ made him redesign the research ‘on the fly’ around a locally meaningful concept to capture participants’ understandings and choices *in situ*. Howard Becker (1998) formulated this strategy as letting the case define the concept, in contrast to bounding the case by a conceptual fiat. The research on meaning within such a strategy is about working back from use rather than testing a definition from outside of the context. Given the contextual use of cases in interpretivist projects, where the field is constructed over time through activities that take an episodic and fluid character (Amit, 2000), interpretivists prefer to speak of ‘casing’ (Soss, 2018) rather than case selection. In contrast to a prior identification of cases, strategically in qualitative-positivist research or through random sampling in quantitative-positivist research, casing relies on situational access and cultivating research relationships. It reflects a developmental approach that corresponds to learning in the field, avoiding a ‘lock-in and tunnel vision’ that case selection risks (Soss, 2018: 26).

Such risk is particularly substantial given the basic premise that meaning is polysemic. Although participants’ understandings and sense-making are at the forefront of interpretive research, we should be sceptical about shared meaning. Making sense of difference in interpretation is instead a crucial analytical entry point. Soss (2006) discusses this commitment in relation to his study on adopting the stigmatised identity of ‘welfare’ clients. The breakthrough in his research happened in the realisation of how differently his participants understood the term ‘number’, as in the formulations: ‘you are just a number’ and ‘I felt like a number’. For some, it evoked the angry feeling of being insignificant; for others, it was a welcome sign of anonymity and therefore privacy of their welfare claims. In his research on ‘democracy’ in

Senegal, Schaffer (1998) demonstrates the different meanings attached to this term in the Senegalese society. Senegalese elites invoked the word ‘democracy’ in ways similar to the usage of many political scientists, as a democratic system in which elections are contested and outcomes uncertain. Lower-class Senegalese used the Wolof equivalent, *demokaraasi*, to mean ‘equality’ or the attainment of ‘collective economic security via mutuality’ (Schaffer, 1998: 85). Such differences translate into crucial political distinctions. Yet they could hardly be captured by surveys or structured interviews, which are framed in the language of the researcher, who decides on the range of meanings attributed to democracy. Insight about difference in meaning can be obtained through conversational interviewing that follows the lead of the participant, while situating them in the wider context. Schaffer (2006) resorts to ‘ordinary language’ interviewing for this task: because the meaning of the word is in its use rather than in a dictionary, we need to study how people use the word in different contexts. The various uses of the word may not, however, fit together neatly. As in the examples above, consistency of language does not necessarily mean uniformity of meaning or equivalence across groups. To construct a coherent account of participants’ understandings and ascertain their sources and consequences, it is useful, Soss (2006) recommends, to start with the following questions: what frameworks do your participants use to make sense of their situation? How are individual comments part of a whole, and how are they commentaries on one another?

To be granted access to people’s experiences and lives for the purpose of research is a privilege that needs to be negotiated and accounted for, however. Interpretivists see reflexivity as a way of becoming more grounded in this reality. Reflexivity brings out the researcher’s role in the construction of the research problem and thus exposes how knowledge is marked by its origins. It involves ‘a keen awareness of, and theorizing

about, the role of the self in all phases of the research process' (Schwartz-Shea, 2006: 102). Reflexivity shows the intertwining of accessing, generating, and analysing data in the production of academic claims to knowledge. In his account of life on the shop floor in Alexandria, Shehata (2006) demonstrates at length how researcher identities simultaneously generate dynamics of situational inclusion and exclusion. Being male and perceived as Muslim enabled entrée to some circumstances in his Egyptian factory studies, while shutting off access to other potentially research-related settings, notably Christian Egyptians and women. Bringing to light one's position in the space of knowledge production, together with the interests and confines it may impose on research practice, helps increase trustworthiness, and as such, reflexivity constitutes the interpretive counterpoint to positivist objectivity (Schwartz-Shea and Yanow, 2012: 100). Strengthening the ethical integrity of research is one important function of reflexivity, but reflexivity may also help theorising informal observations. Becoming more aware of one's own sense-making can turn unplanned observations in the field into valuable sources of data and insight (Fujii, 2016: 1150). As 'there is never nothing going on', any mundane moment in the field can be revealing about the context and a broader social order: Shehata's (2006) realisation in the process of research, that social class and organisational and cultural expectations precluded his wearing sandals, was, for example, simultaneously an evidence-generative and data-analytical moment.

## INTERPRETIVE RESEARCH ACTION

In what follows, we discuss some examples of interpretivist research strategies. Given the wealth of works in this tradition, this cannot be more than a glimpse of some interpretive research in action. We showcase the range and diversity of interpretivist sensibility

through selected examples, some of them fieldwork-based, others working with document-analytical strategies, others again with arts-based methodologies. With regard to fieldwork-based interpretivist research, we first sketch the methodological innovation of Lee Ann Fujii (2008, 2010, 2011, 2015, 2016, 2018) in her interpretive work on violence. Fujii's oeuvre illustrates a comprehensive research agenda that attends to methodological detail at every level of interpretive explanation. Subsequently, Xymena Kurowska (2014, 2019) probes the notion of reflexivity by discussing the polysemy of meaning during her own 'research-at-home' among Polish border guards. Second, we discuss examples from the wealth of approaches to discourse analysis in the field of interpretive policy analysis (IPA), which illustrate interpretivist approaches that work with different types of texts, while not necessarily involving fieldwork. Especially, we draw on examples from IPA's focus on policy narratives, metaphors, frames, and myths (cf. Münch, 2016), and hear from some of Berit Bliesemann de Guevara's (2015, 2016) work on urban legends of international intervention and myths in international politics. Finally, Berit Bliesemann de Guevara describes her use of arts-based methods for interpretive scholarship (Gameiro et al., 2018; Bliesemann de Guevara and Arias Lopez, 2019), arguing that if employed in observing the principles of interpretivist methodology, such creative methods hold particular potential to unearth the polysemy of meaning highlighted in hermeneutical approaches.

### *Examples of Interpretivist Research Based on Fieldwork*

Fujii's (2011) research on the Rwandan genocide harnesses localised interpretations that add contextual nuance to our knowledge about violent conflict. Her research strategy brings out the importance of reconstructing

the local context and local meanings for making sense of violence. It relies on local stories, however they are not taken at face value but instead situated within the context of their social milieu and the research encounter itself. Her central research question, ‘how do ordinary people come to commit genocide against their neighbours?’, addresses the deadlock of much ethnicity-based literature, which cannot explain the different pathways that lead to mass violence or the different forms that participation in such violence takes over time and place. Fujii (2011) shows how social ties and immediate social context explain the processes through which ordinary people came to commit mass murder in Rwanda. It was not, she explains, the primordial hatred, as the ‘ethnic conflict’ literature would have it, but rather local ties that facilitated recruitment to violence. Once involved, participants associated such violence as being part of their identity, which contributed to their ongoing participation. Specifically, Hutu leaders used family ties to recruit male relatives, while ties among members of the killing groups helped to initiate reluctant or hesitant members into committing violence with the group. Yet ties of friendship also attenuated murderous actions, leading Hutu killers to help save Tutsis in specific contexts. Which ties became salient depended on the context. Key to Fujii’s understanding of these local mechanisms were two components: the contextual employment of Granovetter’s (1985) concept of ‘social embeddedness’, and a field-specific set of questions, namely: ‘who were the peasant killers known as Interahamwe? How did they come to participate in the genocide? And why would some Interahamwe try to help the very people they were supposed to kill?’ (Fujii, 2008).

There are at least three methodological contributions that crystallise in Fujii’s research process and help thinking about interpretive research in action. First is the relational approach to interviewing, where data are co-generated in research relationships (Fujii,

2018). Relational interviewing engages participants in a two-way dialogue, which is shaped by the particular context in which it occurs, as well as by the interests, beliefs, and backgrounds that each party brings to the exchange. It is, Fujii claims, through these interactions that data emerge. Their value lies not in their factual accuracy but in what they convey about the speakers’ worlds and how they experience, navigate, and understand them. The basic premise of such an approach is its open design: the researcher learns during encounters with and in the field. Mistakes are gifts in this process, as they reveal flawed assumptions and lead to final conceptualisations over the course of the research process, rather than prior to it. Fujii is adamant, however, about the limitations to such relationships and prefers to call them ‘working relationships’ (Fujii, 2018: chapter 2) rather than rapport. The latter implies familiarity and intimacy, which is not only rare but usually illusive. The researcher neither has the power to cast the locals in the role of research subjects, if they are not interested in participation, nor controls how they themselves are received in the local setting – although such reception affects data generation. Second, Fujii (2010) points to the analytical value of what she calls ‘meta-data’, that is, spoken and unspoken thoughts and feelings that participants do not always articulate in interviews, but which emerge in other ways. She speaks of five types of such data – rumours, inventions, denials, evasions, and silences – which are integral to the processes of data generation and analysis. Meta-data are important as they indicate the operating rules of the community and also reveal features of the research relationship that shape data generation. In violent conflict environments, participants may want to diminish their complicity in atrocities. Yet they may also want to embellish some components of their belonging. Third, Fujii introduces the notion of ‘accidental ethnography’ in political science (Fujii, 2015). Accidental ethnography involves paying systematic attention to the unplanned moments that take

place outside of the scripted research situation. Such moments point to the larger political and social worlds that help one understand the context in which both the researcher and the researched are embedded.

Engaging in accidental ethnography often relies on reflexivity by the researcher. However, and as also indicated by Fujii in her caution about rapport, reflexivity should not be regarded as an automatic resolution of interpretive concerns. Finlay (2002) points to the rhetorical function of reflexivity as a claim to authority and credibility. Pillow (2003) is uncomfortable with validated and thus comfortable reflexive strategies, which involve reflexivity as 'researcher know thyself', reflexivity as recognition of the other, reflexivity as truth, and reflexivity as transcendence. She suggests instead that we engage in 'reflexivities of discomfort', which interrupt uses of reflexivity as a tool of methodological power (clarity, honesty, humility). Rose (1997) formulates a more radical critique against what she sees as a problem of 'transparent reflexivity'. Transparent reflexivity emerges when the researcher claims being able to ascertain both how their own subjectivity translates into data and how the process of knowledge production can be charted within the broader landscape of power.

In this respect, Kurowska's (2019) research-at-home among Polish border guards who had been trained by their German colleagues to become 'European' border guards presented certain dilemmas. An indigenous researcher, that is, one 'native' to the site, arguably possesses a distinct advantage of cultural competence that facilitates insight. We usually associate a variety of interrelated advantages to insidership, such as the value of shared experiences, the value of greater access, the value of cultural interpretation, and the value of deeper understanding and clarity of thought for the researcher (Labaree, 2002: 103). It should therefore follow that Kurowska, being Polish, had a distinct advantage for gleaning meaning about the lived

experience of transformation in the region. And yet, in fieldwork encounters, it soon transpired that this may not be straightforwardly the case. One of the revealing moments happened when a former border-guard trainer winked at the researcher as she was leaving his office and said, 'we are all Germans, no?' There was no way of knowing the meaning of this particular wink. But there was irony that pervaded her interviewees' own recognition of being hailed into becoming European border guards. The acknowledgement of power relations that were hardly in their favour was an occasion to use, play, ridicule, and distinguish themselves in a way that did not deny the 'civilisation shift' but re-appropriated it in local ways. The Polish border guards claimed superiority of having deliberately accepted the initial patronising of their German colleagues to see 'what's on the other side [of the border]' (Kurowska, 2014: 558). Their keen sense of tension between emancipation and paternalism may have exceeded the researcher's range of reflexivity. On this occasion, she may have been the most uncomfortable, although in an unclear way, with the interviewee putting her in the same (ironised) category of 'an aspiring German'.

Such encounters first bring out polysemy of meaning, which is not easily captured even by a 'native' researcher, and, second, point to the intersubjective character of interpretive knowledge production: participants may show the researcher her own co-optation into normative discourses, including scholarly frames. The kind of reflexivity that emerges in such situations is intersubjective, rather than stemming from the researcher's introspection. It relies on the notion that the shifting self is always articulated through specific social interactions and that what we research is our relations with the researched (Rose, 1997: 313). This reverses the hierarchy of expertise in interpretive research as compared with the positivist stance: while the latter posits the researcher as an expert in control of both research subjects and the research process, an interpretivist is a supplicant who

acknowledges that the research subjects have a greater knowledge of the nuances of meaning that structure their everyday lives (England, 1994: 82).

### ***Examples of Interpretive Policy Analysis***

Studying practices of naming and framing is also a core research strategy that interpretive policy analysts have developed to reconstruct meaning-making in public discourse on political ‘problems’. IPA takes issue with policy analysis’ preoccupation with policy-making as problem-solving, epitomised most schematically in the ‘policy cycle’ (Barbehön et al., 2015). Rather, IPA authors draw attention to the processes through which an issue becomes defined as (a specific type of) actionable ‘problem’ in the first place. Interpretive policy analysts, just as interpretivists in general, differ in their approaches both with regard to their poststructuralist or hermeneutical positioning and the specific methods through which they study discourses. Yet they all share an analytical interest in the reconstruction of how certain social interpretations become institutionalised as more or less collectively binding and thereby legitimate. Authors associated with the ‘argumentative turn’ (Fischer and Forester, 1993; Fischer and Gottweis, 2012) or ‘interpretive turn’ (Healy, 1986; Yanow, 1995) in policy analysis have suggested portraying policy-making as an ‘ongoing discursive struggle over the definition and conceptual framing of problems, the public understanding of the issues, the shared meanings that motivate policy responses, and criteria for evaluation’ (Fischer and Gottweis, 2012: 7).

Interpretive approaches to policy analysis do not see political problems as objectively given but focus on the processes by which certain issues become problematised, that is, discursively rendered into politically addressable problems (Barbehön et al., 2015). Problematisations can be conceived of, in

a Foucauldian poststructuralist tradition, as products of larger power/knowledge regimes that precede subjects and let certain ways of thinking about a political issue appear as apparent and factual. The researcher’s task here is to reconstruct the contingent historical processes that have led to the problematisation and that are anything but necessary or definitive – a methodology that Foucault has called genealogy. This is usually combined with a critique of the order that had allowed this specific problematisation, with all its silences and exclusions, come about. Bacchi’s (2012) ‘what’s the problem represented to be’ approach, for example, suggests a range of questions aimed at uncovering the unspoken alternatives and silences of specific problematisations, in order to reveal the larger power/knowledge regime shaping actors’ room for political imagination: which assumptions underpin the representation of the ‘problem’? What is not being problematised? How could we think differently about the ‘problem’? What effects does this representation of the ‘problem’ have?<sup>6</sup>

Hermeneutical reconstructions of problematisations have focused more strongly on those elements that structure discourse and have given actors’ discursive struggles over problem definitions more room, for example, by studying the role of frames, narratives, metaphors, myths, and categories in the process of political problematisation (Goffman, 1974; Yanow, 1992; Hajer, 1997; Stone, 2002). For Rein and Schön (1993), frames are perspectives through which an amorphous and diffusely defined problematic situation makes sense in a specific way. Different frames applied to one and the same situation will create differing social realities with different effects on subsequent ‘problem-solving’ attempts. From a frame-analytical perspective, political struggles take place not over the political aims and measures to solve a given problem but over the framing of the problem as such: is homelessness, for example, an individual problem connected to medical causes, such as mental health, or a

governance problem connected, for example, to a lack of housing or welfare due to economic austerity? Is drug trafficking supplier- or consumer-driven, and is it predominantly a legal, medical, or political problem? (Münch, 2016: 80).

Metaphors are another structuring element of policy discourse that interpretive policy analysts study. Metaphors work by transferring concepts including their meaning from one context into a different one, where its transferred meaning takes effect. They are often used to simplify complexity by placing abstract concepts into contexts of everyday life. Interpretivists analyse metaphors not as mere rhetorical instrument but as powerful discursive meaning-making strategies with tangible effects on how a problem is understood (Lakoff and Johnson, 1980; Maasen, 2000; Gronau and Schneider, 2009). Gronau and Nonhoff (2011) have shown, for example, how dressing the 2008 financial crisis into metaphors of natural catastrophe helped deflect responsibility from bankers' purposeful actions to a 'global financial system', which appeared like a *force majeure*. Other often used fields for metaphorical concept transfers in politics are medicine (metaphors of crisis, intervention, corruption as disease, failing states as patients, etc.), engineering (the state as ship, the bureaucratic machinery), and warfare (war on drugs, defence of the Euro zone) (Münch, 2016: 97–8).

For Stone (2002), metaphors are elements of larger policy narratives that can be reconstructed by looking across different texts. Narratives make sense of the social world through employment: they connect discrete events with each other and thereby do not only order them chronologically (beginnings, middles, ends) but also causally. Narratives ascribe roles such as hero, villain, and victim to actors and thus distribute responsibility and blame. In her analysis of causal stories that structure the discourses on ethnic segregation in the housing sectors in Germany and the UK, Münch (2010) shows that in both countries, the dominant explanatory narrative

blames ethnic segregation of minorities in cities on the voluntary decision of members of these minorities to retreat into ethnically defined neighbourhoods. She then explores alternative explanations of ethnic segregation, ranging from political decisions on housing and social policies, community-council governance, economic considerations of private landlords, and the conscious segregation of housing associations to the strategies of the majority population and general demographic change. She concludes that while the reasons for ethnic segregation are mainly structural, the causal stories remain focused on segregation as a result of human behaviour, since it makes the policy problem of 'segregation' politically more easily addressable than complex structures would allow. Struggles over dominant policy narratives do not only occur in textual form; often they are accompanied by rituals, symbols, and performances in conjunction with which they gain authority. Bliesemann de Guevara (2017) analyses policy narratives and performances around political decisions regarding Germany's participation in the military intervention in Afghanistan and the subsequent question of the withdrawal of troops despite ongoing violent conflict in the country. She shows how politicians employ different narratives to justify their decisions and how they use the staging of insider knowledge through troop visits in Afghanistan to give the weight of 'having been there' and 'seen with one's own eyes' to their interpretations of the 'situation on the ground'.

The analysis of policy narratives that manifest in public discourse raises the question of which sources actually count as text to be studied. In order to reconstruct the way in which UN peacebuilders make sense of the situation of intervention they find themselves in, official documents that adhere to specific templates of writing reports, evaluating projects, and briefing superiors will say a lot about formal organisational practices but reveal little about the sense-making of the individuals who author these reports. Increasingly aware

of the limits of formal interviews and document analyses, and in line with Fujii's idea of meta-data as discussed above, Bliesemann de Guevara and Kühn (2015), for example, started to pay more attention to 'private' conversations with UN peacebuilders, which were replete with anecdotes that recurred in slightly altered forms across space and time. These 'urban legends of intervention', seemingly harmless and entertaining episodes that happened to 'a colleague of a colleague', revealed a deeper level of meaning-making in peacebuilders' own roles, their interactions with 'the locals', and the failures of peacebuilding. The urban legends revolved around three themes: 'the intervened' as barbarians; 'the interveners' as plagued by western/northern hubris; and intercultural interactions fraught with cultural misunderstandings. These meta-narratives resonated in part with much older colonial tropes of encounters between 'civilised explorers' and 'barbarian colonised' and revealed the deeply engrained orientalist thinking on which international peacebuilding interventions are built. Myths are another category of particular narratives – powerful foundational social narratives or widely held beliefs – which have been studied by interpretivist PS&IR scholars as meaning-making devices that help legitimise social order and political practices (contributions in Bliesemann de Guevara, 2016).

### ***Examples of Using Arts-Based Methods in Interpretive Research***

In her reflection on myths in politics, Yanow (2016) refers to Polanyi's (1967: 306) observation that '[t]he fact that we can possess knowledge that is unspoken is of course a common-place and so is the fact that we must know something yet unspoken before we can express it in words'. In order to explore such 'tacit knowledge', arts-based research methods are particularly well suited to help unearth research participants ideas, feelings, and meaning-making. Gameiro and colleagues

(2018), for example, have developed a metaphor-centred drawing method to explore infertility and healthcare experiences among Black and Minority Ethnic (BME) women in Cardiff, whereby both the non-verbal mode of expression and the possibility to express something intangible, such as feelings or ideas, in a tangible metaphor provided ways of rendering unspoken or sensitive knowledge communicable, thus not only generating data but also sensitising the research to the polysemy of meaning that BME women attached to their talk about fertility challenges and experiences with the UK healthcare system. In their study on experiences of violent conflict in Myanmar, Julian and colleagues (2019) have adapted this method to hermeneutically explore core concepts such as 'conflict', 'peace', and 'protection', and to understand the experiential knowledge around these concepts that civilians living amidst political violence hold. Among other things, the research reveals the polysemic use of these concepts, which differs considerably between communities in areas of violent conflict, other communities in Myanmar, and international humanitarian organisations in the country – a difference that remains hidden in analyses of these organisations because they operate with preconceived concepts and also because of the sensitivity of the violent experiences that have formed local understandings. 'Peace', for example, was seen as a 'bad word' by some communities in Myanmar's Kachin state, who associated 'peace' with a ceasefire period that brought economic exploitation and a loss in autonomy to Kachin people. Key to the analysis is again the context, which gives rise to different meanings of terms in different parts of the country, depending on specific historical uses and people's experiences and associations – revealed in this research through the use of drawing as a non-verbal method that allows the 'drawing out' of those differences.

Against the background of limitations of written and spoken language to express full meaning, arts-based research methods promise a useful extension to the qualitative

methods employed by interpretivists. How we know and make sense of the world is also attached to embodied, emotional, and affective ways of knowing, which pose an even more profound challenge to the researcher than the polysemy of meaning. Feelings and abstract ideas and thoughts are difficult to objectify in words, which nonetheless form the core of much of our qualitative social-scientific methods. Arts-based methods have been shown to offer an epistemic way into these other dimensions of hermeneutical knowing. Textiles thematising experiences of violent conflict, for example, have been shown to voice, in their function as object witnesses, the difficult knowledges they bear in documentary, visual, symbolic, material, and sensory registers, some of which are specific to their textile quality. Furthermore, curating such conflict textiles as a methodology of caring for difficult knowledge has been argued to avoid interpretive closures of the political violence addressed in them and to bring about an affective force in their audiences, with the possibility of resulting in a transformation of thought and perhaps even action among the latter (Andrä et al., 2019). Yet the use of textiles in research can go further to include interaction and exchange between different groups of research participants. In a project exploring the subjectivities of former members of armed groups in Colombia, the research team led by Bliesemann de Guevara and Arias Lopez (2019) uses textile narratives to allow former armed actors to unstitch and restitch meaning around their own role in Colombia's war and postwar periods and other members of Colombian society to resonate with their stories.<sup>7</sup> Inspired by Bruno Munari's 'illegible books' (cf. Maffei, 2015), which the Italian modernist artist developed to communicate non-verbal ideas, the textile narrative method chosen in the project invites participants to sew and embroider their stories, experiences, thoughts, or feelings in cloth. These 'textile pages' authored by different types of actors are then arranged into thematic textile

books, which allow onlookers to appreciate the original textiles and their meaning, but also to deconstruct this original meaning when read in conjunction with others, and construct one's own signification or story. In exhibitions of the textiles books, visitors are furthermore invited to embroider their reactions and answers to the textile narratives. The arts-based element thus turns individual textile accounts into powerful means of non-verbal communication and exchange, with the potential to itself make a social intervention into societal meaning-making processes, in order to contribute to peace. Perhaps this example can serve as an invitation to take interpretivist approaches in PS&IR into a new, more activist direction.

## CONCLUSION

Interpretivist approaches to PS&IR see politics, from the global to the state/society and to the local, not in terms of causal laws but as contingent, shifting practices that can be examined through research for the meanings in action that are attached to them (Bayard de Volo, 2016: 244). Interpretivists go beyond the institutionalist understanding of politics to study politics 'from below' and 'from within' and, in the process, make sense of power relations in particular political settings. They are interested in how particular meanings produce and organise power in specific ways. In this chapter, we have shown that rather than constituting a set or toolbox of methods, interpretivism is a methodology that rests on four pillars: the search for polysemic meanings, hermeneutic or poststructuralist analysis that includes the very concepts it studies, an abductive logic of inquiry, and reflexivity. Individual studies will differ in exactly how these principles are employed and which ones are foregrounded, as our research action examples have shown. What all these studies nonetheless have in common is a rejection of the idea of a world

out there that can be objectively known and that the researcher is not enmeshed in. From an interpretivist perspective, the idea of academia as an 'ivory tower' does not make sense – apart from being a powerful, sense-making metaphor used in public discourse to establish or contest a certain hierarchical order of expertise and knowledge. The interpretivist scholar is part of the world she studies, and her methods will both seek to account for the meaning her research participants share with her and reflect on the limits of this sharing. In this lies the rigour of interpretivist research.

## Notes

- 1 We would like thank Sybille Münch and Chiara Ruffa for their comments on earlier drafts of this chapter. Kurowska's work on this chapter was funded through European Commission MSCA Individual Fellowship RefBORDER grant no. 749314.
- 2 On monism and dualism in PS&IR, see Jackson (2011).
- 3 The Latin etymology of the word 'fact' is the verb 'facere', which means 'to do' or 'to make', which, as Lynch (2014: 25, nt. 4) argues, connotes action or construction rather than unchanging truth.
- 4 For a comprehensive overview of a variety of interpretive research methods in use, see 'Introduction' in Yanow and Schwartz-Shea (2014), specifically Table I-1 on p. xvi.
- 5 See Kurowska and Tallis (2013) for an example of research that uses the notion of 'chiasmatic crossings' to describe relational knowledge production that amounts to contextual co-authorship in fieldwork.
- 6 Due to interpretivists' general lack of a substantive critique that deconstructs the logic behind social representations of problems, elaborated earlier in this chapter, many authors of the post-structuralist strand of 'problematization' would indeed not count themselves as 'interpretivists' (cf. Bacchi, 2015).
- 7 Newton Fund/Colciencias project '(Un)Stitching the Subjects of Colombia's Reconciliation Process', 2018–2020 (AHRC project reference AH/R01373X/1; Colciencias project reference FP44842-282-2018), hosted by Aberystwyth University, UK, University of Antioquia, Medellín, Colombia, and the Association of Victims and Survivors of Northeast Antioquia, Colombia (see: <https://gtr.ukri.org/projects?ref=AH%2FR01373X%2F1>).

# Afterword

We conclude our *Handbook's* tour of research methods in political science and international relations with appreciation: appreciation for the tremendous contributions to the volume and to the discipline of these chapters' authors, and of the many colleague scientists they reference; and appreciation also for the great progress and accomplishments in research methodology that have forged an impressive modern science of politics and international relations. From formulating interesting and

important research questions and agendas, to developing powerful positive theories, to effectively conceptualizing and accurately measuring their moving parts, and properly evaluating, precisely estimating, and substantively interpreting their empirical manifestations, modern political science and international relations is indeed an impressive, productive, and useful science, thanks to – and rooted in – these sound research methods.
